We compare Qwen3-1.7B with Qwen3-0.6B in three ways: each accuracy with its own interval, the difference as if the two samples were independent, and the paired difference. For independent samples the half-width is $1.96\sqrt{\mathrm{se}_a^2 + \mathrm{se}_b^2}$, since 1.96 standard errors to either side cover 95% of a normal distribution. The paired bootstrap runs twice with different seeds, which shows how much of its interval is Monte Carlo noise. The last line sets its p-value beside the sign-flip test of Section 36.5.2.6, which simulates two interchangeable models by flipping the sign of each difference at random.

The larger model is 10 points ahead, and every method agrees that the lead is real: 10 points on 500 items is a large effect. The line of interest is the width. The paired interval reaches from 0.06 to 0.14, a half-width of 4.4 points against 5.9 for independent samples, three quarters as wide. Where does the quarter go? The two models disagree on 134 of the 500 items, 92 against 42, so the variance per item of the difference is $\pi_{10} + \pi_{01} - (\pi_{10} - \pi_{01})^2 = 0.268 - 0.01 = 0.258$, where two independent samples have $0.42 \cdot 0.58 + 0.32 \cdot 0.68 = 0.461$. The number of items needed for a given width grows in proportion to this variance, so the unpaired design needs $0.461 / 0.258 \approx 1.8$ times as many questions for the same interval.

The remaining lines are checks. The decomposition printed beside the ratio is Equation 18.13 evaluated on the sample, so its agreement is arithmetic, not a finding. The two bootstrap seeds give the same endpoints to within one item in 500, so ten thousand replicates are enough. Both p-values are below one in ten thousand.

Ten points did not need a paired test. Smaller differences do. The next cell goes through all ten pairs of the five checkpoints and records three verdicts for each: whether the two separate intervals overlap, whether the unpaired interval of the difference excludes zero, and whether the paired interval does.

The separate intervals overlap for eight of the ten pairs. A reader of a leaderboard who takes overlapping error bars for "no difference" would call all eight of them ties, and for three of the eight the paired interval excludes zero. This reader makes two mistakes at once, and the table separates them. The first is to use overlap as a test at all. Two intervals of half-width h overlap until the means are $2h$ apart, but the difference of two independent means has a half-width of only $\sqrt{2}\,h$, so a gap between $1.4h$ and $2h$ is resolved although the bars overlap. The pair of Qwen3-1.7B and Qwen3.5-0.8B-Base is such a case, with a gap of 6.6 points against an unpaired half-width of 5.9. The second mistake is to ignore the pairing. For the other two pairs, Qwen3-0.6B-Base against Qwen3-0.6B and against Qwen3.5-0.8B, only the paired interval excludes zero. Whether the first of them belongs in this count was decided by a hair: its gap equals the unpaired half-width to the third decimal, so the side on which it falls is luck. The paired verdict itself is not in doubt.

The last two columns hold the two p-values. Nowhere in the table do they differ by enough to change a verdict. With 500 items the distinction between the two tests is academic.

18.5.1.2 Clustered Items

So far every item was a separate question. Often items are not separate. The previous section sampled eight answers to each of 100 GSM8K problems from two models, which makes 800 scores per model. Do we have 800 observations? A model that can solve a problem solves it in most of its samples, and one that cannot fails in most, so the eight scores of a problem tell us nearly the same thing eight times. The previous section resampled the problems of this pool, and not its 800 samples. Here is the reason.

Section 36.5 treated a test set of G clusters with m items each. If two scores in the same cluster have correlation ρ and different clusters are independent, the variance of the mean exceeds that of Gm independent scores by the factor $1 + (m-1)\rho$, called the *design effect*. Consider the smallest case, $G = 2$ problems with $m = 2$ samples each and $\rho = 1$. The design effect is 2, and four scores are worth two: two problems asked twice are two problems. We have met ρ before under another name. If p_i is the probability that a sample solves problem i and $\bar{p}$ is its mean over the problems, then $\rho = \mathrm{Var}[p_i]/(\bar{p}(1-\bar{p}))$, the share of a score's variance that lies between problems (Section 18.4.4.2).

The same argument applies to a comparison. Let $d_i = a_i - b_i$ be the differences per item, s_d^2 their variance and ρ_d the correlation of two differences in the same cluster. Then

$$\mathrm{Var}(\bar{d}) = \frac{s_d^2}{Gm}(1 + (m-1)\rho_d), \tag{18.14}$$

so that Gm paired scores are worth $Gm/(1 + (m-1)\rho_d)$ independent ones. Note that ρ_d is not ρ. Most of what the samples of one problem have in common is the difficulty of the problem. Both models feel it, and it cancels in the difference. What stays correlated is whether this problem suits one model better than the other. We should therefore expect a smaller design effect for the difference than for either model, and we measure both.

The remedy is to resample what is independent. The *cluster bootstrap* draws whole problems with replacement, each with all of its samples. This is the general case for which `d2l.bootstrap_ci` was written. With G clusters, their summed scores $\mathbf{y}_{\text{sum}}$ and their sizes $\mathbf{m}$, the matrix $\mathbf{C}$ counts how often each cluster is drawn, and the replicate means are the ratios $(\mathbf{C}\mathbf{y}_{\text{sum}})/(\mathbf{C}\mathbf{m})$ of two matrix products. The argument `cluster` names the cluster of every score.

The function refuses to work with fewer than 30 clusters, and the smallest case shows why. Two problems drawn with replacement give the first twice, the second twice, or one of each, so the replicate means can take only three values. No interval worth the name comes out of three values.

The next cell scores each sample by comparing the number that `d2l.extract_answer` (Section 18.4) reads from the reply with the reference. It computes every interval twice: without clusters, in the column `iid CI`, as if the scores were independent and identically distributed, and with them. The squared ratio of the two standard errors estimates the design effect, printed as `DEFF`, and $(\text{DEFF} - 1)/(m - 1)$ is the correlation that this value implies. The last line of the output confirms that clusters raise the standard error of either model by more than half.

Both models solve a little over 40% of the samples. Resampling problems makes each interval more than twice as wide, from about ± 3.5 points to about ± 8. The design effect is about 5, which corresponds to a correlation of about 0.6 between two samples of one problem, and the 800 scores carry the information of about 150 independent ones. Sampling eight answers per problem multiplied the number of scores by eight and the information by about one and a half.

For the difference between the two models the design effect is about 2.5 and the implied correlation about 0.2. This is smaller, as expected, and far from negligible: the interval without clusters nearly excludes zero, and the clustered one is 1.6 times as wide. The first of these two intervals should not be trusted for a second reason. Pairing sample k of one model with sample k of the other is arbitrary, and the interval without clusters depends on that choice, while the clustered interval does not. The design effect is a diagnostic, and the clustered interval is the result to report.

18.5.1.3 Detectable Effects

An interval that contains zero invites the conclusion that two models are equally good. The data do not say that. They say that the experiment could not see a difference, and the natural next question is how large a difference it could have seen.

Three terms are needed to pose the question. A test that looks for a difference in either direction is *two-sided*. Its *level* is the probability of a false alarm, a difference declared where none exists, and 0.05 is the level that goes with a 95% interval. Its *power* is the probability of finding a difference that does exist, and 0.8 is the customary demand.

Section 36.5 computed the sample size that such a test needs. If δ is the true difference in units of the standard deviation s_d of the differences per item, it takes $n = (z_{0.975} + z_{0.8})^2 / \delta^2$ items, with the normal quantiles $z_{0.975} + z_{0.8} \approx 1.96 + 0.84 = 2.80$. We turn the formula around and let the design effect account for clusters. The smallest difference that n items detect with probability 0.8 is the *minimum detectable effect*

$$\text{MDE}(n) = (z_{0.975} + z_{0.8})\, s_d \sqrt{\frac{\text{DEFF}}{n}} \approx 2.80\, s_d \sqrt{\frac{\text{DEFF}}{n}}. \tag{18.15}$$

The MDE is thus 2.80 standard errors of the difference, although an interval excludes zero already at 1.96. The two numbers answer different questions. A true difference of 1.96 standard errors is detected in half of all experiments, since the estimate falls below the

true value as often as above it. A true difference of 2.80 standard errors is detected in four experiments of five.

Let us put in numbers. If two models disagree on 20% of 500 items and are nearly level, then $s_d^2 \approx 0.2$ and the MDE is $2.80\sqrt{0.2/500} = 0.056$, or 5.6 points. Two independent samples at accuracies near one half have a variance of $0.25 + 0.25$ per pair of items and an MDE of $2.80\sqrt{0.5/500} = 0.089$.

The formula also answers a question that the previous section left behind. On 100 items its larger model gained 7 points from reasoning, 11 items in one direction and 4 in the other, and the interval ended at zero (Section 18.4.5.5). Fifteen discordant items in 100 give $s_d^2 = 0.15 - 0.07^2 \approx 0.145$, so that experiment had an MDE of $2.80\sqrt{0.145/100} = 0.107$, about 11 points. To detect a true gain of 7 points in four experiments of five it would have needed $2.80^2 \cdot 0.145/0.07^2 \approx 230$ items. The measured gain itself lies 1.8 standard errors from zero, just short of the 1.96 at which an interval excludes it, which is why that interval ended where it did.

The function `d2l.min_detectable_effect` evaluates Equation 18.15 for a standard deviation and a number of items, or directly for a standard error.

The next cell draws the MDE against the number of items for three designs. The first is two independent samples at the accuracies of Qwen3-0.6B and Qwen3-1.7B. The second is the paired comparison of these two models. The third is a paired comparison whose items come in clusters of eight, with the design effect that we just measured on the GSM8K samples. It is hypothetical for ARC, where every item is a separate question, and shows what the same number of scores would be worth if they were eight samples each of one eighth as many problems. Each dot is one of the ten pairs of checkpoints, placed at its observed gap and at the number of items for which the MDE of that pair equals the gap. A dot to the right of 500 is therefore a gap that our 500 questions do not reliably detect.

The numbers behind the plot come next: the MDE of each design at 500 items, and for every pair the number of items at which its dot sits.

At 500 items the paired design detects about 6.5 points, two independent samples detect about 8.5, and the clustered design about 10. The three lines of the plot are parallel because every design scales as $1/\sqrt{n}$: pairing saves a constant factor of items, and clustering costs one. Six of the ten dots lie to the right of 500.

Now we can answer the question of the opening. A gap of 9 or 10 points needs about 200 paired items, a gap of 4 points between 600 and 1,000, and the gaps of 2 to 3.5 points between 1,400 and 2,100. The pairs differ in how often the two models disagree, which is why similar gaps need different numbers of items. The smallest gap in the table, 1.4 points, would take 7,600 items. A lead of two points on 500 questions is therefore no evidence that one model is better. It would take three to four times as many questions to make it evidence.

Note also the row of Qwen3.5-0.8B and Qwen3-0.6B-Base. The paired interval of this pair excluded zero at 500 items, yet the table asks for 625. This is the difference between 1.96 and 2.80 once more: our experiment found the gap, and a repetition with fresh questions might well miss it. From here on, every difference that this section reports with an interval is printed with its MDE as well. “No significant difference” is a statement about the experiment, and the MDE says how strong a statement it is.

18.5.2 Benchmarks, Suites and Contamination

The statistics above treat the items as a sample from a fixed population of questions that no model has seen. Benchmarks are less obliging. They age as the field works on them, their identity is easily blurred by a change of subset or prompt, and their questions end up in training data. We take these three problems in turn.

18.5.2.1 The Lifecycle of a Benchmark

A benchmark is useful for a limited time, and its history tends to follow the four stages of Figure 18.6. When it is *introduced*, models score low and far apart, which is what its authors built it for. Then the field *climbs* it: the best published score rises quickly, often past the human baseline that the authors measured. Eventually the benchmark is *saturated*. The best scores bunch just below a ceiling that is lower than 100%, because some reference answers are wrong and some questions are ambiguous, and no model deserves credit for agreeing with a wrong reference. Differences among the leaders are then mostly noise. Finally a harder successor *replaces* the benchmark, and the cycle begins again.

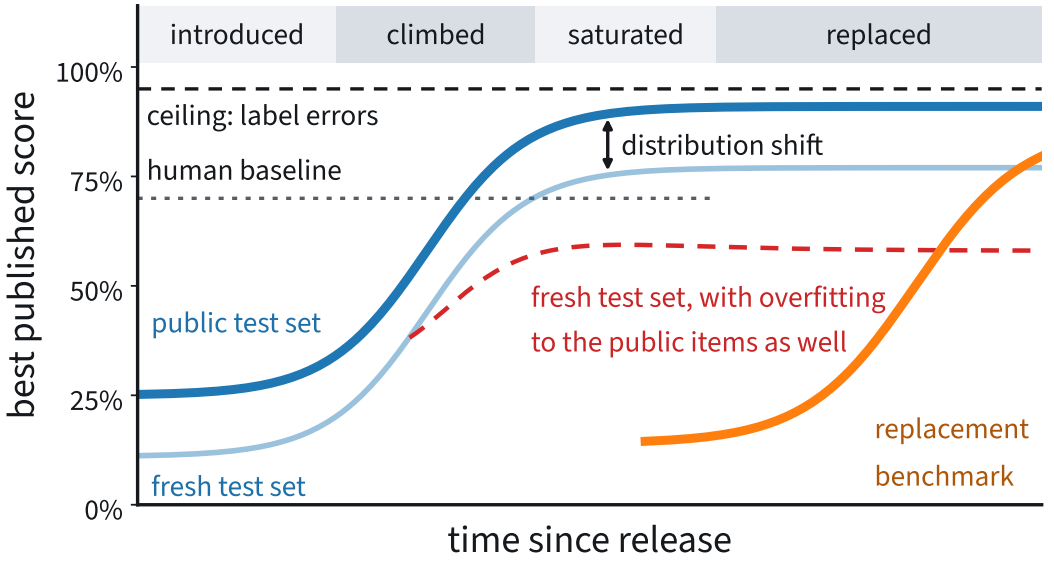

Figure 18.6: The lifecycle of a benchmark (schematic). The best published score climbs, saturates below a ceiling set by label errors, and a harder successor takes over. A fresh test set follows the public one at an offset caused by distribution shift, and the dashed curve shows the further gap that overfitting to the public items would add.

Names and scores of this kind go out of date within months, so they are kept in a data file that is revised with each edition of the book. The cell prints one example of each stage and then puts a number on "saturated". For each benchmark with an estimate of its label errors, the room that is left is the ceiling minus the best published score. We divide it by the MDE of a comparison on the full test set, taking $p(1-p)$ at the best score p as the variance per item of the difference. This is an assumption, and a rough one: it lets two models near the top disagree on a share $p(1-p)$ of the questions, half as often as two independent models would. The quotient counts the detectable steps of progress that the benchmark can still register.

The first block of the output shows how fast the stages pass. Humanity's Last Exam (Phan et al. 2025) was introduced in January 2025 with a best score of 9%. When the file was compiled, less than two years later, the best score stood at 55%, and its row in the table already says "climbed". The best score on GPQA (Rein et al. 2023) rose from 39% to 87% in under two years, and by now its row says "saturated". MMLU-Pro (Y. Wang et al. 2024) replaced MMLU in 2024.

The result to remember is in the last column. An estimated 6.5% of the questions of MMLU (Hendrycks et al. 2021) contain errors (Gema et al. 2025), which puts the ceiling at 93.5%, and the best published score is 93.3%. The MDE on its test set is 0.6 points, so MMLU has less than half a detectable step left. As an instrument for telling the best models apart, it is used up. GSM8K (Cobbe et al. 2021), with the corrected labels of Vendrow et al. (2025) as its ceiling, has fewer than two steps left.

Two columns need a word. The column `status` says which benchmarks this book runs, which are *gated* and which are moving, a kind that we meet below. The questions of a gated benchmark are released only to users who log in and accept terms against republishing them, so that they stay out of scraped training data. The entries of the column `best` come from different sources and settings. They are levels, and cannot be compared with each other.

Does a high score on a public test set mean that the models have overfitted it? The obvious experiment is to collect a fresh test set and compare. But a gap between the old set and the new one mixes two things: overfitting to the public items, and a new set that comes from a slightly different distribution. The best evidence that we have points mostly to the second. Recht et al. (2019) rebuilt the test sets of CIFAR-10 and ImageNet with great care and found that all models lost accuracy, but the ranking of the models was preserved, and the new accuracies fell close to a straight line as a function of the old ones. That is what a shift does, and it is not what overfitting to the old test set would do. For GSM8K, Hugh Zhang et al. (2024) wrote a fresh set of comparable problems, GSM1k, and found drops of up to 8% for some families of models and almost none for the strongest ones. Some overfitting exists, then, and it has to be measured model by model.

Figure 18.6 draws both effects. A shift moves the whole curve of the fresh test set down by a constant offset. Overfitting would add a gap that opens while the field climbs the public set, which is the dashed curve, and on a fresh test set the two cannot be told apart. Only a private split drawn from the same pool as the public one isolates overfitting, since its questions have the distribution of the public ones and no model has seen them. This makes a *held-out tier*, a private set that only the maintainers score, the cleanest design. Humanity's Last Exam keeps such a set, although, as the output notes, no scores on it have been published.

Other benchmarks give up fixed items altogether and release new questions at regular intervals. The table lists two of them, LiveBench (White et al. 2025) and a continually updated edition of Humanity's Last Exam. Such a *moving* benchmark cannot be pinned by a hash, and a report must record the release that it used.

18.5.2.2 Frozen Manifests

When we compare two numbers, we would like to be sure that they were measured on the same thing. "ARC, 500 items" does not say so. Which 500, in which format, under which normalization, after which demonstrations? Section 18.3 showed that one line of instruction can move an accuracy by tens of points. A suite, the fixed list of tasks of the introduction, is fixed only if every such choice is written down. The record that holds the list with these

choices is its *manifest*, a small file or an entry of the library. A manifest is frozen: a suite is never edited, only replaced by a new version.

It is good practice to keep two. A *development suite* is small and fast, and we consult it at every change. A *reporting suite* is larger and is touched rarely, for the reason that a test set is kept apart from a validation set. Every decision taken after looking at a score fits the suite a little, and after a hundred decisions the development score is no longer an unbiased estimate of anything.

18.5.2.2.1 Tasks, Suites and Runs

The next six cells build the software. Only two ideas in them matter for what follows: the hash of a suite covers everything that a model is shown, and the settings of a run are kept apart from it. The rest is there to be used, not studied.

A task is a record of type `d2l.EvalTask`, and its fields answer three questions. What is asked: the dataset with a pinned revision, the split and the subset. How it is shown: the kind of task (`mc` for multiple choice scored by likelihood, `gen` for a generated answer), the scoring convention of Section 18.4, and the layout, demonstrations and chat settings of Section 18.3. How the answer is read: the token limit, the stop strings and the extractor.

Two small functions belong to a task. `d2l.subset_ids` selects a subset as the first n entries of one seeded permutation, so that a subset of 100 is contained in the subset of 500 drawn with the same seed. The previous section used the same rule, which is why its 500 ARC items are ours. `d2l.item_seed` derives the random seed of an item from the seed of the run, the task and the id of the item with a cryptographic hash. An item's random numbers then depend on nothing but its own identity, and adding items to a suite never changes the random numbers of the items that were already there. (The sampled text can still change at a near-tie, through the batch.)

A `d2l.EvalSuite` resolves its tasks, loads the rows at the pinned revision, selects the subset and renders every prompt. Its `hash` is the SHA-256 of all fields of all tasks, followed by the items themselves: their ids, rendered prompts, options and references. Any change to what a model would be shown gives another hash. The loaders, and the adapters that turn a row of a dataset into an item, are library code and are not shown.

Scoring depends on the kind of task. A multiple-choice item is correct if `d2l.score_choices` ranks the gold option first. A generative item is correct if the answer that `d2l.extract_answer` reads from the reply of `d2l.generate` equals the reference, and a task that samples hands every item its own seed. The docstring names three further kinds, which no suite of this section uses.

The method `run` scores every item and returns an `EvalResult`. Not everything that affects a score belongs to the suite. The seed, the batch size, the floating-point type and the versions of the libraries are settings of a *run*, and Section 18.4.5.2 found that in the 16-bit format bf16 the batch size alone changes a few predictions in 500. `run` therefore hashes these settings into a separate *run key*. Results are cached under the model, its revision, the suite hash and the run key, so an interrupted run resumes and a run under other settings never reads a stale cache. Tasks that execute programs written by a model refuse to run unless the caller confirms that the process is isolated in a sandbox. We run no such task here.

The result keeps one row per item, because every interval of this section resamples items, and a stored mean cannot be resampled. `summary` gives the accuracy of each task with a bootstrap interval. `compare` is the paired bootstrap of two results aligned by task and item id.

It raises an error when the suite hashes differ, so the code decides whether two numbers were measured on the same thing.

A few methods are not worth printing: reading and writing manifests, and saving and loading results. The next cell takes them from the library's own copy of the two classes.

18.5.2.2.2 The Development Suite

The library holds two frozen manifests. `dev_v1` has the 500 ARC-Challenge questions in the cloze format of the first part and 100 GSM8K problems, answered by generation after four demonstrations in the chat layout. `report_v1` has 1,000 questions of MMLU-Pro, 2,000 of MMLU and the full GSM8K test set. The cell prints both and then perturbs `dev_v1` twice, by one more ARC item and by other demonstrations for GSM8K.

Each perturbation gives a new hash, as would a change to any other field. Two results can be compared if and only if their hashes agree.

The next cell is plumbing and can be skimmed. It prepares a check of the suite against the scores of the previous section, which came from a different call at another batch size. The previous section measured how far a log-likelihood moves when the same prompt is scored in a batch of another size, and called this the *batch drift*. An item may differ in correctness between the two runs only if it was a near-tie, with a margin that the drift could close.

We run the development suite for the four answerers. Three of them were among the five checkpoints of the first part, and their stored results are first compared item by item with the previous section. On a GPU the ARC task is also scored again live for two of the models.

The lines in the middle are the load reports of `d2l.load_hf`. The live scores reproduce the stored ones on all 500 items, so the suite is repeatable under fixed settings. Against the previous section, one item of 500 differs for two of the models and six differ for Qwen3-1.7B, each a near-tie within the measured drift. Six items are not nothing. The accuracy of Qwen3-1.7B on these 500 questions was 0.420 there, at batch size 8, and is 0.428 here, at batch size 32. The same model on the same questions differs from itself by almost a point when only the batch size changes. This is why the batch size is part of the run key, and why a careful report states it. On GSM8K the four models spread from 0.42 to 0.76, but with 100 problems each of these accuracies has an interval of about ± 9 points.

Six pairs of models on two tasks make twelve comparisons. For each of them the table gives the paired interval from `compare`, whether it excludes zero, and the MDE.

Nine of the twelve differences are distinguishable from zero. For the three that are not, the MDE says what the experiment could have seen. Between Qwen3.5-0.8B and Qwen3-0.6B it could have detected about 5.5 points on ARC and 14 on GSM8K, and it found gaps of 1.4 and 6. Are the two models equally good? The table cannot say. It says that 500 and 100 items cannot tell them apart. The column also shows what 100 problems are worth. Every MDE on GSM8K lies between 12 and 15 points, so this task reliably finds only gaps of that size. It did resolve one gap of 10 points, the lead of Qwen3-1.7B over Qwen3.5-2B, with an interval that ends at -0.02.

That verdict is the least secure of the nine, for a reason that concerns all of them. Twelve tests at level 0.05 are twelve chances of a false alarm. Section 36.5 gave the simplest remedy, the Bonferroni correction, which tests each of m hypotheses at level $0.05/m$ and so widens every interval. The interval that ends at -0.02 is the first candidate to lose its verdict (Exercise 6).

18.5.2.3 Contamination and Perturbed Variants

GSM8K was published in 2021, and its test problems have been on the web ever since. A model trained later may have read them, answers included. How would we know? A model that has memorized a test item can answer that item. It has no such advantage on a variant that needs the same reasoning with other names and numbers. Mirzadeh et al. (2025) built this test into a dataset, GSM-Symbolic, by turning 100 test problems of GSM8K into templates and drawing 50 instances from each. Its licence (CC BY-NC-ND 4.0) excludes commercial use, so we do not reprint its problems. Here is an invented one in the same spirit. The original reads "Mira buys 3 notebooks at 4 dollars each and a pen for 2 dollars. How much does she pay?" The template replaces the name and the three numbers by variables, and one of its instances reads "Tomas buys 7 notebooks at 6 dollars each and a pen for 5 dollars. How much does he pay?"

Let $o_g \in \{0, 1\}$ say whether the model solves the original of template g, and v_{gj} whether it solves variant j of m. We measure the *contamination gap*

$$\frac{1}{G}\sum_{g=1}^{G}\Big(o_g - \frac{1}{m}\sum_{j=1}^{m} v_{gj}\Big), \tag{18.16}$$

which is the accuracy on the originals minus the accuracy on their variants, taken template by template. Take a model that solves both originals of two templates, one of two variants of the first and no variant of the second. The differences per template are 0.5 and 1, and the gap is 0.75. This is a paired and clustered difference, and we have the code for it already: repeat each original once per variant and call `d2l.paired_bootstrap` with the template as the cluster.

Before we run the experiment we should ask what it can see. We test Qwen3-1.7B, which solved about three quarters of the GSM8K problems of the development suite. The originals are 100 scores of 0 or 1, and no number of variants reduces their noise. Let the accuracy be $p = 0.75$, and let any two questions of a template have correlation ρ. The difference per template is the score of the original minus the mean of m variants. Its variance has three terms, the variance of the original, that of the mean of the variants, and twice their covariance: $p(1-p)(1 + (1 + (m-1)\rho)/m - 2\rho)$. For $m = 4$ and ρ between 0.7 and 0.3 the MDE at 100 templates comes out between 7 and 11 points. A contamination gap of a few points would be invisible to this test. We run it anyway and add a second probe with more power.

The cell reads the dataset at run time, keeps the originals and the first four instances of every template, and checks one more thing. Every row carries a *canary*, a unique string by which anyone who assembles a training corpus can find the benchmark and leave it out.

The model receives the 500 questions with the same four demonstrations as in the development suite, and we decode greedily. For the second probe we need no answers at all. A model that has seen a text during training tends to assign it a higher likelihood than it would otherwise, so we compute the log-likelihood per byte of each question text, with the `d2l.score_choices` of Section 18.4.

The model solves 72% of the originals and 72% of the variants. It does find the originals more likely, by 0.08 nats per byte. That alone proves little, because a variant with a randomly drawn name and randomly drawn numbers may simply read less naturally than a problem that a person wrote. To measure how much less naturally, we need a model that cannot

have seen GSM8K, and we own one: the GPT-2 small of Section 11.2 was released in 2019, two years before the benchmark existed. Comparing the likelihood under one model with the likelihood under a reference model is a standard device for separating memorized text from text that is merely predictable (Carlini et al. 2021).

GPT-2 also prefers the originals, by 0.04 nats per byte, so a part of the gap is naturalness. The last cell of the experiment tests the accuracy gap, the two likelihood gaps and the difference of the latter, each with a bootstrap over templates.

The accuracy test confirms what we computed beforehand and nothing else. Row (a) shows a gap of 0.3 points with an interval from -8 to $+8.5$ and an MDE of 12 points, so the test cannot tell a contamination gap of ten points from none. The measured MDE lies just above the predicted range, because the spread of the differences implies a correlation of 0.28, slightly less than we assumed. The line below adds that one ρ for all pairs was a simplification: two variants of a template resemble each other more than a variant resembles its original, with correlations of 0.50 and 0.36. Ignoring the templates would have given an interval of ± 5 points, too narrow by the square root of a design effect of 2.9. In four templates the model solves the original and none of the four variants, which is suggestive and, among 100 templates, proves nothing.

The likelihood rows are another matter. The gap of Qwen3-1.7B is 0.076 nats per byte and that of GPT-2 is 0.043, and their difference of 0.033 has an interval from 0.015 to 0.05. Qwen3-1.7B finds the original texts more likely than their variants by more than a model that cannot have seen them does. This is evidence consistent with exposure to the test set. It is not proof. The reference model removes only the unnaturalness that both models perceive alike, and a much stronger language model may be more sensitive, byte for byte, to an odd name or an implausible price.

Note what the two probes ask. The likelihood probe asks whether the model has seen the questions, and the accuracy test asks whether seeing them helped. For this model the first question gets a tentative yes and the second gets no answer at all. A test that can only question the model can go no further. The other approach, a search of the training data for the test items by their n-grams, is a topic of Section 20.3.

18.5.3 Model Judges

Every score so far compared an answer with a reference, a letter or a number. Ask a model to explain a proof or to draft a polite refusal, and no reference exists. People can say which of two answers is better, but people are slow and expensive. Since L. Zheng et al. (2023) it has become routine to ask a strong language model instead. The idea is attractive and a little alarming. The instrument is itself a language model, with the habits that we met in Section 18.3, where the order of the demonstrations alone changed one prediction in eight. We therefore treat the judge as we would any instrument: we work out what it reads, compare it with people, and measure its known biases, by intervention wherever we can, before a single verdict is used.

18.5.3.1 Judging in Both Orders

Our judge receives a question and two answers, labeled A and B, under a short *rubric* that asks which answer is more helpful and more correct and requests a single letter. The rubric says nothing about detail or length. This is deliberate, since a rubric that praises detail asks

for long answers. The second string of the cell is a paragraph of filler that we need later for an experiment on length.

We do not let the judge write. As with the labels of Section 18.3.1.2, its forward pass already assigns probabilities to the two letters at the next position, and we read the log-odds $l = \log P(\texttt{A}) - \log P(\texttt{B})$, the judge's preference for the answer in the first slot. As there, we also record the probability that the two letters hold together, because the log-odds of two tokens that the model would not write mean little.

One reading is not enough. Judges are known to favor a position (P. Wang et al. 2024), and in a single reading a preference for the first slot is indistinguishable from a preference for the answer that happens to stand there. So we show each pair twice, in both orders, and model the two readings with the simplest assumption that could work. Let Δ be the judge's preference for answer a over answer b and β its preference for the first slot, both as log-odds. With l_1 read when a stands first and l_2 read when b stands first,

$$l_1 = \beta + \Delta, \qquad l_2 = \beta - \Delta, \qquad \text{and therefore} \qquad \Delta = \frac{l_1 - l_2}{2}, \qquad \beta = \frac{l_1 + l_2}{2}. \tag{18.17}$$

Half the difference of the two readings is the preference with the position removed, and half their sum is the *position bias*. With the logistic function $\sigma(u) = 1/(1 + e^{-u})$, the debiased probability that a is the better answer is $\sigma(\Delta)$.

Let us take $l_1 = 2$ and $l_2 = 1$. Read in the first order alone, the judge declares a the winner with probability $\sigma(2) = 0.88$. Read in the second order alone, it declares b the winner with probability $\sigma(1) = 0.73$. Each reading names the answer that it saw first. Together they give $\beta = 1.5$ and $\Delta = 0.5$: a strong taste for the first slot and a mild preference for a, with $\sigma(0.5) = 0.62$. We call a verdict *consistent* if both orders name the same answer, and we count the pair as a tie otherwise, as in this example. Why not take the sign of Δ, which here favors a? We let the experts settle that in Section 18.5.3.2.

The additive model is an assumption, and a rather bold one: it says that the judge's taste for the first slot has nothing to do with how far apart the two answers are. It can be checked. Suppose instead that the judge spoke up more strongly in one order than in the other, $l_1 = \beta + c_1\Delta$ and $l_2 = \beta - c_2\Delta$ with $c_1 \neq c_2$. Half the sum of the two readings is then $\beta + (c_1 - c_2)\Delta/2$, a bias that changes with the preference. Now l_1 and $-l_2 = -\beta + c_2\Delta$ both measure the advantage of a, and plotted against each other over many pairs they fall along a line of slope c_2/c_1. A slope of 1 supports the additive model. Any other slope means that Δ is a distorted summary of the pair. We will fit this slope.

`d2l.judge_pairwise` renders both orders through the judge's chat template with thinking switched off (Section 18.3), reads the two log-odds, and returns Δ, β and the verdict for every pair. The reading itself, with its batching and with the output layer evaluated in fp32 as in Section 18.3.1.2, is in the library.

The judge is Qwen3.5-4B. It belongs to the same family as two of the four models whose answers it will judge, a point to which we return.

Before the judge reads anything, we need something for it to read. It will first be tested on answers that people have already compared. What we prepare now is its second task, the answers of our own models (Section 18.5.3.3). The questions are the 80 opening turns of MT-Bench (L. Zheng et al. 2023), whose two-turn questions were written to compare chat

models, and 220 instructions from Dolly, a public collection written by people, drawn with a fixed seed from those that need no context document.

Each of the four answerers writes one sampled answer per prompt, with thinking off and a request to stay within 200 words. Two of them, Qwen3-1.7B and Qwen3.5-2B, answer a second time under another seed, so that we can see later how much a judged result depends on the draw of the answers.

No answer contains a stray thinking tag, and few were cut off at the token limit. The models differ in how much they write: the median answer of Qwen3-0.6B has about 80 words, that of Qwen3-1.7B about 100, and both Qwen3.5 models write about 150. Keep this in mind for the experiments on length.

18.5.3.2 Validation against Human Labels

Does the judge agree with people? We must know before we use it, and MT-Bench lets us find out. It comes with the answers of six chat models of 2023 to its questions, and with the votes of expert annotators and of the paper's own authors on pairs of these answers. We call all of them the experts. A vote names one of the two answers or declares a tie, and it is *decided* if it names an answer. The verdicts that GPT-4 gave on the same pairs are included.

We keep the first turn of each conversation and draw 400 answer pairs with at least one decided vote. Agreement is easy to obtain when one answer is plainly better, so we split the answer pairs by a rule fixed beforehand. A pair of models is *easy* if the experts preferred one of the two in more than 80% of their decided votes, and *hard* otherwise, and an answer pair is as easy or as hard as the two models that wrote it.

The next cell reads the stored log-odds of the 400 pairs. When it computes them afresh, it first verifies two properties that the two-order design must have exactly: swapping the answers negates Δ and leaves β unchanged, and two identical answers give $\Delta = 0$.

We score three judges against the decided votes of the experts: our judge on its consistent verdicts, our judge forced to decide by the sign of Δ, and GPT-4. As a yardstick the table adds the experts against each other, wherever two of them voted on the same pair. The column `decided` gives the share of pairs on which a judge commits itself. All intervals resample questions, since several pairs belong to one question.

Four things can be read from this table. The first is that the tokens A and B hold all of the probability to three decimals, so the log-odds are the judge's answer. The second concerns the yardstick. Over all pairs our judge agrees with an expert on 83% of its consistent verdicts, and two experts agree with each other on 82%. People are no gold standard, and a judge cannot be expected to agree with them more often than they agree among themselves.

The third is the split. On easy pairs every row stands at 88 or 89%. On hard pairs our judge drops to 73%, with an interval from 0.66 to 0.80 that lies clear of its interval on the easy pairs, and the experts drop to 71%. Intervals that do not overlap always indicate a difference. It was overlap that proved nothing. Agreement measured on easy pairs says little about the pairs for which a judge is needed.

The fourth answers the question that we left open: why not force a verdict by the sign of Δ? The rows marked `forced` do so. They decide every pair and agree with the experts less often, by a few points over all pairs and on the hard ones. Since a forced verdict equals the consistent one wherever the two orders agree, the verdicts that forcing adds are the ones that pull the agreement down. We do better to report them as ties.

On the hard pairs GPT-4 stands at 83%, ten points above our judge. Is the small judge worse? Before we answer, look at how the rows were built. Each judge is scored on the pairs that it decides, GPT-4 decides fewer of the hard pairs than our judge does, and the two rows are separate intervals over different votes. We spent the first part of this section learning not to read such a table. The comparison must be paired: the same expert votes, restricted to pairs on which both judges commit themselves.

On common votes the gap on the hard pairs shrinks from ten points to about three, with an interval from -11 to $+3$ points. Over all pairs it is under two points, with an interval that includes zero. The ten points were mostly a matter of which pairs each judge chose to decide. Our judge is not distinguishable from GPT-4 on these votes, and the two give the same verdict on 95% of the pairs that both decide.

This is not yet a licence to trust the judge. The column `MDE` says how little the hard pairs can show: about ten points for the consistent verdicts and twelve for the forced ones. A deficit of ten points is thus the smallest that the comparison would reliably find, and the two intervals reach down to deficits of 11 and 14 points. And these judgments have been public since 2023, so a judge released later may have been trained on them, which is the contamination problem of Section 18.5.2.3 in a new place. Agreement with people is behavioral evidence in the sense of Table 10.2: it shows that the judge is useful on questions like these, and it identifies nothing about how the judge decides.

18.5.3.3 Position and Length Biases

Now the judge reads our own answers: all six pairs of the four answerers on the 300 prompts, 1,800 pairs in both orders. Two further *arms*, that is, further conditions of the experiment, are judged in the same run. One repeats a single pair of models with the answers of the second seed. The other is an intervention on length, in which each answer of Qwen3.5-2B meets a copy of itself with the filler paragraph appended.

Three quarters of the verdicts on the six pairs are consistent, and the two letters again hold nearly all of the probability. The low consistency of the padded arm is to be expected, since its two answers are the same answer, one of them padded. We look at position first. The cell also fits the slope that tests the additive model. Both readings are noisy, and an ordinary regression of one on the other would be biased toward a flatter line, so the fit is by total least squares, which treats the two axes alike. A second cell plots the two readings of every pair against each other.

The mean position bias is 0.71 in log-odds, with an interval from 0.64 to 0.79. Shown two answers of equal quality, this judge puts about two thirds of its probability on the first, since $\sigma(0.71) = 0.67$. Two thirds is a probability, and a verdict is a choice. The output counts 129 pairs that are nearly tied once the two orders are combined, with $|\Delta| < 0.25$. In a single reading of such a pair the judge prefers the answer shown first almost four times in five. Of two close answers, a single reading mostly names whichever stands first.

The consequences reach beyond the near-ties. Had we judged each pair in one order only, the winner would differ from the debiased one in 14% of the pairs for one order and in 10% for the other. The two shares add up to the 24% of inconsistent verdicts, as they must: when the two orders name different winners, the debiased winner sides with one of them.

The plot shows the two readings of each pair against each other. Without a position bias the points would scatter around the diagonal. They lie below it, by about 2β, and parallel to it, which is the more important fact: the fitted slope is 1.00, with an interval from 0.96 to

1.04. The additive model holds for this judge, and Δ is a fair summary of a pair. This does not make the bias small or uniform. Its quartiles over the pairs are 0.13 and 1.25, so for a quarter of the pairs the first slot is worth more than 1.25 in log-odds. What the slope shows is that the bias does not grow or shrink with Δ, and the model needs no more than that.

For length we have two measurements. The intervention compares each answer with its padded copy, so that nothing but the padding differs. The observation regresses Δ on the logarithm of the ratio of the two answers' word counts across the six pairs of models, after dropping the pairs with a truncated or empty answer. Each pair of models gets its own intercept. Otherwise a better model that also writes more would pass for a taste for length.

The intervention is unambiguous. The padded answer loses, by $\Delta = -0.79$ with an interval from -0.86 to -0.72, an effect eight times the MDE of this arm. It wins a consistent verdict in fewer than 1% of the prompts, against 45% for the plain copy. The judge penalizes this filler. We should be careful about what that shows. The paragraph adds about 54 words that say nothing, so it changes the quality of an answer along with its length, and the result is that this judge does not reward empty padding. It does not follow that the judge ignores length when length comes with content.

On that question the observed slope is our only evidence, and it is weak: 0.3 per unit of the log ratio, with an interval from slightly below zero to 0.7. No association of the verdict with the length of an answer is detectable at this sample size. Even a clear slope would have been hard to read, because a longer answer is often a more complete one, and this confounding is the reason for running the intervention at all.

The table puts the mean Δ of each pair of models on the scale of a probability, as measured and after an adjustment to answers of equal length. The adjustment moves no pair by more than four points, and the pair of Qwen3-1.7B and Qwen3.5-2B by two. Other automatic judges have been found to favor long answers (Dubois et al. 2024), so a length bias has to be measured for the judge and the rubric at hand.

A third bias is out of our reach. A judge may prefer text that resembles its own (Panickssery et al. 2024), and ours shares a family with two of the answerers. With one judge this preference cannot be separated from the possibility that those two models simply write better answers. It takes a second judge from the other family and a crossed design, which Exercise 8 sets up.

18.5.3.4 Rankings from Pairwise Verdicts

Six pairwise results are awkward to report, and nothing forces them to be transitive. The Bradley-Terry model of Section 15.3 turns them into one number per model. It assigns each model i a strength θ_i and assumes that i beats j with probability $\sigma(\theta_i - \theta_j)$, which is logistic regression on comparisons. In these terms the judge's Δ for a prompt is a noisy reading of a difference of strengths. `d2l.bradley_terry` maximizes the likelihood by Newton's method with a small penalty on the strengths. Strengths are determined only up to a common shift, and the penalty together with a final centering makes the solution unique. The function accepts a matrix of weights with one row per bootstrap replicate and solves all replicates at once, each a linear system with one unknown per model.

A consistent verdict enters as one comparison and a tie as two comparisons of half weight, one each way. The bootstrap resamples prompts, with all six pairs of a prompt together. From its replicates we read an interval for every strength and the probability that one model ranks above another.

The judge orders the four models as Qwen3.5-2B, Qwen3-1.7B, Qwen3.5-0.8B, Qwen3-0.6B, and the bootstrap probability of each of the six orderings rounds to 1.000. A difference of strengths is a log-odds, so the gap of about 0.4 between the first two means that the judge prefers the answer of Qwen3.5-2B in about six prompts of ten.

How should we read so decisive a ranking? Set it beside the development suite. There Qwen3-1.7B was 10 points ahead of Qwen3.5-2B on GSM8K, and the two were not distinguishable on ARC. Here Qwen3.5-2B wins with a bootstrap probability of one. The judge also separates Qwen3.5-0.8B from Qwen3-0.6B, which the suite could not. There is no contradiction, since open questions are a different task from arithmetic and science. But consider what the two models that moved up have in common: they write the longer answers, and they belong to the family of the judge. The first suspicion we have checked. An adjustment for length moved the pair at the top by two points, on a scale on which Qwen3.5-2B leads by more than twenty, so length does not explain this ranking. The second we have not checked, and with one judge we cannot. The bootstrap resamples prompts. It knows nothing of other judges, other rubrics or other kinds of question, and its narrow intervals say that this judge is consistent, not that it is right.

The last check concerns the answers. Each was one sample at temperature 0.7. Would another draw change the result? We compare the win rate of Qwen3.5-2B over Qwen3-1.7B on the answers of the two seeds, paired by prompt.

The verdict survives a second draw. The win rate of Qwen3.5-2B is 0.62 with the first seed and 0.66 with the second, and both intervals lie clear of one half. How much a redraw moves the win rate is less certain. The difference of four points has an interval from -1 to $+9$ points and an MDE of about 6.5 points. An effect of the answer seed is thus not detectable at this sample size, and the interval allows anything from none to about nine points. A report of a judged comparison should therefore say that each answer was a single draw.

Everything measured in this part comes back when a model is no longer ranked by a judge but trained against one: a reward model is a judge whose biases the optimizer will find (Section 25.1).

18.5.4 Reproducible Reports

18.5.4.1 The Protocol

We have seen a score move with the prompt (Section 18.3), with the scoring convention (Section 18.4), with the batch size and with the choice of the items, and we have seen its interval change with the way the items are resampled. A number that somebody else is to check must come with everything that it depends on. Table 18.6 lists what a report should state. None of it is difficult to record at the time of the experiment, and most of it is impossible to reconstruct afterwards.

Table 18.6: What a reported score must carry so that another lab can check it.

item	what to state	what goes wrong without it
model	identifier and revision	weights and templates change under one name
data	dataset, revision, split, subset rule, suite hash	two “identical” benchmarks differ in their items

item	what to state	what goes wrong without it
prompt	layout or template, instruction, demonstrations and how they were chosen	the prompt moves a score by tens of points
decoding	greedy or sampled, temperature, token limit, stop strings, thinking mode	cut and overlong replies change what is extracted
scoring	format, normalization, extractor	conventions rank models differently
run	seed, batch size, floating-point type, library versions	near-ties flip with the batch
result	number of items, estimate, 95% interval, and whether it is paired or clustered	a difference cannot be told from noise
power	the MDE at this number of items	"no difference" has no meaning
comparison	what was held fixed between the systems compared	the gap may belong to the protocol

The list is also the first step of any project that builds on a published result: reproduce the baseline under a stated protocol before changing anything.

18.5.4.2 Example: A Published GSM8K Score

Let us try the protocol on a number that somebody else published. The technical report of Qwen3 (A. Yang et al. 2025) lists a GSM8K accuracy of 59.59 for Qwen3-0.6B-Base, described as "4-shot, CoT". That is, the prompt holds four demonstrations whose answers write out the steps of the solution before the result, a *chain of thought*. We run the GSM8K task of `report_v1` on all 1,319 test problems, with four demonstrations and their worked solutions from the training set in the `qa` layout of Section 18.3.2.1, and with greedy decoding. The cell prints the protocol as a card, filled in from the metadata of the result, and ends the card with the items that the source leaves open.

Our protocol gives 0.51, with an interval from 0.48 to 0.54. The published 0.596 lies far outside it. The card's MDE of 3.9 points is that of one accuracy against a fixed number, and the miss is more than twice as large. What went wrong? Perhaps nothing. The last line of the card lists what the report does not say: which four problems were shown, in which template, where generation stopped, and how the answer was extracted. We made a choice for each of these, and the authors made theirs. We could stop here and write "not reproduced under this protocol; the cause may lie among the unstated items". It is better to measure how much such choices matter.

The lm-evaluation-harness of Section 18.4 (Biderman et al. 2024), which does for many benchmarks what our `EvalSuite` does for a few, has its own protocol for GSM8K with a chain of thought. It shows eight demonstrations whose solutions are written out in prose and end in "The answer is", taken from Wei et al. (2022). We adopt its prompt, its demonstrations, its stop string and its token limit, keep our own extractor, and run the same model on the same 1,319 problems. The two protocols can then be compared item by item.

Under the protocol of the harness the model scores 0.61, with an interval from 0.59 to 0.64, and the published value lies inside it. The paired difference between the two protocols is 10 points, with an interval from 8 to 13 and an MDE of under 4 points. The published number

is thus reproduced under the chain-of-thought protocol of the harness and not under ours. The two protocols differ in the number of demonstrations, in their wording, in the stop string and in the token limit, and together these choices move the score by about ten points, for the same weights and the same questions. We have not identified the protocol of the authors, who speak of four demonstrations where the harness has eight. We have shown that a standard protocol exists under which their number is reproduced, and that a reader who is given the number without its protocol cannot know what it means to within ten points. Recall that the section began with gains of two.

Even a score with its full protocol attached says what a model does on a population of questions. It does not say how the model arrives at an answer, and whether a correct solution of a GSM8K problem was computed or recalled is a question about the model's activations. Section 18.6 intervenes on them.

18.5.5 Summary

A benchmark score is a sample mean, and a difference between two scores counts only if its interval excludes zero. Resampling the differences on shared items removes the common difficulty of the questions, and resampling whole clusters respects their dependence: pairing narrowed an interval by a quarter, and eight samples per problem were worth about one and a half. The minimum detectable effect says what an experiment could have seen, about 6.5 points for a paired comparison on 500 items, so a gain of two points on such a test is no evidence. A suite frozen under a hash makes "the same benchmark" checkable, and a likelihood probe against a reference model older than the benchmark tests for exposure to its items where accuracy cannot. A model judge is one more instrument: ours agreed with experts as often as they agree with each other, put two thirds of its probability on the first of two equal answers, and penalized empty padding. A published score was reproduced under one protocol and missed by more than eight points under another, so a reported number must carry its protocol, and even then it does not say how the model arrives at an answer.

18.5.6 Exercises

1. **Overlapping error bars.** Two models are scored on the same n items. Each has variance v per item, and their scores per item have correlation r.
   1. Show that the two separate 95% intervals overlap as long as the gap between the two accuracies is below $2 \cdot 1.96\sqrt{v/n}$, and that the paired interval excludes zero as soon as the gap exceeds $1.96\sqrt{2v(1-r)/n}$.
   2. For which values of r is there a range of gaps for which both statements hold? How wide is the range at $r = 0$, and which of the two mistakes of Section 18.5.1.1 does that case isolate?
   3. Estimate r for Qwen3-1.7B and Qwen3-0.6B from the two accuracies and the discordant counts printed in the text. Between which gaps, in points, do overlapping bars hide a resolved difference at $n = 500$?
   4. A leaderboard publishes the accuracy of every model with an interval. Explain why no reader can carry out a paired comparison from these numbers, and say what the leaderboard would have to publish instead.
2. **Planning a comparison.** You will compare a fine-tuned model with its base model on ARC-Challenge, which has 1,172 test questions. You expect a gain of 3 points, and you expect the two models to disagree on 27% of the questions, as our pair did.

1. How many questions does a paired test at level 0.05 need for a power of 0.8? Compare with the size of the test set. A common shortcut sets the half-width of the interval equal to the expected gain, as the exercise on sample size in Section 18.3 did. By what factor does the demand for power raise its answer, and what is the power of the test that the shortcut plans?
2. What is the power of the test on all 1,172 questions? Use the fact that the estimate is approximately normal around the true gain, with the standard error of the difference.
3. Instead of more questions you sample m answers per question. Suppose that two differences on the same question have correlation $\rho_d = 0.2$. Using Equation 18.14, find the variance of the mean difference as $m \to \infty$, and conclude how many independent questions one question with many samples is worth at most. What does more sampling fix, and what does it leave? Which quantity of Exercise 5 in Section 18.4 plays the part of ρ_d?

3. code **Clusters of unequal size.** The 2,000 MMLU questions of `report_v1` are clustered by subject, and the subjects differ in size.
   1. Consider G clusters with sizes m_g and $N = \sum_g m_g$ items, each with variance v, with correlation ρ inside a cluster and independence between clusters. Show that the mean over all items has variance $(v/N)(1 + (\sum_g m_g^2/N - 1)\rho)$.
   2. Let $\bar{m}$ be the mean cluster size and c the coefficient of variation of the sizes, their standard deviation divided by $\bar{m}$. Show that the design effect is $1 + ((1+c^2)\bar{m} - 1)\rho$. Do unequal sizes make clustering better or worse than equal sizes with the same mean?
   3. Count the questions per subject in `report_v1.items('mmlu')`, compute $\bar{m}$ and c, and evaluate the design effect for $\rho = 0.02$ and $\rho = 0.1$. By what factor would an interval that ignores the subjects be too narrow?
   4. `d2l.bootstrap_ci` divides two matrix products. Why would the average of the resampled clusters' own means be the wrong replicate for the accuracy over all items when the sizes differ?

4. **A compressing judge.** Suppose that a judge reports its preferences on a compressed scale: $l_1 = \beta + c\Delta$ and $l_2 = \beta - c\Delta$ with $0 < c < 1$.
   1. Show that the estimate $(l_1 - l_2)/2$ is $c\Delta$, that the estimate of the position bias is unaffected, and that the slope check of Section 18.5.3.1 cannot detect c.
   2. Suppose that strengths are fitted to the readings themselves, by least squares with $\Delta \approx \theta_i - \theta_j$. Show that they shrink by the factor c and that the ranking is unchanged.
   3. The text fits the strengths to verdicts instead. Show that a verdict is consistent only if $c|\Delta| > |\beta|$. Which pairs turn into ties under compression, and why is the shrinkage of the strengths then no longer c?
   4. Now let the compression differ between the two orders, $l_1 = \beta + c_1\Delta$ and $l_2 = \beta - c_2\Delta$, the alternative of the text. The mean position bias of Section 18.5.3.3 averages $(l_1 + l_2)/2$ over pairs in which answer a always comes from the model whose name sorts first. Under which condition on these pairs does the mean still estimate β?

5. code **Hard pairs.** ● Agreement with people is easy to obtain on pairs that people find easy.
   1. Among the hard pairs of the stored validation results, take those with at least two decided expert votes. Compare the judge's agreement on the pairs where these votes name the same answer with its agreement on the pairs where the experts

split. The second group has fewer than 30 pairs, so report counts and no interval. What can "agreement with humans" mean on such a pair?
2. With a GPU of 12 GB or more: from the candidate pairs of the validation cell, take the hard pairs that were not among the 400 judged in the text and judge them with `d2l.judge_pairwise`. Report the agreement on consistent verdicts, the share of pairs decided, and the agreement of the experts with each other on the same pairs, each with an interval that resamples questions. Do the new values lie inside the intervals of the hard rows in the text?
3. A paper reports 85% agreement between its judge and human raters on pairs sampled at random. Which two further numbers would you ask for before you let this judge rank two models of similar quality?

6. code **Twelve comparisons.** This problem runs on stored results, without a GPU.
   1. Apply the Bonferroni correction to the twelve comparisons of the development suite in Section 18.5.2.2: recompute every paired interval at level $0.05/12$ by passing `alpha` to `d2l.paired_bootstrap`. Which verdicts change? Why does the correction need more bootstrap replicates than a 95% interval?
   2. The MDE column was computed for level 0.05. Recompute it at level $0.05/12$ with `d2l.min_detectable_effect`. By what factor does the number of items grow that a corrected test needs to detect the same difference?
7. code **Percentile and BCa intervals.** The percentile interval takes the quantiles of the replicate means at face value. The bias-corrected and accelerated (BCa) interval shifts the two quantile levels, to correct for replicates whose median misses the estimate and whose spread depends on the value that is estimated.
   1. For Qwen3-0.6B and its base model on ARC, recompute the paired interval as a BCa interval with `scipy.stats.bootstrap`, and compare it with the percentile interval.
   2. Do the same for the lead of Qwen3-1.7B over Qwen3.5-2B on the 100 GSM8K problems of the development suite, whose percentile interval ends at -0.02. Does the verdict survive?
   3. `d2l.bootstrap_ci` warns below 100 items. Take an accuracy of 0.96 on 50 items. Which values can a replicate mean take, and what can the upper end of a percentile interval never do? Explain why small samples and skewed statistics are where the two kinds of interval differ most.
8. code **A crossed judge design.** ●● The judge of this section shares a family with two of the four answerers. Judge the 1,800 pairs again with Qwen3-4B, which belongs to the family of the other two (a GPU with 16 GB is enough), so that each judge is related to two answerers.
   1. For each judge, compute the win rate of the Qwen3.5 answers over the Qwen3 answers in the four pairs that cross the families, per prompt. The preference for the own family is the difference of this win rate between the two judges. Report it with a bootstrap interval paired over prompts.
   2. Explain why the design identifies an interaction between the family of the judge and the family of the answerer, and why it cannot identify a preference for Qwen models in general.
   3. Fit Bradley-Terry strengths from each judge's verdicts. Do the two judges agree on the ranking? On which pair do they differ most?
9. code **Contamination tests with more power.** ● The accuracy test of Section 18.5.2.3 could not have detected a gap below 12 points.
   1. GSM-Plus (Li et al. 2024) contains, among other perturbations, one numerical substitution for each of the 1,319 test problems of GSM8K. Read its licence, then

repeat the accuracy test for Qwen3-1.7B on these pairs. Compare the MDE with that of the design with 100 templates, and explain the difference from the numbers of originals.

2. A variant may be harder than its original for every model. On GSM-Symbolic, compute the accuracy gap for Qwen3-1.7B and for Qwen3.5-2B, and test the difference of the two gaps with a bootstrap over templates. Why is the MDE of this difference larger than that of either gap? What would a difference of zero show, and what would it leave open?

10. [extended] **A report that another lab can check.** ● Choose one published score of a model that you can run, and reproduce it by the recipe of Section 18.5.4. Write down the card with every item of Table 18.6, the interval and the MDE. List the items that the source leaves unstated. If the published value lies outside your interval, vary one unstated item at a time (the text changed several at once) and report by how much each moves the score, with paired intervals. An exercise of Section 18.4 audits the scoring convention of one published number in this way. Here the object is the whole card.

18.6 Interpretability

When we ported Qwen3-0.6B to the book's own code, we recorded four tensors in every block, to find the layer at which a faulty port leaves its reference (Section 18.2.4). A neuroscientist would envy us those hooks. We can read every intermediate result of the model, on any input and as often as we like, and we can also overwrite it and let the computation run on.

So let us ask the model something whose answer we know. Given the text "The Eiffel Tower is located in the city of", it continues with " Paris". Somewhere in its 28 blocks the name of a tower became the name of a city. Where? And once we have an answer, how would we know that it is true and not merely plausible?

The obvious first step is to read. Every block adds its output to one vector per position, the residual stream, and at the end the output layer turns that vector into logits. Nothing stops us from applying the output layer to the stream after an earlier block. This is the *logit lens* (nostalgebraist 2020), and it shows the answer taking shape on the way up. K. Meng et al. (2022) asked a sharper question. They damaged the input until the model no longer recognized what the sentence was about, then restored single activations from an undamaged run, and recorded which of them brought the answer back. We do the same with a gentler kind of damage. We replace the tower by the Colosseum, copy one activation from that run into the run on the Eiffel Tower, and see whether Paris gives way to Rome. Reading the stream suggests where the fact is handled. Overwriting it tests the suggestion.

The distinction matters because explanations of neural networks are cheap to produce and hard to refute. A classifier that reads grammatical categories from the stream may be accurate because it has memorized the words, and a direction that we would happily name "Chinese text" may respond to under half of it. Both will happen below. The protection is an experiment that could have come out otherwise, and where a threshold decides its verdict, we fixed the threshold before the run. An intervention also has a cost. A model that has been pushed into writing Chinese and has forgotten what it was writing about is of little use, so we measure the damage beside the effect.

The study of a network through its internal computations is called *mechanistic interpretabil-*

ity. Table 10.2 ordered the evidence for the induction heads of a two-block model by strength, from behavior through activations and weights to interventions. This section goes through the same levels on a released model. It is long, and it holds two investigations. The first asks where a computation happens: we read the stream of Qwen3-0.6B with two lenses and a probe, and then overwrite it. The second asks whether the stream can be written in units that we can name and use. For it we move to Qwen3-1.7B-Base, for which a dictionary of such units has been released, and from landmarks to a concept that can be checked token by token, the language of a text. Each of the four parts ends on a result of its own and can be read in one sitting.

The setup cell loads Qwen3-0.6B with `d2l.load_qwen3` (Section 18.2), in fp32 and with its parameters frozen. A few objects of this section had to be trained, which takes longer than a reader should have to wait. As in Section 18.4, a run with the environment variable `D2L_RERUN` set, the *regeneration run*, produced them once and published them under versioned names. An ordinary run downloads them and repeats every measurement. Without a GPU the notebook takes a reduced path, `SMALL`: it uses fewer examples, stays with Qwen3-0.6B to the end, and prints beside each of its results the number of the full run, which is the one that the text quotes. The `d2l` helpers that the cells call without showing them are plumbing: partial reads of files on the Hub, resampling for intervals, and the files of the regeneration run.

The model has 596 million parameters in 28 blocks of width 1,024. One more repository joins the pinned revisions of Section 18.1. It holds the released dictionary, which we meet in Section 18.6.3.3.

The small files of the section are registered next: a treebank for the probe, a list of landmarks with their cities, and the trained objects just mentioned.

Two sources supply text. Each is read at a pinned revision and in a fixed order, so that every subset below is the same in every run. FineWeb-Edu (Penedo et al. 2024), a collection of web pages selected for their educational content (ODC-By license), is our ordinary English text: we measure on it and cut prompts from it, and the trained objects were trained on it. The Chinese and the English Wikipedia (CC BY-SA) give us, for the second investigation, two sets of articles that differ in language and in little else. To these the cell adds our own list of 40 landmarks, `lm-interp-recall-v1`. Its printout lists what was read, and each set of documents is introduced where we first use it.

18.6.1 Reading the Residual Stream

Before we can look for Paris we need two tools: a way to read and to overwrite the stream at any block, and the formula for what the output layer makes of the vector that it finds there. The first subsection supplies both, and the Eiffel prompt gets its answer in the second.

18.6.1.1 The Residual Stream as a Sum

In the attention-only model of Section 10.7, each block added the outputs of its heads to the vector at each position, and the output layer scored the final vector against the embeddings. The sequence of these vectors was the *residual stream* (Figure 10.13). A block of Qwen3 adds twice (Section 11.1): first the output of its attention layer, then the output of its feed-forward network, each computed from a normalized copy of the stream. The interpretability literature calls the feed-forward network the MLP, and in this section so do we.

We count blocks as the code does, from 0 to $L-1 = 27$, and look at one position. Let $\mathbf{h}^{(\ell)}$ be the stream after block ℓ, and $\mathbf{a}^{(\ell)}$ and $\mathbf{m}^{(\ell)}$ what the attention layer and the MLP of block ℓ add to it. (Section 10.7 counted blocks from 1 and wrote $\mathbf{h}^{(0)}$ for the embedding, so its index is ours plus one.) The final stream is then the embedding $\mathbf{e}_x$ of the input token x plus 56 additions:

$$\mathbf{h}^{(L-1)} = \mathbf{e}_x + \sum_{\ell=0}^{L-1} \left(\mathbf{a}^{(\ell)} + \mathbf{m}^{(\ell)}\right). \tag{18.18}$$

The identity holds for any network with skip connections and says nothing about how the blocks compute. Its use is that every term in it is a place where we can read or write. `d2l.intervene` names five such places in each block, which we call *sites*. The left half of Figure 18.7 shows them, and its right half belongs to Section 18.6.2.1. `attn_out` and `mlp_out` are the two additions. `resid_mid` and `resid_post` are the stream after each of them, so that `resid_post` of block ℓ is $\mathbf{h}^{(\ell)}$. These are the four tensors of Section 18.2.4. The fifth, `head_z`, is the input of the output projection $\mathbf{W}_o$ of the attention layer, where the outputs of the individual heads still lie side by side. A site is written as a pair such as `('resid_post', 14)`. The text works with `resid_post`, `attn_out` and `mlp_out`, and the other two wait for the exercises.

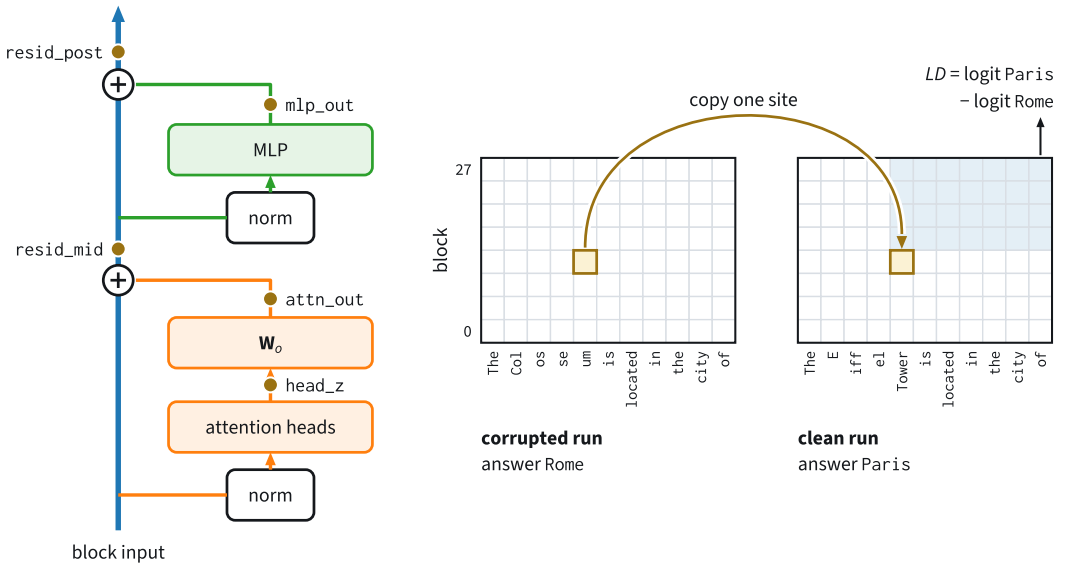

Figure 18.7: Activation patching. Left: the five sites at which `d2l.intervene` reads or overwrites one block. Right: the experiment that these sites serve. One activation is copied from the run on a corrupted prompt into the run on the clean prompt, and the change of the logit difference (LD) is measured at the final position. The shaded region is the part of the clean run that the patch can change: the same and later positions, in the blocks above.

The next cell implements the sites with PyTorch hooks, functions that a module calls before or after its `forward`. `d2l.intervene` returns a context manager. Inside its `with` block, every site listed in `record` is stored in `ctx.cache`, and every site in the dictionary `sites` is passed through the function given for it, whose return value takes the place of the activation. The smallest use is `with d2l.intervene(model, record=[site]) as ctx: model(X)`. Afterwards `ctx.cache[site]`

is a list with one tensor for each forward pass made inside the block, of shape (batch, tokens, width). Most cells below make one pass and take `ctx.cache[site][0]`.

The class is long because hooks are fiddly, and most of it can be skimmed. One detail is worth knowing. The stream is not the output of any module, since the block's own `forward` does the adding. To overwrite the stream with a value $\mathbf{y}$ where it would have been $\mathbf{r}$, the hook shifts the output of the sublayer by $\mathbf{y} - \mathbf{r}$ and lets the block add as usual. Of the remaining arguments, `stop_after` ends a forward pass at a site when nothing above it is needed, and `record_grad` waits for Section 18.6.2.3. Libraries such as TransformerLens offer these operations for many models. We write them out so that nothing stands between us and the activations.

What does one term of Equation 18.18 contribute to the output? The output layer of Qwen3-0.6B is an RMSNorm followed by the embedding matrix $\mathbf{E}$, which the model uses a second time as its output weights. RMSNorm (Section 11.1.2.4) divides a vector $\mathbf{v} \in \mathbb{R}^d$ by its root mean square $\rho(\mathbf{v}) = \sqrt{\frac{1}{d}\sum_i v_i^2 + \epsilon}$ and multiplies the result, coordinate by coordinate, with a learned gain γ. The logit of token t is therefore

$$z_t = \frac{\mathbf{e}_t^\top(\gamma \odot \mathbf{h}^{(L-1)})}{\rho(\mathbf{h}^{(L-1)})} = \sum_{\mathbf{p}} c_t(\mathbf{p}), \qquad c_t(\mathbf{p}) = \frac{\mathbf{e}_t^\top(\gamma \odot \mathbf{p})}{\rho(\mathbf{h}^{(L-1)})}, \tag{18.19}$$

where $\mathbf{e}_t$ is the row of $\mathbf{E}$ for token t and the sum runs over the 57 parts $\mathbf{p}$ of Equation 18.18: the embedding, 28 attention outputs and 28 MLP outputs. Once the denominator is fixed, the logit is linear in the stream. Each part then has a contribution $c_t(\mathbf{p})$ of its own, and the contributions add up to the logit exactly.

It is tempting to print the 57 contributions for " Paris" and to read off who wrote the answer. We shall not, because the list would mislead. A contribution counts only what a part writes directly into the output. A part that writes for the parts above it, say an early layer that works out which landmark is meant, may contribute next to nothing in this sense while the answer depends on it entirely. Contributions describe the last step of a computation. For the steps before it we need the interventions of Section 18.6.2.1.

The logit lens applies the same output layer to the stream after an earlier block:

$$\mathbf{z}^{(\ell)} = \frac{\mathbf{E}\,(\gamma \odot \mathbf{h}^{(\ell)})}{\rho(\mathbf{h}^{(\ell)})}. \tag{18.20}$$

It is instructive to compare this with Equation 18.19. The numerator holds the contributions that have arrived by block ℓ. Only the denominator differs: the lens divides by the size of the stream at block ℓ, the model by its size at the end. The lens at block ℓ is thus the partial sum of the model's own contributions, multiplied by the positive number $\rho(\mathbf{h}^{(L-1)})/\rho(\mathbf{h}^{(\ell)})$. A positive factor on all logits changes how confident the read-out looks. It cannot change the order of two tokens.

A case small enough to compute by hand shows both effects. Take $d = 2$, $\gamma = \mathbf{1}$, $\epsilon = 0$ and $\mathbf{E} = \mathbf{I}$, an embedding $(1, 0)$ and a single block that adds $(0, 3)$. The final stream $(1, 3)$ has the root mean square $\sqrt{5} = 2.24$, so the logits are $(0.45, 1.34)$, the sum of the contributions $(0.45, 0)$ of the embedding and $(0, 1.34)$ of the block. The second token wins. The lens at the embedding sees $(1, 0)$, with root mean square 0.71, and reads $(1.41, 0)$. It names the

first token, as the partial sum $(0.45, 0)$ does, because the block that will decide otherwise has not written yet. The factor $2.24/0.71 = 3.2$ only makes the lens three times surer of its wrong answer.

The function `d2l.logit_lens` is Equation 18.20 in code, computed in fp32.

How large is the factor in practice? The next cell records all 56 additions and the stream after every block on eight prompts of the landmark list. It asserts that the 57 contributions to the logit of the correct city sum to that logit and that the lens at the last block returns the model's logits, and it prints the factor $\rho(\mathbf{h}^{(27)})/\rho(\mathbf{h}^{(\ell)})$ at every fourth block.

Both assertions pass. The stream grows about 55-fold from the first block to the last, and at block 20 it is still two and a half times too small. A lens at block 0 thus reports logits 55 times larger than the contribution of the same vector to the final logits. Its probabilities are far too sharp, and every measure built on probabilities, such as an entropy or a KL divergence, inherits the error. Ranks do not.

18.6.1.2 Logit Lens and Tuned Lens

Now for the question of the introduction. We print the five most probable next tokens for the Eiffel prompt, and then, at every fourth block, the token that the logit lens puts first and the rank that it gives to " Paris".

The model gives " Paris" a probability of 0.91. Through block 16 the lens has no idea of it: among some 150,000 tokens the city ranks in the thousands, and at the lowest blocks in the tens of thousands. At block 20 it is third, and from block 24 on it is first. What the lens reads at the lowest blocks, " construction" and " substance", has nothing to do with towers or cities. So early, the last position knows little beyond its own token.

Is the city really absent below block 20, or is it written in a form that the output layer cannot read? The logit lens assumes that every block writes in the coordinates in which the output layer reads, and nothing in training enforces that. The *tuned lens* (Belrose et al. 2023) drops the assumption. For each block it learns an affine map, a *translator*, which is applied to the stream before the output layer,

$$\mathbf{h}^{(\ell)} \mapsto \mathbf{h}^{(\ell)} + \mathbf{A}_\ell \mathbf{h}^{(\ell)} + \mathbf{b}_\ell,$$

and it trains $\mathbf{A}_\ell$ and $\mathbf{b}_\ell$ on ordinary text so that the lens's distribution over the next token comes close, in KL divergence, to the final distribution of the model. Both start at zero, so training starts from the logit lens. A translator can correct the scale and a change of coordinates. It cannot do the work of the blocks above it, except for the part of that work that happens to be an affine function of the stream at the same position.

Fitting the 27 translators takes 250 steps on a million tokens of FineWeb-Edu and belongs to the regeneration run. Your run loads the result and prints the hash of its file.

One prompt is an anecdote. We repeat the measurement on all 40 prompts of the list, "The X is located in the city of" for 40 landmarks X in 25 cities. Each row of the list also names a second landmark in another city, which we need from Section 18.6.2.1 on. The cell keeps a row only if the model answers it correctly and tells the two landmarks apart: the logit of the right city minus that of the other city, the `LD` of the code, must fall by at least 2 when the landmark is exchanged. For each lens the cell finds the first block at which the median rank

of the correct city is 10 or better. The interval comes from a bootstrap (Section 18.5) that resamples cities and not prompts, since two landmarks in Paris share their answer.

The city becomes readable at block 22 under the logit lens and at block 20 under the tuned lens, and the two intervals do not overlap. A bootstrap over as few as 25 clusters tends to understate the spread, so both intervals are somewhat too narrow. The conclusion does not hang on their last digit: under either lens the answer cannot be read at the last position during the first two thirds of the network, and training the lens gains two blocks.

The plot shows the whole course, together with a second quantity: the KL divergence from the final distribution of the model to that of each lens, averaged over the positions of 200 held-out documents.

A logarithmic axis is hard to read to within a factor of two, so the next cell prints three points of each curve: the first block, the middle of the network, and the last block but one.

The left panel shows the median rank of the correct city (solid) and its quartiles (dashed), on a logarithmic axis with rank 1 at the top. Below block 20 the tuned lens ranks the city far better than the logit lens, and still far from well. At block 14 the median rank is 260 under the tuned lens and about 18,000 under the logit lens. Neither is a rank at which anybody would say that the lens reads the city. The translators of the tuned lens have removed what was a matter of coordinates. What remains, we suspect, is computation that has not happened yet, and Section 18.6.2.1 will put the suspicion to a test.

The right panel shows the KL divergence in nats. Its 95% intervals over documents, the dotted lines, are so narrow that they hide behind the curves. The tuned lens is closer to the final distribution at every block: 3.4 nats against 11 at block 0, 2.1 against 6.1 at block 14, and 0.2 against 0.4 one block before the end. It has to be closer. It was trained to minimize this very quantity, and with zero weights it is the logit lens. The gap between the two curves is therefore no finding. Part of it is the scale error of the logit lens that we computed above. Ranks, on the left, do not see the scale.

Both lenses are read-outs of activations. They show at which depth an answer can be decoded. They are silent on which component put it there, and on whether the model itself reads it in this way.

18.6.1.3 Linear Probes and Control Tasks

A lens reads the model's own prediction. A *probe*, a linear classifier fit to the activations of a frozen model (Section 18.3.4.2), reads anything that we have labels for. The classic question for a probe is whether a model that was trained only to predict the next token knows grammar. If the stream at some block records whether a word is a noun or a verb, a linear classifier should be able to read the part of speech from it.

Our labels come from the English Web Treebank (Silveira et al. 2014) in its Universal Dependencies version (CC BY-SA 4.0), in which every word carries a part-of-speech tag such as NOUN, VERB or ADP. The cell reads every tenth sentence of the training split and every fifth of the other two and runs the model on them. It keeps two vectors per word, both taken at the last token of the word: the token embedding, which knows nothing of the context, and the stream after block 14, halfway up.

This gives about 20,000 words for fitting and 5,000 each for choosing the weight decay and for testing. Almost half of the distinct words of the test set never occur in the training set. They are rare words, however, and make up only a fifth of the running text.

A probe that reaches a high accuracy has shown less than it seems. Most words have one usual tag, so a classifier can score well by recognizing words, without any grammar in the representation. Hewitt and Liang (2019) proposed a test. In a *control task* every distinct word, or word *type*, is assigned a tag at random, once and for all of its occurrences. These tags mean nothing, so a probe can learn them only by memorizing which word is which. The *selectivity* of a probe is its accuracy on the real task minus its accuracy on the control task, that is, the part of its success that memorization does not explain. We fit a multinomial logistic regression to each of the two representations, for the real tags and for five control tasks. Beside the probes stands a baseline that is all memory, a *lookup table*: for each word type it returns the most frequent tag that the type had in training. Intervals resample sentences.

The first surprise is in the first two rows. NOUN, the most frequent tag, covers 16% of the test words, and a probe on the bare token embedding reaches 0.88. Does the embedding encode grammar, then? The lookup table, the row "majority tag per type", encodes nothing and reaches 0.80. It even scores higher on the control task, 0.83, than on the real one, and its selectivity is negative. The reason is simple. A random tag is a function of the word, so the table reproduces it for every word that it has seen. A real tag depends on the sentence: *run* is a noun in one and a verb in the next. A lookup table is better at nonsense than at grammar.

The stream at block 14 raises the accuracy by four points, to 0.92. If accuracy were all we had, we would conclude that the context adds little. The control task says otherwise. Its accuracy falls from 0.77 on the embedding to 0.51 at block 14. The stream has mixed in the context: it has become a worse record of which word stands at a position, and a better record of what the word does there. Selectivity rises from 0.11 to 0.41, a difference of 0.30 with an interval of 0.29 to 0.31. Accuracy barely separates the two representations. Selectivity does.

Even a selective probe is evidence about activations only. It shows that the tag can be read from the stream by a linear map. Whether any later block reads it there, the probe cannot say, and to find out we must intervene. Before we do, note the simplest probe of all. For two classes it is the projection on the difference between the two class means, which needs no fitting. We use this direction twice below, once to detect and once to steer.

18.6.2 Activation Patching

18.6.2.1 Clean and Corrupted Runs

An intervention takes three decisions: which behavior to measure, which activation to change, and what to change it to. The ablations of Section 10.7 set a component to zero. That shows whether the component is needed, and it also pushes the stream to values that it never takes in ordinary operation. *Activation patching* replaces an activation by the value that it has on another input. The model then stays within its ordinary range, and the experiment isolates whatever differs between the two inputs.

For recall, the two inputs are a *clean* prompt, "The Eiffel Tower is located in the city of", and a *corrupted* prompt, "The Colosseum is located in the city of". They differ only in the landmark, which this literature calls the *subject* of the prompt (Figure 18.7, right). We measure the behavior by the *logit difference* at the final position,

$$\mathrm{LD} = z_{\mathrm{Paris}} - z_{\mathrm{Rome}},$$

in which each city stands for its first token, and Rome is the city of the corrupted prompt. LD is large and positive in the clean run and large and negative in the corrupted run. Now we run the clean prompt again and, at one site s and at some of the positions, overwrite the activation $\mathbf{v}_s$ with the value $\mathbf{v}_s^{\mathrm{x}}$ that it had in the corrupted run. The *patching effect* is the logit difference that is lost, and the *normalized effect* divides it by the whole distance between the two runs:

$$\mathrm{PE}(s) = \mathrm{LD}(\text{clean}) - \mathrm{LD}(\text{clean},\ \mathbf{v}_s \leftarrow \mathbf{v}_s^{\mathrm{x}}), \qquad \mathrm{NE}(s) = \frac{\mathrm{PE}(s)}{\mathrm{LD}(\text{clean}) - \mathrm{LD}(\text{corrupted})}. \tag{18.21}$$

An NE of 0 means that the patch made no difference, and an NE of 1 that it did all the damage that replacing the whole prompt would do. One case can be predicted. If we patch `resid_post` of some block at *every* position, everything above that block computes on the corrupted stream, the output is that of the corrupted run, and NE is 1. A complete cut through the network recovers the total effect. Do the effects of the single sites of a cut add up to 1 as well?

Let us consider the smallest case: two sites a and b that are 1 in the clean run and 0 in the corrupted run. If the output is the product ab, an AND, patching either site alone destroys it. Each site has NE 1, and the two effects sum to 2 where the joint effect is 1. If the output is $\max(a, b)$, an OR, patching either site alone changes nothing. Each site has NE 0, and the joint effect is still 1. So the effects of single sites need not add. They count twice what two sites compute together, and they miss what one site can do in place of another. Copying from the corrupted run into the clean one, as we do, is called *noising*, and it tests whether a site is necessary. The opposite direction, *denoising*, copies clean activations into the corrupted run and tests whether a site is sufficient. There the two cases change roles (Heimersheim and Nanda 2024).

The corrupted prompt needs as much care as the metric. Meng et al. corrupted the subject by adding noise to its embeddings, which gives the model an input unlike any text. Later studies replace tokens by other tokens of the same kind (K. Wang et al. 2023; Zhang and Nanda 2024), as we do. Three rules went into our list of pairs. The two prompts differ in one thing only, the landmark, or we could not say what an effect is an effect of. The two landmarks have the same number of tokens, so that positions correspond. And no two cities of the list begin with the same token: for New York and New Delhi the logit difference would compare ” New” with itself.

The next cell collects the pairs that passed the test of Section 18.6.1.2 and sorts the tokens of each prompt into eight classes of positions. The tokens of the subject before its last are pooled into one class. The last token of the subject is a class of its own, and so is each of the six tokens of ” is located in the city of”.

All 40 pairs are kept. The mean logit difference is 8.6 on the clean prompts and -8.9 on the corrupted ones, so exchanging the landmark moves it by about 17.5. The prompts have 9 to 12 tokens.

18.6.2.2 The Patching Map

We patch three kinds of site, `resid_post`, `attn_out` and `mlp_out`, at each of the 28 blocks and each of the eight classes of positions. This makes 672 patched runs per pair. `patched_ld` runs them in batches: one forward pass serves one site, with all pairs of one prompt length and

all eight classes. After the sweep the cell checks the two cases that we can predict at every block, the complete cut with NE 1 and a patch that copies nothing with NE 0.

Before the map, we settle the question left by the AND and OR example. We expect the effect to sit at the subject in the lower blocks, where nothing else distinguishes the two prompts, and at the final position in the upper blocks, where the answer is read. Let us call the first block at which the final position has a larger effect than the last token of the subject the *handover* block. Both positions matter there, so we patch each of the two alone and then both together.

The handover is at block 20. The single effects, 0.11 and 0.55, sum to 0.66, and the joint patch gives 0.68. Here, then, the effects do add, to within 0.02. The example showed that this cannot be assumed, and it took one more run to find out. That the joint effect is 0.68 and not 1 has a plain reason: the two positions are not a complete cut. At block 20 the rest of the effect still sits on the earlier tokens of the subject and at " in".

The next two cells give the map, first in numbers and then as a picture. Look at the picture first. The printed lines are the numbers that the paragraphs below the picture quote. They begin with the entries of the map (the printout calls them cells) whose effect is reliably large: the lower end of a 95% bootstrap interval over cities exceeds a threshold. The threshold is 0.5 for the stream and for attention, and 0.1 for the MLPs, of which no single one was expected to carry much. The remaining lines are explained as we use them.

Each panel has the 28 blocks as rows and the eight classes of positions as columns, and its color is the mean NE over the 40 pairs. Negative means are drawn as zero.

We start with `resid_post`, on the left. Its dark entries form two bands and little else. Up to block 19 the effect sits on the subject, and from block 20 on it sits at the final position, " of". Of the five tokens in between, only " in" shows at all, as a faint column from block 20 on. The bootstrap interval of the handover consists of block 20 alone. Block 20 is also where the tuned lens first read the city. The lens was right, then, about when the answer arrives at the last position. It is the map that tells us so.

Two cautions apply to the band at the subject. First, its large values at blocks 0 to 3 teach us nothing. Overwriting the stream of a subject token just above the embedding is nearly the same as typing the other landmark. Second, the printed list ends at block 3, although the band in the plot runs down to block 19. The reason is that the effect of the subject is divided among its tokens. Through blocks 0 to 19 the two subject classes together have an NE near 1 (median 0.97 over the pairs), and neither class alone stays reliably above 0.5.

Nor is the division the same for all pairs. In 17 pairs more than two thirds of the effect lies on the earlier tokens, as for the Bolshoi Theatre and the Shibuya Crossing. In 11 pairs it lies on the last token, as for Big Ben and the Pantheon, and the other 12 fall in between. It is tempting to look for a rule, for instance that the effect sits on the word that tells one landmark from another. The pairs do not bear it out. The White House and the Western Wall end in a generic word, as the Bolshoi Theatre does, and have their effect on that last word. A column of the map pools tokens that play different roles in different prompts, and its mean describes neither kind.

How does the information get from the subject to the final position? Positions interact only through attention, so the middle panel should show it, and it does. One entry stands out at the final position, at block 20, with a mean NE of 0.42 (interval 0.38 to 0.47). The next largest attention layers at that position have 0.14 and 0.09. A single attention layer has by far the largest share, three times that of any other. It does not do the moving alone: its

patch removes well under half of the logit difference. Geva et al. (2023) describe the same sequence in other models: a representation of the subject is built up at the subject's own position, and attention in the upper part of the network extracts the attribute from there to the last position.

The right panel is the quiet one. An MLP output passes its threshold of 0.1 only at the tokens of the subject in blocks 0 to 2 and at the final position in blocks 21 and 22. The causal tracing of Meng et al. located factual recall in the MLPs of the middle blocks, at the last token of the subject, and our map shows no such band. The two results do not contradict each other. We replace the output of one MLP while the other 27 still compute on the clean subject. If several of them can supply the fact, single patches hide them all, as in the OR example. Meng et al. restored a window of several adjacent layers, in the denoising direction, after a different corruption and in a different model. Our map shows where single sites are necessary. It does not show where a fact is stored.

One entry is clearly negative: the MLP of the last block at the final position, with -0.17. Giving this MLP the output that it had in the corrupted run *raises* the logit difference. The simplest reading is that the last MLP dampens whichever city leads, so that the copy taken from the Rome prompt dampens Rome.

18.6.2.3 Attribution Patching

The map took 672 forward passes per pair, for three kinds of site and coarse classes of positions. Single heads or single positions would multiply that number, and a larger model multiplies the cost of each pass. *Attribution patching* (Nanda 2023) estimates all effects from three passes.

Fix a site, and regard the logit difference of the clean run as a function $g(\mathbf{v})$ of the value at that site, with everything below the site as in the clean run. The patching effect is $g(\mathbf{v}^{\mathrm{c}}) - g(\mathbf{v}^{\mathrm{x}})$, where $\mathbf{v}^{\mathrm{c}}$ and $\mathbf{v}^{\mathrm{x}}$ are the clean and the corrupted value. A first-order expansion of g around the clean value gives

$$\mathrm{PE}(s) \approx -(\mathbf{v}^{\mathrm{x}} - \mathbf{v}^{\mathrm{c}})^{\top} \nabla g(\mathbf{v}^{\mathrm{c}}). \tag{18.22}$$

The estimate is the change of the activation times the sensitivity of the output to it. One forward and one backward pass on the clean prompt yield $\nabla g(\mathbf{v}^{\mathrm{c}})$ at every site at once, because backpropagation computes the gradient with respect to every intermediate result, and one forward pass on the corrupted prompt yields every $\mathbf{v}^{\mathrm{x}}$.

The estimate is exact if g is affine on the segment between the two values. Otherwise it follows the tangent of g at the clean value, wherever the tangent leads (Exercise 4). Let us consider a gate, $g(v) = 1/(1 + e^{-v})$, that is open at the clean value 6 and shut at the corrupted value -6. Exchanging the two takes g from 0.998 to 0.002, an effect of 0.995. At $v = 6$ the gate is saturated and its slope is 0.0025, so the estimate is $12 \times 0.0025 = 0.03$, too small by a factor of more than 30.

Nothing is wrong with the gradient in this example. A gate that is firmly open does not respond to a small change, and the exchange is not a small change. In a transformer, functions that are flat where they stand and steep elsewhere are nothing exotic. A softmax that puts nearly all of its weight on one position is another.

The cell computes Equation 18.22 for all 672 entries of the map and times the computation against the sweep. It needs gradients at sites that are not parameters, and some of them

not even the output of a module. With `record_grad=True` the hook therefore adds to each recorded activation a term that is exactly zero but depends on a fresh variable, a copy of the activation. The forward pass is unchanged, and a backward pass leaves in `ctx.grad_cache` the gradient with respect to that copy, which is the gradient at the site.

The estimate is about 20 times faster. The count of passes, 3 against 672, promises more. The sweep recovers most of the difference by running about a hundred patches in one batch.

Speed is of no use if the estimate is wrong, so we compare the two maps by the rank correlation between estimated and exact effects. It is taken over the entries whose exact effect exceeds 0.05 in absolute value, since among entries near zero the order is noise. Our bar was set in advance: the two maps agree if the lower end of the interval of the pooled correlation is at least 0.6. At its end the cell also walks from the clean stream to the corrupted one in eight equal steps, at one block. We shall need that walk to explain the verdict. The cell after it plots one map against the other.

The estimate fails that test by a wide margin. The pooled correlation is 0.42, with an interval of 0.17 to 0.56, and no kind of site does better. The intervals for attention, which rests on 14 entries, and for the MLPs include zero. The next three lines show where the error lies. In blocks 21 to 27 the mean absolute error is 0.05, and at the final position from block 20 on the estimate is low but close, 0.62 against 0.75. Below the handover it collapses. The two subject classes together have an exact effect of 0.98, and the estimate says 0.10. Attribution patching misses the largest effects of the whole map.

In the plot, every point is an entry of the map, and on the dashed diagonal the estimate would be exact. The points that run along the diagonal, somewhat below it, belong to the final position in the upper blocks. The cloud at the lower right, large exact effects with estimates near zero, is the subject below the handover.

Why there? The estimate follows the tangent of g at the clean value, and the tangent accounts for a tenth of the drop. The rest must come further along the segment between the two landmarks, and the last lines of the printout go and look. After block 10, halfway up to the handover, the cell moves the stream at the tokens of the subject a fraction t of the way from its clean to its corrupted value and measures the NE. On a straight line an eighth of the way would cost an eighth of the effect, 0.12. It costs 0.02, and a quarter of the way costs 0.09. Then the curve turns steep. Between three eighths and five eighths the NE rises from 0.25 to 0.71, almost half of the whole effect in a quarter of the way, and towards the corrupted end it flattens again, at 0.97.

This is the gate of our small example, drawn by the model itself. A small step away from the Eiffel Tower still leaves the model with the Eiffel Tower. The gradient says what a small change of the activation would do, and it says so correctly: not much. Replacing one landmark by another is not a small change.

The walk shows the shape of g and not the mechanism behind it. Kramár et al. (2024) study such misses and name two main sources, a saturated attention softmax and the cancellation of a direct effect by indirect ones. Which of them flattens g at the subject, neither our three passes nor the nine points of the walk can say.

In practice the estimate serves as a screen. Where it reports an effect, an exact patch confirms and measures it at little cost. Where it reports none, it has shown nothing, and no site can be ruled out with it.

18.6.3 Sparse Autoencoders

18.6.3.1 Dictionary Learning on the Residual Stream

Patching told us where the stream matters, and when. It told us nothing about what the stream contains. So we turn to the second question: can a vector of the stream be written in units that we could name? For this question we leave the landmarks. Such units have to be learned from millions of positions. A good set has been published for Qwen3-1.7B-Base and none for Qwen3-0.6B, and a released set is what we want to examine. The model will therefore change below, and the concept with it, from the city of a landmark to one that can be checked token by token: the language of a text.

The coordinates of the stream are of no help as units: no single one of them has a meaning that we could read. Besides, a model has many more things to represent than its stream has coordinates, so the things that it represents, its *features*, must share directions. This is called superposition (Elhage et al. 2022).

A small case shows why sharing need not end in confusion. Take three features and give them three directions in the plane, 120 degrees apart. Two coordinates cannot give each of the three an axis of its own. But suppose that at most two of the features are present at a time, in nonnegative amounts. Every vector of the plane lies between two of the three directions, and it can then be written in one way only, as a combination of those two. Now let all three be present in equal amounts. They cancel, and the stream reads zero. Features that outnumber the coordinates can be told apart as long as few of them are active at once.

The proposal for taking such a mixture apart is older than deep learning. Olshausen and Field (1996) described patches of natural images as sums of a few elements chosen from a learned *dictionary*, which may hold more elements than a patch has pixels, and the elements that they learned resembled the receptive fields of simple cells in the visual cortex. Applied to a language model (Bricken et al. 2023; Cunningham et al. 2024), the idea is to write each stream vector $\mathbf{x} \in \mathbb{R}^d$, the stream $\mathbf{h}^{(\ell)}$ of one block at one position, as

$$\mathbf{x} \approx \mathbf{W}\mathbf{z} + \mathbf{b}, \qquad \mathbf{z} \geq 0 \text{ with few nonzero entries.}$$

The columns $\mathbf{w}_j$ of $\mathbf{W} \in \mathbb{R}^{d \times m}$ are $m \gg d$ candidate directions of features, and the entry z_j of the *code* $\mathbf{z}$ says how strongly feature j is present. We say that a feature *fires* at a position where its entry is positive. The letter $\mathbf{z}$ follows the literature and our code. Logits, which had it until now, do not occur in the rest of the section. A *sparse autoencoder* (SAE) computes the code with one linear layer and a nonlinearity, its encoder, and is trained to reconstruct $\mathbf{x}$ (Figure 18.8).

How is the code made sparse? The classical choice is a penalty on its size. With the bias left out,

$$\min_{\mathbf{W},\, \mathbf{z} \geq 0} \ \tfrac{1}{2}\|\mathbf{x} - \mathbf{W}\mathbf{z}\|^2 + \lambda \|\mathbf{z}\|_1, \tag{18.23}$$

summed over the training vectors, each with a code of its own. Two properties of this objective explain the design of current SAEs.

The first is a loophole. Multiply a column $\mathbf{w}_j$ by c and divide z_j by c: the reconstruction is unchanged and the penalty is c times smaller. Without a bound on the columns the penalty

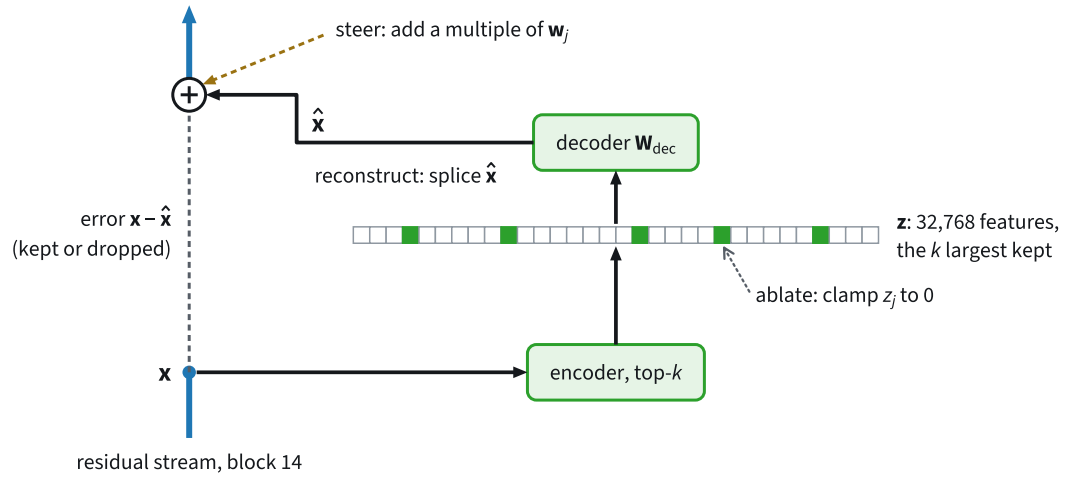

Figure 18.8: A sparse autoencoder on the residual stream. The encoder keeps the k largest of many feature activations, and the decoder adds up the directions of these features. Splicing the reconstruction $\hat{\mathbf{x}}$ into the stream in place of $\mathbf{x}$ drops the error $\mathbf{x} - \hat{\mathbf{x}}$ (dotted) and shows what the dictionary loses. The figure also marks two interventions on a single feature, of which we use the second: setting z_j to 0, and adding a multiple of the direction $\mathbf{w}_j$ to the stream.

can be scaled away, and the minimum is never attained. The columns are therefore held at unit norm.

The second is a bias. Suppose that the columns are orthonormal. This requires $m \leq d$ and is not the case of interest, but it shows the mechanism. Write $y_j = \mathbf{w}_j^\top \mathbf{x}$. The objective then separates into one problem per feature, with the solution

$$z_j = \max(y_j - \lambda,\, 0). \tag{18.24}$$

Features below the threshold λ are switched off, which is the intent. Every active feature is also reported too small by λ, which is not. For $\mathbf{x} = 3\mathbf{w}_1$ and $\lambda = 1$ the code is 2, and the reconstruction $2\mathbf{w}_1$ misses the input by 1, although the dictionary holds the direction of the input exactly.

Top-k autoencoders (L. Gao et al. 2025) do without the penalty. The encoder keeps the k largest entries of $\mathbf{y}$ and sets all others to zero. Sparsity is then a setting, at most k active features at every position, and nothing shrinks: the top-1 code of $3\mathbf{w}_1$ is 3. All dictionaries of this section are of this kind. They keep the unit norm, so that the activations of different features can be compared.

18.6.3.2 A Top-k Autoencoder

Before we open a released dictionary we build one ourselves: 8,192 features, of which $k = 50$ are active, for the stream after block 14, halfway up the network. It will not be a good one and does not have to be. Its use is to show what goes into such an object, and to stand beside the released one when we measure both. The code is a class, a training loop, and

four short cells that train the dictionary in the regeneration run and download it otherwise. In your run these print a parameter count and a hash, and all of it may be skimmed. Two explanations on the way should not be missed: why the model changes, and why the first position of every window of text is left out.

The class uses the parameter names and shapes of the released files that we load later, so that one class serves both: an encoder `W_enc` with bias `b_enc`, and a decoder `W_dec` with bias `b_dec`. With `center=True` the encoder first subtracts `b_dec` from its input, as Gao et al. do. Top-k and the unit norm we have just met, and `topk_relu` and `normalize_decoder_` implement them. One more idea deserves a sentence, that of *dead* features. A feature that is never among the k largest receives no gradient and stays out for good. The method `loss` therefore returns an auxiliary term, in which the features that have not fired for a while are asked to reconstruct what the others left over. The last method, `remove_parallel_grad_`, removes the part of a gradient that the return to unit norm would undo anyway, and can be forgotten.

The training loop, `d2l.train_sae`, is plain Adam over random rows of a table of activations. It starts the decoder bias at the mean of the data and the encoder at the transpose of the decoder, and it counts for each feature the steps since it last fired.

Training takes 5,000 steps. The first of the four cells trains a dictionary for Qwen3-0.6B, which only the `SMALL` path uses. On a GPU it does nothing.

Here is the change of models that we announced. It is a nuisance and cannot be helped, since the comparison with a released dictionary is the point of what follows. The cell frees the small model and loads Qwen3-1.7B-Base with the same loader, in bf16. Both models use the same vocabulary, so the token ids of our data remain valid.

The last two cells record the stream of the new model after block 14 and train our dictionary on it, or download the result. One detail of the recording matters for every measurement that follows. The text is cut into windows of 256 tokens, and as in Section 18.2.4 the first position of every window is left out. The first token is an attention sink whose stream is far larger than any other (Section 11.3.3.3), and it alone would decide a squared error. The few other positions of extreme norm are dropped for the same reason. About seven million positions of FineWeb-Edu remain.

18.6.3.3 A Released Dictionary

A good dictionary takes far more data and care than we have spent, and research groups have begun to publish theirs, as they publish models. Qwen-Scope (Deng et al. 2026) is such a release for several Qwen models. Among its dictionaries is, for Qwen3-1.7B-Base, one top-k SAE with 32,768 features and $k = 50$ for the stream after each of the 28 blocks. Its model card carries a paragraph headed “Caution”, which restricts what the SAEs may be used for. Terms of this kind are part of what we download, so we print the paragraph from the pinned revision before anything else.

Measuring what steering does to a base model is scientific research in the sense of the paragraph, and we use the SAE for nothing else. Its file is downloaded when the notebook runs, 537 MB for the one block that we need, and none of its contents is distributed with the book.

The loader fetches one file and checks its tensors against the shapes in the configuration of the repository. One of its arguments deserves attention. A `.pt` file is a pickle, and unpickling can run code that the author of the file put there. With `weights_only=True`, `torch.load` refuses everything but tensors and plain containers. Current versions of PyTorch do so by

default. We write the argument out all the same, and no downloaded `.pt` file should be loaded without it.

How good is a dictionary? `d2l.sae_metrics` computes three numbers on held-out text. L_0 is the mean number of active features per position. The *fraction of variance unexplained* (FVU) is the squared reconstruction error divided by the squared deviation of the stream from its mean, so 0 is perfect and 1 is no better than a constant. The third number asks what the model makes of the reconstruction. The function splices $\hat{\mathbf{x}}$ into the stream in place of $\mathbf{x}$, lets the model run on, and measures the cross-entropy of the next token. Two reference points turn this into a scale: the cross-entropy of the unchanged model, and that of a model whose stream is replaced by its mean, which is called *mean ablation*. Then

$$\text{loss recovered} = \frac{\text{CE}_{\text{mean}} - \text{CE}_{\text{splice}}}{\text{CE}_{\text{mean}} - \text{CE}_{\text{orig}}}$$

is 1 if the splice costs nothing and 0 if it is as bad as the mean.

Before we believe any feature of the release, we check that we apply it as its authors do. One convention is at stake: whether the encoder first subtracts the decoder bias from its input, as Gao et al. and our own class do, or reads the stream as it is, as the example on the model card does. Nothing in the tensors of a file says which convention it was trained with. A wrong guess raises no error. It yields a dictionary whose features fire, have contexts on which they fire most and can be given names, and which describes the model badly.

So we do not take even the card's word for it. The cell tries both conventions on 200 held-out documents and keeps the one with the smaller FVU. By a rule set in advance, it uses the release only if its FVU is then below 0.5 and its loss recovered above 0.5.

The release reads the raw stream, as its card says. Under that convention a quarter of the variance is unexplained, and under the other 88%. The check is of the same kind as the one in Section 18.2, where the port was compared with its reference before any use. A released artifact is an instrument, and an instrument is checked before it is read. Note also what the loss recovered says of the wrong convention: 0.95. We return to this number in a moment.

Now our own dictionary, on the same positions.

The table is not a contest. The released dictionary is four times wider, and its card does not say on how many tokens it was trained, presumably far more than our seven million. That our FVU of 0.29 comes close to its 0.26 is pleasant and proves little. The table is here for what it teaches about the instruments.

FVU says that a quarter of the variance of the stream is missing from either reconstruction. Loss recovered says 0.98, which sounds as if almost nothing were lost. Both are right. Loss recovered is measured against mean ablation, and mean ablation is a catastrophe: it takes the cross-entropy from 2.48 to 9.2 nats per token, most of the way to the 11.9 nats of a uniform guess over the vocabulary (Section 18.3.4.1). On a scale that long, anything that leaves the model working scores close to 1, including the release under the wrong convention. The number to look at is the cross-entropy that the splice adds: 0.13 nats per token for the release and 0.17 for ours. That is a real loss. Even for the better dictionary the perplexity rises by about 14%. An analysis that goes through an SAE describes this slightly worse model, and not quite the one that we set out to understand.

The last row counts the features that never fire on these 51,000 positions: 3 of ours, and 8,147 of the release, a quarter of its dictionary. It would be rash to call them dead. Our held-

out text is English prose from educational web pages, and a large dictionary has features for other languages, for code and for much else that such text does not offer. The next subsection meets a feature that fires on a third of all positions in Chinese text and hardly ever in English.

One warning before we use the features. A dictionary describes the checkpoint that it was trained on. Applying it to another one, say to the post-trained sibling of a base model, is an assumption, and the reconstruction check tests it.

18.6.3.4 Features and Their Labels

What do the features of the released dictionary stand for? The usual procedure is to look at the text on which a feature is most active and to give it a name. Which features we look at must not depend on whether we like what we see, so we choose three by rules. The first comes from a contrast: among all 32,768 features we take the one whose firing rate differs most between 300 Chinese and 300 English Wikipedia articles. Both sets have the same source, so language is what separates them. (The data cell took the articles from 20 places spread over each Wikipedia file, because neighbors in such a file share topics.) The other two features are drawn at random among those that fire on between 0.1% and 1% of the held-out positions.

For each of the three we print its *top contexts*, the eight on which its activation is highest. A line shows the activation, the text up to and including the token at which the feature fires, and in brackets the token that follows.

The contrast is clear-cut. Feature 24946 fires on 35% of the Chinese positions and hardly ever on an English one, and four more features follow with rates between 14% and 27%. Its top contexts are Chinese prose on organizations, archaeology and software, and a label suggests itself: *Chinese text*. The printout also counts 12 *dense* features, which fire on more than a tenth of the held-out positions and can stand for nothing as specific as the examples here. The random draw leaves them out.

Feature 24639 was drawn at random and is just as easy to name. It fires at ” Fort” before ” Worth”, at ” San” before ” Francisco”, and at ” the” before ” Atlanta”, ” Vancouver” and ” Arizona”: a place name is about to be written or completed. The feature concerns the token to come and not the one that it sits on. Its first context lies in a Chinese article, so it does not care about the language around it. Feature 11270, the third, fires in Chinese and in English, before ” calls”, ” who” and “tra”, and we cannot name it. Galleries of published features show the first two kinds. A random draw also returns the third.

A name given on the strength of eight contexts is a hypothesis about the largest activations of a feature. It claims nothing about the weaker ones, nor about the text on which the feature should fire and does not. So we test the label “Chinese text” as a rule, on 100 Chinese and 100 English articles that took no part in the choice. A token counts as Chinese if it contains a *Han character*, which is Unicode’s name for the characters of the Chinese script, or Chinese punctuation. The feature predicts “Chinese” wherever it fires. The rule is an instrument, too. A rule that asked for a Han character alone would score every Chinese comma on which the feature fires as a false alarm, and we would blame the feature for an error of the label. Tokens that are fragments of the bytes of a character cannot be labeled alone and are left out.

Two competitors are scored beside the feature. One is the five features of the contrast table together, active where any of them is. The other needs no dictionary. It is the two-class

probe of Section 18.6.1.3: the projection of the stream on the difference between the mean Chinese and the mean English stream of the contrast articles, with its threshold halfway between the two means. Precision is the fraction of the predicted tokens that are Chinese, and recall the fraction of the Chinese tokens that are predicted. The AUC is the probability that a Chinese token receives a higher score than a token that is not Chinese.

The label is right about where the feature fires and wrong about how much it covers. Where the feature is active, the token is Chinese in 88% of the cases. Since the feature fires in none of the English articles, the other 12% are tokens inside Chinese articles that the rule does not count, such as numerals and Latin names. But the feature is active on only 44% of the Chinese tokens, with an interval of 37% to 51%. "Chinese text" would describe a feature that fires on all of them. This one fires on some Chinese text, and its top contexts do not reveal on which.

The five features together reach a recall of 0.81. The dictionary has spread the concept over several features, each of which covers a part. This is known as *feature splitting*. A general feature may also fall silent in the cases that a more specific one has taken over (Chanin et al. 2024). Either way the label of a feature promises more than the feature keeps.

As a detector, the plain projection beats them all. It finds 98% of the Chinese tokens, and its AUC of 0.97 exceeds the 0.70 of the feature by 0.27, with an interval of 0.23 to 0.30. Its precision of 0.81 is lower, and it crosses its threshold somewhere in 65 of the 100 English articles, where the feature never fires. Kantamneni et al. (2025) and Smith et al. (2025) report the same, the first over many probing datasets: for detecting a concept that is known in advance, the features of sparse autoencoders have not reliably beaten linear probes.

A direction that is read from the stream while a model runs is called a *monitor*. R. Chen et al. (2025) watch for traits of a model's character with directions of this kind, obtained from contrasting prompts. Our table shows what a monitor is: a detector, whose precision and recall have to be measured before its flag means anything.

What a dictionary offers is of another kind. A probe answers a question that we thought to ask. The dictionary proposed "a place name comes next" without being asked, and every such proposal then has to be tested as we tested the first.

18.6.4 Steering

18.6.4.1 Steering Directions

If a direction of the stream stands for Chinese, then adding it to the stream should make the model write Chinese. This is *steering*, the most direct intervention of all, and the Qwen-Scope report demonstrates it with features for languages. What such demonstrations tend to leave out is the cost. A vector added to the stream at every position disturbs everything else that the model computes there. We therefore measure both the behavior and the damage, as functions of the strength.

At block 14 we replace the stream at every position $i \geq 1$ by

$$\mathbf{h}_i^{(14)} + \alpha\, \bar{n}\, \mathbf{u}, \tag{18.25}$$

where $\mathbf{u}$ is a direction of unit length and $\bar{n}$ is the median norm of the stream at this block on English text. The *strength* α is thus a fraction of the typical length of the stream. This puts

the strengths of different directions on one scale. What a given strength costs still has to be measured. Position 0, the attention sink, is left alone.

Four interventions compete. The first direction is the decoder column of feature 24946. The second is the difference between the mean streams on Chinese and on English text, which served as a probe above. Rimsky et al. (2024) steer with such a difference of means, and Zou et al. (2023) with a principal component of such differences. We call these two the *informed* directions, as the code does. Five random directions give the floor: they show what any vector of this length does. The fourth intervention changes no activation. It puts a Chinese sentence in front of the prompt, which announces that the text will continue in Chinese. We wrote the sentence down before any run and did not tune it.

The stream has a median norm of about 190. The two directions that both "mean" Chinese are far from parallel, with a cosine of 0.28. A concept does not single out one direction of the stream. The random directions are nearly orthogonal to both.

18.6.4.2 The Steering Frontier

We measure behavior on 100 prompts, the first 32 tokens of English web documents. The steered model continues each of them greedily for 48 tokens, and a continuation counts as *switched* if at least 30% of its characters are Han characters. This rule is cruder than that of the label test, which also counted punctuation, and it can afford to be: at 30% of a whole continuation a few commas decide nothing.

We measure cost on 200 other English documents, as the increase of the cross-entropy per token under the same intervention. The cost comes in two versions. The plain cross-entropy charges the model for all the probability that it moves to Chinese tokens, which is the very thing we asked for. The second version first renormalizes the distribution of the model over the tokens without Han characters. (The data cell marked the others, about one token in six of the vocabulary.) It measures the collateral damage: how much worse the model predicts English once we disregard its new inclination to switch. A cost of 0.5 nats per token, which raises the perplexity by about two thirds, is the largest that we consider, and we call it the *cap*.

The strengths run from 1/16 to 2, each larger than the last by a factor of $\sqrt{2}$. A first run on this grid showed the whole transition of both informed directions inside one step, so between 1/16 and 1/4 these two get a finer grid, in steps of about 6%. For each of them the cell prints the largest strength whose plain cost stays below the cap, and the next one.

Three things stand out. First, random directions do not switch a single prompt at any strength, although they do their share of damage: 0.35 to 0.41 nats at $\alpha = 0.7$. The switch is the work of the direction and not of the disturbance. Surprisingly, the model tolerates a great deal of disturbance as long as it points nowhere in particular: a random vector 70% as long as the stream itself costs about as much as an informed one of 10% to 16%.

Second, steering is not a dial with a comfortable range. Between $\alpha = 0.157$ and $\alpha = 0.167$, a step of about 6%, the feature goes from 29% to 52% of the prompts, and its cost from 0.25 to 0.62 nats. The difference of means makes the same jump near $\alpha = 0.1$. That it acts at a smaller strength is no advantage, since it does its damage at a smaller strength as well. A strength alone says little, then, and from here on we compare the two directions by cost.

Third, the prefix switches 1 prompt in 100. Its cost is small, 0.05 nats per token, and so is its effect. A base model continues the document in front of it, and an instruction placed

before an English document is one more sentence that the document then ignores. Wu et al. (2025) found prompting ahead of every steering method that they tried, on models trained to follow instructions. Our prefix does not test their claim. Exercise 7 does.

To compare the directions, we plot the fraction of switched prompts against the cost and take for each direction its *frontier*: the largest fraction that it reaches at a given cost or less. One number summarizes a frontier, the area under it between zero cost and the cap. A direction that switched every prompt at no cost would have an area of 0.5, the width of the cap. The cell computes the area under both versions of the cost, the fraction switched at the cap, and the cost at which half of the prompts switch. The cap falls between two measured strengths, in the middle of the cliff, so the fraction at the cap is read off the frontier by linear interpolation. The intervals come from 2,000 bootstrap replicates that resample prompts and documents and use the same resample for both directions, so that differences are paired.

The first result is that the question "does steering work within the cap?" has no answer until we say what counts as damage. Under the plain cost neither direction switches half of the prompts within the cap. The largest strengths below it switch 29% and 17%, at the cap itself the frontiers stand at 45% and 37%, and half of the prompts takes about 0.6 and 0.9 nats. Under the cost without Han tokens the feature gets there, with half of the prompts at about 0.3 nats and 65% at the cap. The difference of means comes to about one half at the cap: 54%, with an interval of 45% to 63%. A report on steering has to say which cost it used.

The second result reverses the order of the label test. As a detector, the difference of means was far better than the feature (Section 18.6.3.4). As a direction to push along, it is no better. The direction that best separates two sets of activations need not be the best one for moving the model from one to the other. On these prompts the feature is in fact slightly ahead. Its area under the plain cost is 0.124, a quarter of the 0.5 that a free switch would give, against 0.099. The paired difference of 0.025 has an interval of 0.001 to 0.052, and without Han tokens it is 0.036, with an interval of 0.007 to 0.067. One hundred prompts barely resolve a lead of this size: 2% of the replicates have the other sign. The reversal does not depend on it.

The last lines of the printout add nothing new. Below the cap no random direction switches a prompt, and the prefix, with its one prompt, is no better than either direction at its cost of 0.05 nats.

In the plot, the lines are the two frontiers, the markers on them the single strengths, and the dashed line is the cap. The cost axis is logarithmic above 0.01 nats, so the areas that we computed, which belong to a linear axis, cannot be compared by eye. Both curves do rise to nearly all prompts, far to the right of the cap.

The gray points are strengths beyond the best one of each direction. There the fraction falls again, at the largest strengths to zero. More of a direction that stands for Chinese does not give more Chinese. What it gives instead is best seen in the text that the model writes.

So, finally, what does a steered model write? The cell takes each direction at its largest strength below the cap, where 29% and 17% of the prompts switch. It prints the continuations of three of the prompts and of the Eiffel prompt, with the collateral cost of each setting. Then it goes to the gray points and prints the Eiffel prompt at two of them for each direction: the first strength past the peak, and the largest, $\alpha = 2$.

None of the three web prompts switches to Chinese under any intervention, as most prompts do not at these strengths. The second is a Dutch title and stays Dutch. They are

not untouched, though. Under the difference of means the apricot of the first prompt becomes “a popular fruit in China”. A direction computed from the Chinese and the English Wikipedia separates more than the language.

The Eiffel prompt switches under both directions, in the middle of a sentence. With the feature the model writes “It is 324米高” and goes on to say in Chinese what the unsteered model said in English: that the tower was built in 1889 for the hundredth anniversary of the French Revolution. The language changed and the facts did not. With the difference of means the sentence turns after “324米 high” into a school exercise that asks for the unit of the 324, and then into another exercise altogether. Two directions of almost the same cost produce very different text, and no number on the frontier shows it.

The last four continuations belong to the gray points. One step past its peak, at $\alpha = 0.71$, the feature still switches 80% of the prompts, and its Eiffel Tower is Chinese from the first token on: the tower stands in the center of Paris (巴黎), rises into the clouds, and is made of iron. The city has survived. The engineer has not: he is now a Henry Edgar Edgar. The difference of means, one step past its peak at $\alpha = 0.35$, still switches 65% of the prompts. To this one it replies with a multiple-choice question, “A. Paris B. London C. Berlin D.莫斯科” (the last is Moscow). It gives A as the answer and starts on a second question, in which Chinese characters stand inside English words. It is the school exercise again. The prose is gone, and the answer is still Paris.

At $\alpha = 2$ the two directions meet. Both print rows of brackets, full-width ones under the feature and plain ones under the difference of means, and no prompt counts as switched. The cost does not keep track of this decline. The difference of means costs 9.1 nats one step past its peak and 6.8 nats at $\alpha = 2$, and in the plot the gray points at the bottom reach as far left as about 1 nat. Past the peak, neither axis of the frontier orders the strengths any more, and only the text shows what has happened.

18.6.4.3 Levels of Evidence

Table 18.7 arranges the checks of this section as Table 10.2 arranged those of the induction heads, by the level of evidence that each provides. Its last column is the one to read. Every check that only read activations left open whether the model uses what was read, and each time it took an intervention to say more.

Table 18.7: Evidence about Qwen3 gathered in this section, by level.

check in this section	evidence level	supported conclusion	remaining limitation
continuation of the prompt	behavioral	the model recalls the city	identifies no component
exchange of the landmark	input intervention	the answer follows the subject	says nothing about the inside
logit lens, tuned lens	activation	the city can be decoded at the last position in the last third of the network only	a read-out; the scale of the logit lens is wrong
probe with a control task	activation	the stream at mid-depth records the part of speech beyond the identity of the word	does not show that the model uses it

check in this section	evidence level	supported conclusion	remaining limitation
activation patching	component intervention	recall needs the subject in the lower blocks and the final position in the upper ones; one attention layer has the largest share of the transfer	single sites, one direction, one corruption; redundancy stays hidden
attribution patching	gradient	a fast estimate that is close in the upper blocks	misses the largest effects, at the subject below the handover
splice of the reconstruction	component intervention	the release, applied as checked, leaves the model nearly as good a predictor	a quarter of the variance is not in the dictionary
feature label	activation	one feature fires on Chinese text	drawn from the strongest activations only
label as a tested rule	activation, with a baseline	the label is precise and covers under half of the concept; a difference of means detects better	one concept, one rule for the label
steering against cost	component intervention	two directions switch the language, random ones do not	the cost rises as steeply as the effect; one concept

Every row below the second needed the weights of the model, and the interventions needed write access to its activations. The largest models cannot be opened in this way at all. They answer over a network, and what comes back is text. Section 18.7 has to make do with that.

18.6.5 Summary

A claim about what a model computes is tested by changing its activations, and reading them only suggests what to test. Lenses and probes show what can be decoded from the residual stream, and a control task, or a baseline as plain as a lookup table, shows how much of a probe's accuracy is the model's doing. Activation patching located the recall of a landmark's city in Qwen3-0.6B at the subject up to block 19 and at the final position from block 20, with one attention layer carrying the largest share across. The fast first-order estimate of the same map missed its largest effects. A sparse autoencoder decomposes the stream into features that can be named, at a loss that the reconstruction measures. Such a name is a hypothesis: ours had a precision of 0.88 and a recall of 0.44, and a difference of means detected the same concept better. Steering along a direction changes the language of the model only near the strength at which it begins to damage everything else, so an effect is reported together with its cost and with a random direction as the floor.

18.6.6 Exercises

1. **The lens at the embedding.**
    1. The lens at block 0 multiplies the contributions that have arrived there by the factor 55 that we measured. Suppose that these contributions favor one token

over another by 0.1. Which odds between the two tokens does the lens report, and which odds do the contributions imply? Why does the factor leave the rank of every token as it is?

2. Applied to the embedding $\mathbf{e}_x$ alone, the lens is a function of the current token only. Which statistics of text can such a read-out reproduce at best?
3. code Compute this read-out for the 1,000 most frequent tokens of the held-out documents. For how many of them is the first-ranked token the input token itself? Explain the result from the fact that the model uses $\mathbf{E}$ both as its embedding and as its output weights.

2. **Reading a control task.**
   1. Our control task draws one tag for each word type. Suppose that it drew a tag anew for every occurrence of a word. Which accuracy could a probe then reach on the control task, whatever the representation, and why would such a control say nothing about memorization?
   2. The lookup table reaches 0.83 on the control task. Predict this value from two numbers that the section prints: the fraction of the test words whose type does not occur in training, and the frequency of the most frequent tag.
   3. code Compute the task accuracy, the control accuracy and the selectivity of a probe on the stream after blocks 0, 4, 8, 12, 16, 20, 24 and 27, with `d2l.lm_word_features`. At which depth is the selectivity largest, and how does it change towards the last block? Relate what you find to the job of the last blocks, which is to predict the next token.
3. code **Denoising.** ● Compute the map of Section 18.6.2.1 in the denoising direction: run the corrupted prompt, copy single sites from the clean run, and normalize the gain in logit difference as in Equation 18.21.
   1. List the entries in which the two maps differ by more than 0.2, and explain each group with the AND and OR cases.
   2. Does the `mlp_out` panel now show a band at the last token of the subject? Restore the MLP outputs of five adjacent blocks at once and compare.
   3. Add `resid_mid` to both maps. In which blocks does it differ from `resid_post`, and what does the difference isolate?
4. **The error of attribution patching.**
   1. Derive Equation 18.22 from Taylor's theorem, and show that its error is at most $\frac{1}{2}\sup_{t\in[0,1]}|\delta^\top \mathbf{H}(\mathbf{v}^{\mathrm{c}}+t\delta)\,\delta|$, where $\delta=\mathbf{v}^{\mathrm{x}}-\mathbf{v}^{\mathrm{c}}$ and $\mathbf{H}$ is the Hessian of g. When is the estimate exact?
   2. For the gate of Section 18.6.2.3 the estimate was too small. Let now $g(v)=v^2$, with the clean value 1 and the corrupted value 0, and compute the effect and the estimate. Then find a clean and a corrupted value for which the estimate has the wrong sign.
   3. Show that $\mathrm{PE}=-\delta^\top\int_0^1\nabla g(\mathbf{v}^{\mathrm{c}}+t\delta)\,dt$ holds exactly.
   4. code Approximate the integral by the mean of the gradients at 8 points of the segment, for `resid_post` at the two subject classes in blocks 0 to 19. A site can be overwritten and recorded with its gradient in the same `d2l.intervene` context. How close does the estimate come to the exact effect of 0.98, and how many passes does it take? Which of the 8 points contribute most to the mean? Compare with the walk that the section printed for block 10. Then repeat the walk at blocks 2 and 18. Does the curve keep its shape?
5. **Shrinkage.** Let the columns of $\mathbf{W}$ be orthonormal.
   1. Derive Equation 18.24 from Equation 18.23.

2. Let $\mathbf{x} = \sum_{j \in S} y_j \mathbf{w}_j$ with $|S| = k$ and all $y_j > \lambda$. Show that the squared reconstruction error of the L1 code is $k\lambda^2$, and that the top-k code reconstructs $\mathbf{x}$ exactly.
3. Give an input for which the L1 code and the top-k code have different sets of active features. Which of the two reconstructs it better, and which one would you call sparser?

6. code **A second concept.** ● Repeat Section 18.6.3.4 and Section 18.6.4.1 for French against English Wikipedia.
   1. Report the precision, recall and AUC of the best contrast feature and of the difference-of-means probe on held-out articles.
   2. Report the areas of the two frontiers under both costs, with the paired interval of their difference. The switching rule needs a replacement for the test on Han characters. State yours.
   3. Is the order of the two directions the same as for Chinese, in detection and in steering?
7. code **Prompting a model that follows instructions.** ● The prefix of Section 18.6.4.1 was tested on a base model. Load the post-trained Qwen3-1.7B with `d2l.load_qwen3`.
   1. Compute the FVU and the loss recovered of the released dictionary on this model. Does it pass the rule of Section 18.6.3.3?
   2. Render the 100 prompts with the chat template, once with the request to continue the text in Chinese and once without, and measure the switched fraction and both costs of the request.
   3. Steer the model with the two directions on the prompts without the request, and put all three on one frontier. Does the request beat both directions at equal cost, as Wu et al. (2025) report for their models?
8. code **Induction heads by ablation.** ●● The experiment of Section 18.3.4.1 showed that Qwen3-1.7B-Base copies a repeated random sequence and named no component.
   1. With the `head_z` site, replace the output of one head at a time by its mean over all positions and sequences, for every head of the model, and record the rise of the loss on the second copy.
   2. Which heads matter most, and in which blocks do they lie? Compare their effect with that of five heads drawn at random.
   3. Ablate the five most important heads together. Is the joint effect larger or smaller than the sum of the single effects, and which of the two cases of Section 18.6.2.1 does this resemble?
9. [extended] **Transcoders and an attribution graph.** ●● A *transcoder* is a sparse dictionary that is trained to reproduce the output of an MLP from its input. Since its features replace the MLP, the effect of a feature in one block on a feature in a later block is linear once the attention patterns and the normalization factors are fixed, and these effects form an *attribution graph* (Ameisen et al. 2025). Gemma Scope 2 publishes transcoders for the Gemma 3 models but none for Gemma 4, and Qwen-Scope releases dictionaries for the residual stream only, so we train our own for `google/gemma-4-E2B-it`, the second model family of Section 18.1. This is a project for a weekend.
   1. Pick a block in the middle of the model and record, on held-out text, the input of its MLP (the output of the normalization in front of it) and the output of the MLP. Change `d2l.train_sae` so that a `d2l.TopKSAE` encodes the input and is trained to reconstruct the output, and train one with 16,384 features.
   2. Apply the reconstruction check of Section 18.6.3.3 to the output of the MLP, and measure the loss recovered when the transcoder replaces the MLP.
   3. For one prompt of the landmark list, find the ten transcoder features with the

largest contribution to the logit of the correct city in the sense of Equation 18.19, and look at their top contexts on held-out text.

4. Test one of these features by intervention: set it to zero and measure the change of the logit difference. Does the contribution predict the change?

18.7 Models behind an API

Every model in this chapter so far ran on our own GPU. We read its files, ran its tensors in the book's code, prompted it, scored it and opened it up. None of these models had more than a few billion parameters.

The open models that people use most are far larger. DeepSeek-V4.1-Flash, whose weights anyone may download, has about three quarters of a trillion parameters, more than a server with eight 40 GB GPUs can hold even at four bits per weight. Yet anyone with an account can send it a grade-school word problem and read the answer a second or two later, for less than a hundredth of a cent. The model is then somebody else's service, reached through an *application programming interface* (API): we send a request over the network and receive text. What can we still measure about a model that we cannot hold, and how do we keep those measurements as trustworthy as the earlier ones?

A hosted model shows its client three things: a protocol, a price and limits. The protocol is the *chat-completions* request, which OpenAI introduced with its chat models in 2023 and which nearly every company that hosts models, and every local server, has since adopted. The price is charged per token, for what we send and for what comes back. The limits are of two kinds: a service refuses requests that arrive too fast, and it cannot return most of what we read from our own models.

A service says little about itself, so whatever we learn about it we must time and count from outside. The client becomes the measuring instrument. Its first question, how many requests to send at once, is older than the computer: telephone engineers developed queueing theory to decide how many lines an exchange needs. And since a service changes without notice and cannot be run again, each of its numbers needs a date, the name of the company that served it, a cost, and a stored copy of the response.

We read the protocol, build the client, and run three numbered experiments. Experiment 1 asks how many requests a server can usefully hold at once, Experiment 2 which model to use and at what price, and Experiment 3 whether the same request returns the same reply. They reuse the prompt builder of Section 18.3, the answer extractor and the GSM8K problems of Section 18.4, and the paired comparison of Section 18.5. At the end we ask which measurements of this chapter can still be made through an API.

18.7.1 The Chat-Completions Protocol

18.7.1.1 Hosted Models and Their Providers

Open weights are hosted by many companies at once, each of which sells access by the token. We call such a company a *provider*. A *router* is a service that puts one address and one account in front of many providers and forwards each request to one of them. We use the router OpenRouter. Providers differ in their prices and in the precision at which they serve the same weights, so for each model we *pin* one provider: every request for that model is served by the same company.

Calling a service costs money, and a service need not answer the same way twice. The outputs on this page are therefore a recording. We sent every request once, on 13 November 2026, and stored the responses, and the cells below replay them without touching the network (Section 18.7.2 shows how). With a key of your own you can make your own recording. Most of the next cell configures that machinery, and only its four model names matter now. DeepSeek-V4.1-Flash is the model that the code and the tables call the *flagship*. Qwen3.8-27B is a much smaller open-weight model. The third, gpt-5-nano, is a *closed* model: its weights are not published, and it appears in one test only. Qwen3-4B is the model that will run behind a server on our own GPU.

The cell reports that it replays. Two tables come before the first request, and the first of them answers a question: what does a router know about its providers? It publishes a *listing*, a table with one row for each provider of a model. A row gives the context length, the prices and the request fields that the provider says it supports, and most rows give the precision of the served weights. The next cell prints the rows of our three pinned providers from a snapshot that was taken during the recording.

Prices are in dollars per million tokens, and a generated token costs four to nine times as much as a prompt token. The ratio has a reason that we know from decoding: the whole prompt passes through the model in one parallel step, while every generated token needs a step of its own. The column `cached` is a much lower price for prompt tokens at the start of a request that repeat the start of an earlier one. The provider has kept the keys and values of that prefix, the key-value cache again, and need not compute them a second time. The last four columns are claims, which we shall test. All of these numbers are dated, since a listing changes without notice.

The suffix `fp8` in the provider column says that both pinned providers serve 8-bit weights. For Qwen3.8-27B that is half the precision of the release, which is in bf16. The flagship was released at low precision in the first place, one part of its weights in 8 bits and the larger part in 4.

Why not download these models, as before? The next cell multiplies each parameter count by 2 bytes (bf16), 1 byte (fp8) and half a byte (4 bits), as if all weights of a model had one precision. It reports the highest of the three that fits one 24 GB card and servers with eight GPUs of 40 GB or 80 GB.

At four bits per weight the flagship still needs 382 GB, and its release, with part of the weights in eight bits, needs more. Only the server with eight 80 GB cards can hold it, and that is before a byte is spent on the key-value cache. Qwen3.8-27B is another matter. At four bits it would fit our 24 GB card, and we could indeed have run it ourselves. We call it through a provider all the same, because Experiment 2 needs a second hosted model, at a second company, to compare prices. Qwen3-4B fits the card in bf16, which makes it our local model.

18.7.1.2 Requests and Responses

A chat-completions request is a JSON object sent by HTTP `POST`. The first request of this section reads as follows, apart from two fields that only the router understands and to which we shall come.

```
{"model": "deepseek/deepseek-v4.1-flash-1017",
 "messages": [{"role": "user",
               "content": "Carmen has $100, Samantha has $25 more ..."}],
```

```
    "temperature": 0,
    "seed": 0,
    "max_tokens": 512}
```

The field `messages` holds the conversation as a list of roles and contents, the structure that we passed to a chat template in Section 18.3. Here the server applies the template, so the client never sees the tokens that the model reads. Most other fields set the sampler of Section 8.6. The fields `temperature` and `top_p` shape the distribution from which a token is drawn, `max_tokens` bounds the length of the reply, `stop` lists strings at which the reply ends, and `seed` asks for a draw that can be repeated. Newer servers also accept the bound on the length under the name `max_completion_tokens`.

A few fields request extras. `logprobs` asks for the log-probabilities of the generated tokens, `response_format` for output that follows a JSON schema, `n` for several alternative replies to one request, and `stream` for the reply in pieces, called chunks, as it is generated.

The question in this request is the first of our GSM8K test problems, the grade-school word problems with a number as the answer that we scored in Section 18.4. The client that the next cell creates may spend the fraction `share` of the recording's cost cap, and it switches off a feature called reasoning, to which we come in a moment.

The cell prints the text of the reply and a few numbers from the response, which is again a JSON object. Abridged to the fields that we use, it reads

```
{"model": "deepseek/deepseek-v4.1-flash-1017",
 "provider": "Novita",
 "choices": [{"finish_reason": "stop",
              "message": {"role": "assistant",
                          "content": "Let's break it down ..."}}],
 "usage": {"prompt_tokens": 36, "completion_tokens": 118,
           "cost": 0.000084}}
```

The reply sits in a list called `choices`, which has one entry unless the request asked for more with `n`. The most important part is the `usage` block: 36 prompt tokens, 118 completion tokens and, an addition of this router, the cost in dollars. The client cannot check these counts itself. It never sees the rendered prompt, and for a closed model it has no tokenizer either. With the released tokenizer of an open model we could count our own words, and we still would not know what the server wrote around them. The `usage` block is therefore the only record of what was processed and the basis of the bill, here less than a hundredth of a cent.

The other fields are quickly told. The field `finish_reason` says why generation ended: `stop` at the end-of-sequence token, `length` at `max_tokens`. The field `model` names the model that served the request, and the router adds the provider. A field `system_fingerprint` is meant to identify the serving configuration, and it came back empty in every response of our recording. The answer, 400, is correct.

In Section 18.4 we let Qwen3 think before it answered, inside a think block that we could read and count. Many hosted models *reason* in the same way, and a service treats that text as output: it bills it as completion tokens and counts it against `max_tokens`. This sets a trap. Qwen3.8-27B reasons unless it is told not to. Of our 100 test problems we send it the one with the longest reference solution, with a budget of 64 tokens, and then again with reasoning switched off and a budget of 1,024.

The first reply is empty. All 64 completion tokens were reasoning tokens, and the budget ran out before the answer began. The response does return the reasoning, 258 characters of it in a field of its own, but no answer. An empty reply that ends with `length` and has as many reasoning tokens as completion tokens is the signature of this failure. With reasoning off the model writes 871 tokens and ends on the correct answer.

The cell prints the last line of that reply and not an extracted answer, for a reason that is worth knowing. The reply uses `####` for its Markdown headings, and the extractor of Section 18.4, which takes the first number after the last `####`, would have returned 96,000, a number under the last such heading. The extractor expects a format, and this request showed the model none.

The three numbered experiments of this section all run with reasoning off, so that every arm answers in the same mode and every token that we pay for is one that we can read. Each of them asserts that no response contains reasoning.

Services that reason usually provide a dial as well, on OpenRouter the field `reasoning` with an `effort` of `low`, `medium` or `high`. We try it on the flagship, with the five of our 100 problems that have the longest reference solutions. The fifteen requests go out together through `d2l.chat_batch`, a helper that Section 18.7.2 shows, and the word `await` in front of it waits until all of them have returned.

The dial is a request, and the model decides what to make of it. At `high` the flagship spent more reasoning tokens than at either other setting on each of the five problems: in the median about one and a half times as many, at nearly 40% more cost than `low`. The settings `low` and `medium` could not be told apart. Their medians lie within a few tokens of each other, and `low` spent more than `medium` on three of the five problems. The response has the same fields at every setting, and only the token counts in `usage` show what the dial did. Five problems make an anecdote, of course, and the cell says nothing about accuracy.

18.7.1.3 Endpoints and Their Fields

Providers, routers and local servers all accept the protocol. An address at which a server accepts it is called an *endpoint*. The router's is `https://openrouter.ai/api/v1`, its *base URL*, to which the client appends a path: `/chat/completions` for a request, `/models` for the list of models that the endpoint offers. One client class therefore reaches every model of this section, and to move from one endpoint to another it changes two strings, the base URL and the model name.

Our local endpoint is `transformers serve`, the server that comes with the Transformers library. We start it with *continuous batching*: the server does not wait for a batch to finish, and admits a new request into the running batch between two decoding steps. It serves Qwen3-4B and not a model of the newer Qwen3.5 family that earlier sections used. Transformers' continuous batching has no cache for the recurrent layers that Qwen3.5 mixes with its attention layers (Section 18.1), and the server would run such a model one request at a time. Programs that serve models are called serving engines, and Chapter 30 treats them in their own right. Here the server is only an object to measure.

One flag deserves attention now: `--cb-max-memory-percent 0.2` gives the server's key-value cache at most a fifth of the card's free memory. Left to itself the server would claim most of that memory. A fifth leaves the card room to spare, and it has a consequence that we shall meet again. A server can decode only as many sequences at once as its cache has room for, so this budget bounds the capacity that Experiment 1 will measure.

On this page the server does not start: its responses were recorded like all the others.

That every endpoint accepts a request does not mean that every endpoint does the same thing with it. We make the router refuse what it can: we forbid fallbacks to other providers and set `require_parameters`, so that a request fails unless the pinned provider lists every field in it. That still leaves the provider that lists a field and ignores it. The only defense is to test each field by its effect.

The next cell writes out two such *detection rules*. The field `seed` is honoured if two requests with seed 7 return the same text and a third with seed 8 returns a different one. The three requests sample at temperature 1 wherever the endpoint accepts a temperature, because at temperature 0 nothing is drawn and a seed has nothing to fix. The field `stop=['5']` is honoured if a request to count from 1 to 10 returns a 4 and no 5. The rules in the library follow the same pattern.

The table of verdicts has one column per endpoint, named by its model: `flagship` is DeepSeek-V4.1-Flash at Novita, `Qwen3.8-27B` is served by Parasail, `gpt-5-nano` by OpenAI, and `local` is our own server. Three verdicts fill most cells. *Rejected* means an error status, *ignored* that the request succeeded and the rule failed, and *honoured* that the rule held. Two more mark half-answers: *partial*, where the endpoint did part of what the field asked, and *inconsistent*, where the response contradicts itself. Most rows are named by the field that they send, and we explain the others as we come to them.

Read the `seed` row first. All three hosted endpoints list `seed`, and none of the three returned the same text for the same seed. The rule cannot tell whether a provider dropped the seed or applied it to logits that differ from one request to the next, which Experiment 3 will show they do. For a client the two come to the same thing.

The flagship's provider lists log-probabilities and returned them for only part of the reply. No endpoint returned two choices for `n=2`. The row `prompt log-probabilities` sends two fields that are not in the protocol and that some servers add, and no endpoint answered them with the log-probabilities of a prompt.

Now read down the column `local`. Our own server is the least obliging of the four: it honours the seed and the thinking switch, and it ignores `stop`, `logprobs`, `response_format`, `n=2` and the token cap. Having the weights on our own card is no help as long as we speak to them through a server that somebody else wrote. What a field does is decided by the program that answers.

The remaining rows need less attention. The row `thinking switch` turns reasoning on and off, and `stream usage` asks a streamed reply to end with its `usage` block. The row `/v1/models` asks the endpoint to list its models. It reads *ignored* for the local server, which builds its list from the branches in the Hugging Face cache, where a model that was downloaded at a pinned commit, like ours, has none. The server serves a model that it does not list. The last row sends four requests at once. It reads *batched* if the slowest of them took less than twice as long as a single request, and *rate-limited* if the endpoint answered with the status 429, "too many requests". Three endpoints batched the four requests. The provider of Qwen3.8-27B answered with 429s, and the client retried until every request had succeeded.

Two columns hold details that a first reading can skip. All three rejections in the column of the closed model came from the router. It refused `logprobs` and `stop` because the listing of this model lacks both fields and we had set `require_parameters`, and it refused the switch that turns reasoning off because it marks reasoning as mandatory for this model. The *inconsistent* in the same column is stranger. Under a cap of 16 completion tokens the `usage`

block reported more reasoning tokens than completion tokens. Our statement that reasoning tokens are counted inside completion tokens is therefore limited to the endpoints of our experiments.

The last column compares the local server with its own source code, which keeps a list of request fields that the server accepts and does not act on. The server agrees with that list in all rows but two. It ignores `stop`, which is not on the list, and it honours `stream usage` although `stream_options` is on it, because it sends `usage` with the last chunk of every stream, asked or not. A declaration in the source is a claim, like a row in a listing.

A table like this one is a snapshot of a single day, and it is cheap. The two open-weight columns cost less than a cent together. Make one before any experiment that relies on a field.

18.7.2 A Measuring Client

18.7.2.1 Records, Replays and Cost

Every call so far went through one class, `d2l.ChatAPI`. Its plumbing is in the library, and the methods that carry ideas are shown here. The first idea is the record. A response from a service cannot be recomputed, so the client appends each one to a file and looks there before it sends anything. The lookup key is a hash of the request, and the design lies in what enters it.

Every field that can change the response must be in the hash: the host, the model, the messages, the sampling and format fields, and the routing fields, since a different provider is a different service. If one is missing, the cache silently returns a stale answer to a changed question. Nothing secret may be in the hash, which excludes the headers with the API key. The key has a second reason to stay out: with it, a reader who has another key, or none at all, would miss every entry. Nor does the hash hold anything that leaves the response unchanged, such as the choice of streaming.

One part of the key exists only on the client, the number `replica`. Without it two identical requests would share one cache entry, and we shall soon want twenty answers to one question. Which of the five variations in the next cell should change the hash?

Streaming and a different API key leave the hash unchanged. A replica number, a seed and a provider each change it.

The client uses the cache in one of three modes. In mode `replay` a miss raises an error, so a page that replays can never reach the network. Mode `record` sends only what is missing, and mode `live` always sends. A replay returns one recorded draw from the service. It makes this page reproducible, and it does not make the service deterministic, as we shall see.

The second idea is that cost is arithmetic on `usage`. A provider charges per token at up to three rates, in dollars per million tokens: r_{in} for prompt tokens, r_{out} for completion tokens, and the lower rate r_{cache} for the prompt tokens of a prefix that is still in its *prompt cache* from an earlier request. A response with n_{in} prompt tokens, of which n_{cache} were cached, and n_{out} completion tokens costs

$$\frac{(n_{\text{in}} - n_{\text{cache}})\, r_{\text{in}} + n_{\text{cache}}\, r_{\text{cache}} + n_{\text{out}}\, r_{\text{out}}}{10^6} \tag{18.26}$$

dollars. Reasoning tokens need no term of their own, because they are part of n_{out}. For the first response of this section, with 36 prompt tokens, none of them cached, and 118 completion tokens, Novita's rates of 0.165 and 0.66 dollars per million tokens give 0.000084 dollars, the amount that the router billed.

Round numbers are easier to check by hand. At the same rates, a response with 1,000 prompt tokens and 300 completion tokens should cost $0.000165 + 0.000198 = 0.000363$ dollars. The next cell checks this. It then asks the listing what a second provider, DeepSeek itself, charges for the same model at 02:00 and at 12:00 UTC of one Thursday.

At two in the morning, UTC, DeepSeek's own endpoint lists twice its noon price. That hour is ten in the morning in Beijing, and the listing doubles the price for the working hours of a Chinese weekday. A cost therefore needs the hour of the request as well as the day.

Since the cost of a request can be bounded before it is sent, the client also enforces a budget. Before each live call it reserves the worst case, one prompt token per byte of the request plus `max_tokens` completion tokens, and it refuses to send when the reservation would cross the cap.

18.7.2.2 Retries and Full-Jitter Backoff

A service fails in ways that a local model does not. Connections drop, requests time out, and a busy provider answers with the status 429, sometimes with a header `Retry-After` that says how long to wait. The client should retry these failures, but not a malformed request or a bad key (the statuses 400 and 401), which would fail forever. How long should it wait?

The standard answer is *exponential backoff*: after the failed attempt a, counted from 0, wait for the time $d_a = \min(d_{\max}, b\,2^a)$, with a base b and a cap $d_{\max}$. Every failure doubles the wait. But consider many clients that fail at the same moment. If each of them waits d_a, they all return together and fail together again. *Full jitter* (Brooker 2015) breaks the tie: each client sleeps for a time drawn uniformly from $[0, d_a]$.

A uniform draw from $[0, d_a]$ has mean $d_a/2$. Suppose that each attempt fails independently with probability p. This is the bold assumption of the calculation, since a provider that has just rejected a request will probably reject the next one as well, and we shall drop it shortly. The client sleeps after attempt a only if the attempts $0, \dots, a$ all failed, which has probability p^{a+1}. With at most K retries the expected total sleep is therefore

$$\mathbb{E}[S] = \sum_{a=0}^{K-1} p^{a+1}\,\frac{d_a}{2}. \tag{18.27}$$

Take $b = 1$ s and $d_{\max} = 60$ s. A client that fails six times in a row sleeps $(1 + 2 + 4 + 8 + 16 + 32)/2 = 31.5$ s on average, against 63 s without jitter. With $p = 0.3$ and $K = 6$ the terms are $0.15, 0.09, 0.054, \dots$, each 0.6 times the one before, and they sum to 0.3575 s. In words: even when three attempts in ten fail, retrying costs a request about a third of a second on average. Backoff is cheap as long as failure is the exception.

The method `achat` puts the parts in order: the cache lookup, the cost reservation, then the retry loop. It is an `async` function, the first in this book. Python suspends such a function at every `await`, here while it sleeps or waits for the network, and runs other pending calls in the meantime, all in one thread. This is how a single notebook cell keeps dozens of requests

in flight. A caller writes `await` in front of the call to wait for its result, and a notebook cell may do so directly.

The loop treats a `Retry-After` header as a floor under the jittered sleep, and it counts every 429 itself. That takes a precaution. The client sends its requests through the OpenAI Python package, which by default retries twice on its own and would hide those failures from us, so its retries are switched off.

The function `chat_batch` sends a list of requests with a bound on how many are in flight, and it returns the results in the order of the requests. Its few lines are the mechanism of all three experiments. The semaphore holds `concurrency` permits. A request takes one before it is sent and gives it back when its response has arrived, and at that moment the next request starts. The call to `asyncio.gather` starts all requests and waits until the last of them has returned.

We test the retry loop on `d2l.FakeChatServer`, a stand-in inside the notebook's process that answers after a fixed service time, a given number of requests at a time. Here it is scripted to answer 429 twice before it succeeds, and then to answer 401.

The first request needed three attempts, and the client counted two 429s. The second raised its error after one attempt. Next we check Equation 18.27 with 200,000 simulated clients.

The simulation agrees with the formula. Jitter halves the mean sleep, which is welcome, but that is not why it exists. The reason shows only when many clients fail together. Their failures are then anything but independent, so we leave the formula and simulate. In the last simulation 64 clients send at the same instant to a server that admits ten requests in any window of one second and rejects the rest, once with the fixed waits d_a and once with full jitter.

Without jitter the clients return in lockstep. Each wave gets ten of them through, and the last four finish after 63 s, the sum of the six waits above. With full jitter all clients are done after about 15 s in the median run, and after about half a minute in the slowest of 200. The number of attempts hardly differs: jitter saves about ten of 238, on nearly every seed. What jitter changes is when the retries arrive: spread over the interval, they find the windows that synchronized clients leave empty.

18.7.3 Concurrency and Throughput

18.7.3.1 Little's Law for a Closed Loop

How many requests should a client keep in flight? One at a time wastes a server that batches, and a thousand at once are answered with a stream of 429s. The answer rests on a result from 1961. *Little's law* (Little 1961) relates three averages of any system in a steady state: the number L of requests inside, the rate X at which requests pass through, and the time W that a request spends inside. It says that

$$L = XW.$$

A shop that serves two customers a minute, each of whom stays for five minutes, holds ten customers on average. The law assumes nothing about how requests arrive or how long each one takes.

Our client runs a *closed loop*: it keeps c requests in flight and sends a new one the moment one returns, which is what `chat_batch` does with `concurrency=c`. Then $L = c$ is not measured

but set, and the law ties together the two quantities that we do measure, the throughput X in requests per second and the latency W in seconds: $XW = c$. A server has two regimes. Lightly loaded, it answers each request in its unloaded latency W_0, so that $X = c/W_0$ grows in proportion to c. But a server also has a capacity $X_{\max}$, and once the throughput has reached it, the law leaves the latency no choice: $W = c/X_{\max}$. Together,

$$X(c) = \min\left(\frac{c}{W_0},\, X_{\max}\right), \qquad W(c) = \max\left(W_0,\, \frac{c}{X_{\max}}\right). \tag{18.28}$$

The two regimes meet at the *knee* $c^* = X_{\max}W_0$. Below the knee, more concurrency gives more throughput at the same latency. Beyond it, more concurrency gives only more latency. With $W_0 = 2$ s and $X_{\max} = 8$ requests per second the knee lies at $c^* = 16$. A client that keeps 32 requests in flight receives the same 8 answers per second and waits 4 s for each.

To measure X and W we avoid the two ends of a run, where all c requests start together and where the loop drains. The function `closed_loop_stats` uses only the *steady window*, from the c-th to the $(N - c)$-th of the N completions. For streamed replies it also reports the *time to first token*, the delay between sending a request and receiving the first token of its reply.

Two further numbers check the measurement and not the server. A first reading may take them on trust, since both stay close to 1 in all our runs. The first, `little`, is the ratio XW/c. We set $L = c$ and the law always holds, so only the way we measure can move this ratio away from 1. The window may be too short to be steady. Or the latencies vary so much that the requests wholly inside the window, the only ones that W averages, are the short ones, and the ratio falls below 1. The second number, `sustained`, is the mean number of requests in flight divided by c. It falls below 1 when slots of the loop stand empty, because a request failed or the client was slow to send the next one. Check that both are near 1, and then read X and W.

We first point the instrument at a server whose answer we know. The fake server takes 0.1 s per request and serves 8 at a time, so $X_{\max} = 80$ requests per second and $c^* = 8$. Up to 8 requests in flight the throughput should be about $10c$ per second. At 16 and 32 it should stay at 80, while the latency doubles to 0.2 s and again to 0.4 s.

The measured throughput follows Equation 18.28 at every level, and both ratios stay within 2% of 1, as the cell asserts. The instrument works.

18.7.3.2 The Knee of a Local Server

Experiment 1 runs the closed loop against Qwen3-4B on our own server, where a knee must exist and requests cost nothing. Each request asks a GSM8K training question, streams the reply, and stops after 64 tokens. We sweep c from 1 to 128 in powers of two with $8c$ requests per level, twice and in shuffled order, so that a drift of the server cannot pass for an effect of c. A helper cell defines one level of the loop and the printed table.

Besides X and W, the table gives the throughput in completion tokens per second (`X_tokens`) and the median and the 90th percentile of the time to first token. The column `in decode` applies Little's law a second time, to a part of the server. A request first waits for its first token and then decodes. Requests enter the decoding stage at the rate X and stay in it for W minus the time to first token, so the product of the two is the mean number of requests that are decoding at once. The table is large. Read one pass at a time: follow `X_tokens` down the levels, then `W`, and then the three columns `ttft_p50`, `ttft_p90` and `in decode`.

Alone, a request takes about 2.7 s for its 64 tokens, or 24 tokens per second. Up to 16 requests in flight the throughput nearly doubles with every doubling of c, while the latency creeps up to about 3.1 s. Between 32 and 64 the curve bends. At 128 the server delivers no more than at 64, about 12 requests or 750 to 800 tokens per second, at twice the latency. The two passes agree closely, and both check ratios stay within a few percent of 1. The ratio `little` falls furthest below 1 at $c = 128$, where the requests that fit wholly inside the window are the faster ones.

The columns `ttft_p50`, `ttft_p90` and `in decode` show what happens inside the server. At $c = 32$ about 28 requests are decoding at once, and nine in ten receive their first token within about half a second: the server takes in every request as it arrives. At 64 about 46 are decoding, and the slowest tenth of the requests wait more than 3.5 s for a first token. At 128 no more are decoding than at 64, and now the median request waits almost 8 s before its reply begins. The server admits about 45 sequences into its batch and queues the rest.

This is a limit of admission, and it belongs to the server as we started it, not to the GPU. By the sizing rule in the Transformers source, a fifth of the free memory of our card comes to a cache of fewer than 50 blocks of 256 tokens, and each of our short requests occupies one block. The GPU itself could have taken more. Dividing `in decode` by X gives the time that a sequence spends decoding: with 64 requests in flight it receives its 64 tokens in about 3.7 s, against 2.6 s when it is alone. A batch of 46 slows each sequence by less than half, so batching had not stopped helping when the cache was full.

It remains to fit the two parameters of Equation 18.28. For each pass we take W_0 as the latency at $c = 1$ and $X_{\max}$ as the largest throughput observed. As a check that does not rest on the model we also compute the *efficiency* $E(c) = XW_0/c$, the fraction of the linear speedup that level c achieves. We say that a level is past the knee if E stays below 0.7 from that level on, and we claim a knee only if both passes put it at the same level. The threshold is a convention. In the model of Equation 18.28 the efficiency is $\min(1, c^*/c)$, so a value below 0.7 means a level more than 1.4 times the knee.

Both passes give $W_0 \approx 2.7$ s and $X_{\max} \approx 12.4$ requests per second, so the two straight lines of Equation 18.28 meet at $c^* \approx 33$. The efficiency rule names $c = 64$, again in both passes. The two statements agree: the corner lies just above 32, and 64 is the first level of our grid that is clearly past it.

But did the server not decode 45 sequences at once? It did, and 33 and 45 are one capacity, computed with two different times. The model assumes that a request in a full batch is as fast as a request alone. It is not: a sequence in the full batch decodes for about 3.7 s, and 12.4 requests per second times 3.7 s gives the 46 sequences of the table, where 12.4 times the unloaded 2.7 s gave 33. The latency starts to grow long before the cache is full.

The plot shows the two passes with the fitted curves, the throughput in tokens per second on the left and the mean latency on the right. The fit is good at both ends and too sharp in the middle: at $c = 32$ the server delivers about 550 tokens per second where the model promises more than 750. Real servers round the corner.

What should a client of this server do? Raising c from 32 to 64 still adds more than 40% to the throughput, while the mean latency grows from about 3.6 s to 5.2 s. Beyond 64 nothing is gained but waiting. A client that wants throughput keeps about 64 requests in flight, and one that wants short waits stays near 32.

Does a hosted provider have a knee as well? Surely, but one client will not find it. We run three levels of the same loop against the flagship.

The throughput at 32 requests in flight is about 30 times that at 1, the latency stays at about 1.4 s, and no level drew a 429. The check ratio `little` drops to about 0.95 at the two higher levels. Hosted latencies vary more than local ones, so the requests wholly inside the window are the shorter ones, the effect that we described. We are far below this provider's knee, so the 21 requests per second are a lower bound on its capacity and nothing more. Most of the 1.4 s is the wait for the first token, about 1 s, which is why a time to first token should be reported apart from the latency of a whole response. One more caution for anyone who times a stream: chunks are not tokens. A provider may pack several tokens into one chunk, so a token rate must come from `usage`.

18.7.4 Accuracy, Cost and Reproducibility

18.7.4.1 Hosted and Local Models on GSM8K

Experiment 2 asks the question that a user of these services faces: which model, at what price? We take the 100 GSM8K test problems of Section 18.4 and send every model the same request. It opens with four worked examples as alternating user and assistant turns, built by `d2l.fewshot_prompt` of Section 18.3, followed by the question. We decode at temperature 0 with seed 0, at most 512 tokens and reasoning off.

Each example ends on a line of the form `#### answer`, the format that `d2l.extract_answer` looks for first. Where a reply has no such line, the extractor falls back on the last number in it. One model, sent the 100 requests once, is an *arm* of the experiment. The prompt, the decoding settings and the extractor are the same for every arm. What differs is the model, and that includes how well it follows the format of its examples.

There are four arms. The flagship runs twice, as replicas 0 and 1 of identical requests. The second run costs little and gives what no single run can: the disagreement of a model with itself, the floor below which no difference between models means anything. Qwen3.8-27B and the local Qwen3-4B complete the set, each arm with eight requests in flight.

The flagship solves 97 of the 100 problems in both replicas, Qwen3.8-27B solves 94, and the local Qwen3-4B 83, each with a bootstrap interval several points wide. The flagship is also the fastest, at about a second and a half per problem in the median.

The reasoning trap taught us to ask how a reply ended before we count it as wrong. The table does not say, so we looked in the recorded responses. Three hosted replies ran into the limit of 512 tokens and count as errors: one of the flagship's first run, on a problem that its second run solved in about 100 tokens, and two of Qwen3.8-27B's, among them the problem that this model solved earlier in this section with a budget of 1,024. These replies ran out of budget, which is not the same as wrong arithmetic. Three of them are too few to change any verdict below.

Not every reply copied the format of its examples. Many end on a boxed or a bold number, those of the local model most often, and for these the fallback of the extractor finds the answer.

Note the token columns. The same messages are 462 prompt tokens for one model and 566 for another, since each has its own tokenizer and template, and the replies of one model are nearly twice as long as those of another. Tokens cannot be compared across models, and neither can a price per token. The quantity to compare is the price of a correct answer: the cost of an arm divided by the number of problems that it solved. For the local arm the currency is GPU time.

A hundred problems cost less than a cent on the flagship and about five cents on Qwen3.8-27B. Per correct answer the smaller model is about six times as expensive as billed and still almost four times at list prices, while the accuracies differ by three points. Part of the gap is the price list: Parasail's price for output tokens is more than three times Novita's. Part is the model, since Qwen3.8-27B writes longer replies. The rest is a discount. Novita billed about three quarters of the flagship's prompt tokens, the four examples that open every request, at its cached rate. Parasail's row in the listing shows a cached price too, and in our run it cached nothing.

The size of a model is a poor guide to its price. Here the model with about 27 times the parameters is the cheaper one per correct answer. One reason is its architecture. The flagship is a sparse *mixture of experts*: in every layer it holds several hundred expert sub-networks and sends each token through a handful of them, so most of its parameters do no work on any given token. The parameter count tells a provider how much memory to hold, and much less about the computation that a token costs.

The local model gets its price from the GPU. It needs about 1.3 GPU-seconds per correct answer with eight requests in flight, which is 0.37 GPU-hours for 1,000 correct answers. In November 2026 an RTX 4090, the 24 GB card that we used, rented for 0.30 to 0.50 dollars an hour (Table 39.2), so the 1,000 answers cost between 10 and 20 cents. That is more than the flagship's 9 cents, and it is the price of the least accurate of the three models. A small model on a card of our own is not automatically the cheap option.

Its price depends on how busy we keep the card. With eight requests in flight, the server of Experiment 1 delivered less than a quarter of the tokens per second that it reached with 64. If this experiment could fill the server as well as that one did, the same 1,000 answers would cost 2 to 4 cents, less than half the flagship's price. This is an estimate and not a measurement: we did not run that arm, and the longer prompts of this experiment take more of the cache per request. Either way, what a local answer costs is decided by how full we keep the server, and here that moves the price from well below the flagship's to twice as much. Exercise 6 derives the rental prices at which the comparison turns.

Are these differences real at 100 problems? Three tools come from Section 18.5. All arms answered the same problems, so we compare two arms problem by problem, and the difference in accuracy gets a paired bootstrap interval. The *discordant* problems are those that one arm solved and the other did not. The table counts them in the column `b` (only the first arm solved the problem) and the column `c` (only the second; this `c` is not the concurrency). The minimum detectable effect (`MDE`) is the smallest true difference that a sample of this size would detect with 80% power.

Two tools are new, and both are needed because the sample is small. With a handful of discordant problems no normal approximation can be trusted, so we use the exact *McNemar test*. If two arms were equally accurate, each discordant problem would fall to either side with probability one half, and the test computes the binomial probability of a split at least as uneven as the one observed. Moreover, three comparisons on the same 100 problems give chance three opportunities. *Holm's method* adjusts for that: it multiplies the smallest of the three p-values by three and the next by two.

A difference counts as resolved only if its adjusted p-value is below 0.05 and its interval excludes zero. We ask for both because the test and the bootstrap interval are two different approximations, which can disagree on so few discordant problems, and we believe a difference only when neither objects. The fourth row is the noise floor, replica 0 against replica 1. Read `difference`, the interval and the counts `b` and `c` first, and the verdict last.

The two replicas of the flagship differ on two problems, one in each direction: identical requests at temperature 0 did not give identical outcomes. One of the two is the reply that the limit of 512 tokens cut short in the first run. Against this floor, a difference of 0.00 with an interval of $[-0.03, 0.03]$, the three points between the flagship and Qwen3.8-27B are unresolved. Five discordant problems split four to one, the interval $[-0.01, 0.08]$ includes zero, and the minimum detectable effect is about six points. In fact no split of five problems could have passed the test, since even five to none has a p-value of $2/32 \approx 0.06$. We cannot say from this experiment which of the two models is more accurate, and the comparison rests on the price of a correct answer.

Both differences to the local model are resolved, 14 points $[0.07, 0.22]$ and 11 points $[0.05, 0.18]$. One caution carries over from Section 18.5.2.3. GSM8K has been public for years and may be in the training data of every one of these models, so the scores order the models on these 100 problems and say nothing absolute about their arithmetic.

18.7.4.2 Determinism and Model Identity

The two replicas raise a question that Experiment 3 asks directly. We send the same request many times, at temperature 0 and with a fixed seed, and count the different replies. The field test found that the flagship's provider gives no repeatable draw for a seed. At temperature 0 that should not matter, since nothing is drawn: the model emits the token with the largest logit. What the experiment asks is whether the largest logit itself is stable.

The requests are the 4-shot prompts of three problems, those of our 100 with the longest reference solutions. Long solutions make long replies, and every token of a reply is one more place where two candidates can nearly tie. The flagship receives each request 20 times. The local server receives each of them five times in sequence with nothing else running, and five more times while eight other clients keep it busy.

For each problem and condition the next cell counts the distinct replies, the character at which a reply first departs from the most common one, and the distinct final answers.

Twenty identical requests to the flagship return five to seven different texts. They part ways within the first hundred characters, on one problem at the very first, and all reach the same final answer.

How can a model that draws nothing give different replies? The mechanism is the one that moved our own scores with the batch size in Section 18.4.5.2. Floating-point addition is not associative, so the same sum taken in a different order differs in its last bits. A serving engine batches whatever requests happen to be in flight, and its kernels choose the order of their reductions by the shape of the batch. The logits of our request therefore depend on who else is being served (He and Thinking Machines Lab 2025). The smallest change flips a near-tie between two tokens, and from that token on the texts diverge. The seed is beside the point.

The surprise is the local server, where we chose the seed and nothing else was running: on two of the three problems the five replies are not all equal either. No other client changed the batch here. What changed the order of the sums is the cache. Continuous batching shares the stored keys and values of a common prompt prefix between requests. The first request computes the prompt, and the later ones reuse its cached blocks, which is another sequence of operations with other last bits. We checked this cause. A field of Transformers' `ContinuousBatchingConfig`, which `transformers serve` does not expose, switches prefix sharing off, and then the five replies agree.

Under load every reply is different, and now the answers differ too: two distinct answers on one problem and three on another. Whether a problem counts as solved then depends on what else the server was doing at the time. This reaches back to Experiment 2, whose local arm ran with eight requests in flight. Its score of 83 is one draw. The gaps of 11 and 14 points to the hosted models are far above any floor that we saw, but we measured that floor for the flagship only.

A seed promises reproducibility only for a sampler and kernels that we control, and behind an API we control neither. Section 29.3 shows what it takes to make inference repeatable. Note also what would not have been evidence. Had all 60 hosted replies been identical, that would not have shown determinism, only that no near-tie happened to flip.

A second kind of drift is slower. The string that we send as `model` names an entry of a listing, not a set of weights. We used an identifier with a date in it, since an undated alias may be pointed at a newer release at any time. One set of weights is served by many providers at precisions from 4 to 16 bits, and by default a router spreads requests over them by price and load. An experiment that does not pin its provider may therefore compare a model with a differently quantized copy of itself.

Whether a provider serves the weights that it names is a statistical question that a client can ask. I. Gao et al. (2025) compared samples from 31 commercial endpoints with samples from the released weights by a two-sample test, and for 11 of them the two distributions differed. Cai et al. (2025) show that such tests are hard to make reliable against a provider that wants to hide a substitution. Our client does the least that can be done, and records the served model and the provider with every response.

That ends the experiments, and the local server is stopped.

The last cell adds up the logs of all clients: live calls, retries, 429s and dollars per cache, the served model and the provider of every arm, and a reconciliation of the bill.

The committed recording, about 740 paid requests, cost about ten cents. The cost computed from the listing equals the cost that the router reported, to four digits. The router bills by its listing, then, and `d2l.api_cost` computes Equation 18.26 as the router does. A provider's own invoice is not part of this check. Each arm was served by one provider under one model identifier, as the pins demanded.

The remaining numbers are for a reader who audits the recording. The clients of this page made 4,950 live calls, most of them to our own server. The committed recording holds 5,184, since it also contains the background load of Experiment 3 and the field test of the local server. It leaves out the test of the closed model. The seven 429s all came from Parasail. The column `failed` counts failed attempts and not failed requests: the client retried each of the seven, and no request was lost.

18.7.5 Limits of a Hosted Model

Everything that the three experiments measured came through the protocol. Two kinds of limit remain: what we may do with the replies, and what no reply contains.

18.7.5.1 Licenses and Terms of Service

The first limit is not technical. A prompt that is sent to a service leaves our machine, and the reply comes back under somebody's terms. Two documents govern every call: the license

of the weights, and the terms of service of whoever runs them. Table 18.8 records what these documents say about the responses that we stored with the book's data.

Table 18.8: Licenses and terms of service behind the recorded responses. We read the licenses on 14 November 2026 and the terms of service on 18 November 2026. Terms change; the dates in the table are those printed on the documents.

Document	What it says	Consequence here
MIT license of the DeepSeek-V4.1-Flash weights	use, copying and redistribution permitted with the notice	responses stored with attribution
Apache-2.0 license of the Qwen3.8-27B and Qwen3-4B weights	use and redistribution permitted with the notice	responses stored with attribution
OpenRouter terms of service (updated 31 August 2026)	inputs are not stored unless the account opts in to prompt logging; the user agrees to the terms that apply to each model, and rights in an output follow those terms	the router adds no rights of its own, so we read the license of each model and the terms of its provider
Novita terms of service (updated 5 August 2026)	by default, customer content is not used to train Novita's models and is not kept once the output is delivered; we found no clause on training with outputs or on publishing measurements	responses stored for replay
Parasail terms of service (dated 10 November 2025)	customer content is not used to train Parasail's models; the customer owns inputs and outputs; content available through the platform may not be used to train or develop machine learning models; performance information about the platform may not be disclosed publicly	responses stored for replay only, never used as training data

The table has no row for the closed model, whose replies are not in the book's data at all: we kept only the verdicts of the field test.

The two provider rows differ, and that is the reason to read them. The Parasail row shows why the second document matters even when the first is permissive. Apache-2.0 would let us train on the outputs of Qwen3.8-27B. Whether the service that produced them allows the same is a separate question, and the clause in the table suggests that it does not.

The last clause of that row is easy to overlook, and it concerns measurements like ours: the customer may not "publicly disclose to any third party any performance information or analysis relating to the Platform". The latency and the rate limits of a named provider are performance information, and this section prints both for Parasail. We read the clause only after the recording had been made, which is the wrong order. Our requests reached Parasail through the router's account and not through one of our own, and how the clause applies to such requests is for the provider to say. Whoever plans to publish numbers of this kind should look for such a clause before the first request, and ask.

Later chapters let hosted models write questions and training examples. Before any of them does, we read both documents and record the answer with the data. And whatever the terms say, a prompt is disclosed to the provider the moment it is sent, so we send only public data, here the questions of GSM8K.

18.7.5.2 Quantities the Protocol Withholds

The other limits are technical. Let us go back through the chapter and ask, method by method, what a client can still obtain. Figure 18.9 does so for four kinds of endpoint, from weights that run in the book's own code to a closed model behind a router.

	weights in the book's code	local server	open weights via a router	closed model via a router
weights and activations	●	○	○	○
prompt log-probabilities	●	◐	○	○
generated-token log-probabilities	●	◐	◐	◐
rendered prompt and chat template	●	●	○	○
sampler beyond temperature and top-p	●	◐	◐	○
seed and batching control	●	◐	○	○
token counts from usage	●	●	●	●
structured output	●	◐	◐	◐
many samples	●	●	●	●

● available ◐ depends on the provider or server ○ not available to the client

Figure 18.9: What each kind of endpoint gives a client. The rows are the quantities and controls that the methods of this chapter relied on. A filled circle marks what is available, a half circle what depends on the provider or the server, and an open circle what a client does not get.

Start with the log-probabilities. The chat-completions protocol has no field for the log-probabilities of a prompt. None of the four endpoints that we tested returned them, although some servers add such a field of their own. Scoring answer options, cloze scoring and bits per byte (Section 18.4) all need these log-probabilities, so behind an API an evaluation falls back on generating text and extracting an answer, as in Experiment 2. Log-probabilities of generated tokens come only where the provider returns them, and our field test found one provider that returned them for part of a reply.

Weights and activations are gone, and with them everything of Section 18.6: one cannot patch an activation that one cannot read. The prompt is rendered on the server, and the sampler is whatever subset of fields the provider honours. The row on seeds and batching needs a remark. The protocol does have a `seed` field, and the figure still shows an open circle for the hosted models, because no hosted endpoint returned a repeatable draw for it. For the batch there is no field at all. It is the provider's business, which is why Experiment 3 came out as it did.

What survives is text, the `usage` block, structured output where the provider enforces a schema, and as many samples as one is willing to pay for, drawn by repeated requests, since

no endpoint honoured `n=2`. That is enough for accuracy with error bars, cost, latency and throughput, the measurements of this section. It is not enough to check a port layer by layer, to score a given continuation, or to test a claim about a mechanism.

For those we need the weights, and so the rest of this part works with models that we hold. The first thing that we shall ask of them is something that no chat endpoint returns at all: a vector for each text, which a system that retrieves documents needs. That is the subject of Chapter 19.

18.7.6 Summary

A hosted model is a service that a client can measure. The chat-completions protocol returns text and a `usage` block, and a client that stores every response under a hash of everything that can change it makes its measurements replayable. Little's law, $XW = c$ in a closed loop, turns two timestamps per request into throughput, latency and the knee beyond which more concurrency only adds waiting. From `usage` and a dated price follow the cost of a response and the price of a correct answer, which separated two hosted models that accuracy on 100 problems could not. The service itself is not deterministic: identical requests at temperature 0 returned different texts from a hosted endpoint and from our own server. The protocol has no place for the log-probabilities of a prompt, for activations or for weights, so scoring by likelihood, layer-wise checks and interventions cannot be done through it.

18.7.7 Exercises

1. **A detection rule of your own.** The field test trusted a request field only after a rule had seen its effect.
   1. Write a detection rule for `max_tokens` in the style of `seed_honoured`. Which request does it send, and which parts of the response does it compare?
   2. Describe two responses that a careless rule would wrongly call honoured: one from a reply that is short of its own accord, and one like that of the closed model in the field test, whose `usage` reported more reasoning tokens than completion tokens under its cap. Change your rule so that it excludes both.
   3. Write a rule for `top_p`. Why does it need a control request, as the rule for `seed` needed the request with seed 8?
2. code **The contents of the request hash.** The demonstration in the text settled five changes to a request. Consider three more: the order of the keys in its parameters, `max_tokens`, and the port of the base URL.
   1. For each change, decide whether the hash must change, and give the reason in one sentence. Verify your answers with `d2l.request_hash`.
   2. The hash contains the hostname and not the port. Describe an experiment that this choice makes possible, and a situation in which it would return a wrong cache entry.
3. code **Equal jitter.** Equal jitter sleeps for $d_a/2 + U$ with U uniform on $[0, d_a/2]$.
   1. Derive the mean and the variance of this sleep and compare them with those of full jitter. Which schedule spreads clients that failed together more widely?
   2. Add equal jitter to `retry_storm` and compare the finish time and the number of attempts of the three schedules over 200 seeds. Explain the order of the finish times from the first sub-problem.
4. **The closed loop beyond the knee.** Consider the model of a closed loop in Equation 18.28.

1. Show that the efficiency $E(c) = XW_0/c$ equals $\min(1, c^*/c)$. At which c does it cross 0.7? With levels at the powers of two and $c^* = 33$, which is the first level whose efficiency is below 0.7?
2. Compute $E(32)$ for both passes of Experiment 1 from the printed table. The model predicts a value close to 1. Which of its two assumptions fails below the knee, and which column shows it?
3. Our client keeps the number of requests in flight fixed. In an *open loop*, requests arrive at a rate λ that does not depend on the server. What does Little's law say about the number of requests inside the server when $\lambda < X_{\max}$? What happens when $\lambda > X_{\max}$, and why can a closed loop never show it?

5. code **Chunks and tokens.** The caches of Experiment 1 (`rec.cache('lm-api-sweep-v1', arm)` for the arms `'local'` and `'flagship'`) hold one JSON object per line. Its field `n_chunks` is the number of chunks of the stream, and its field `result` holds `usage`, `t_send`, `t_first_content`, `t_total` and the gaps `itl` between consecutive chunks.
   1. For each arm, compute the ratio of chunks to completion tokens. What does a chunk hold on each endpoint?
   2. Compare two estimates of the time per token: the time after the first content token divided by the completion tokens, and the median gap between chunks. Explain the difference on the hosted endpoint from the distribution of the gaps.
6. **The price of a local correct answer.** Experiment 2 reports the dollars per 1,000 correct answers of the two hosted models and the GPU-seconds per correct answer of the local model.
   1. For each hosted model, derive the rental price per GPU-hour below which the local model costs less per correct answer. On which side of these two prices do the 0.30 to 0.50 dollars of the text fall?
   2. The local figure was measured with eight requests in flight, and the text estimates 2 to 4 cents per 1,000 correct answers for a full server. Derive this estimate from the table of Experiment 1, and state the assumption that it makes about the length of the prompts and the replies. How do the two break-even prices change?
   3. Name two things that the comparison leaves out, one in favor of the hosted models and one in favor of the local model.
7. **The exact McNemar test by hand.** If two arms are equally accurate, each discordant problem falls to either side with probability one half.
   1. With five discordant problems, compute the two-sided p-value of every possible split. Which splits reach $p < 0.05$?
   2. How many discordant problems must an experiment collect before a split with all of them on one side reaches $p < 0.05$? How many before that split survives Holm's factor of three?
   3. The flagship and Qwen3.8-27B disagreed on 5 of 100 problems. Explain from the first two parts why a benchmark that both models nearly solve cannot separate them at this size, and say what you would change: the number of problems, or the problems.
8. code **Replicas needed to see non-determinism.** Use the 20 replies per problem of the flagship in Experiment 3 (`rec.cache('lm-api-determinism-v1', 'flagship')`).
   1. For each problem and for $k = 2, 3, 5, 10$, estimate the probability that k replies drawn without replacement from the 20 are all identical.
   2. Suppose that each reply of a service equals its most common reply independently with probability q, and that all other replies differ from one another. How many identical replies in a row must you observe before you can reject $q \leq 0.9$ at the 5% level? What does this say about a claim of determinism that rests on five

repetitions?

9. code **Prompt caching, measured.** This exercise makes live calls that cost about a cent. Build a prefix of about 2,000 tokens that five requests share, and give each request its own short question. Send the five requests to a provider that lists a cached price. Send them again at once with new replica numbers, and a third time five minutes later. The delay tests how long the provider keeps a prefix.
    1. From `usage`, report the fraction of prompt tokens that were cached in each round.
    2. Compute the saving with `d2l.api_cost`, and compare it with the cached share of the flagship in Experiment 2. Which requests were billed at the full rate, and why?
10. code **One set of weights at two precisions.** ● This exercise makes live calls that cost about five cents. The listing names providers that serve the flagship's weights in a 4-bit format and others that serve them in an 8-bit format. The release already stores the larger part of the weights in 4 bits, so the two labels describe a smaller difference than they suggest.
    1. Run Experiment 2 for the flagship through one provider of each kind, with two replicas each, and test the difference in accuracy with the exact McNemar test. Compare it with the replica noise floor of each provider.
    2. Accuracy on 100 problems is a blunt instrument for this question. Following I. Gao et al. (2025), describe a test on the generated texts themselves that could show that two endpoints serve different distributions, and say what it needs as a reference.

Chapter 19

Encoders, Embeddings and Retrieval

The previous chapter left us able to do a good deal with a released language model. We can load one, check that it computes on our machine what its authors computed on theirs, prompt it, and put an error bar on its score. Two ordinary requests still defeat it. Ask it how this book's old `load_array` helper decides whether to shuffle its data, and it answers from whatever it absorbed in training. The answer we will meet is fluent and wrong, although the paragraph that says so is somewhere in the book. Ask it to sort the messages of a support desk by topic, ten thousand of them an hour, and it reads its solved examples again for every message. The first request needs a way to find a passage. The second needs a model that learns from labels once and then labels cheaply.

Both requests are met by models that turn text into vectors, so that texts with similar meanings lie close together. The idea is older than neural networks. Linguists of the 1950s proposed that a word is known by the company it keeps, and word2vec made vectors built on that idea cheap to learn from billions of words. BERT computed a vector for every token from the words on both sides of it, and a small layer on top turned those vectors into labels. Contrastive training then taught such *encoders* to place a question next to the passage that answers it. Encoders still do much of the routine work of search, filtering and tagging, and once they have found the passage, a decoder can answer from documents it never saw in training. One old tool holds its ground through all of this. The word index of a search engine, which does little more than count the words a question shares with a passage, turns out to be the hardest baseline to beat on this book.

The chapter moves in three steps. First we compute vectors: for words, from co-occurrence counts (Section 19.1); for tokens in context, from a pretrained encoder that we fine-tune and set against a prompted decoder (Section 19.2); and for whole texts, by contrastive training (Section 19.3). Then we find passages with a word index and a vector index together, and ask what an approximate index gives up for speed (Section 19.4). Last we hand what was found to a generator, and when an answer comes back wrong, we ask which stage lost it (Section 19.5, Section 19.6).

From the third section on, every experiment runs on one collection: this book without the Language Models part, cut into passages and paired with questions whose answers and source passages we know. Language models, not people, drafted and checked those ques-

tions, and Section 19.5 says what that can miss. The `load_array` question is one of them. We follow it from a search that misses its passage, through a retriever that ranks the passage first, to a generator that answers it from the page. The corpus, the retriever and the questions return later in this part; the agents of Chapter 27, for instance, search the book with this retriever and decide for themselves when to do so.

We start from released encoders and do not pretrain one; Section 11.4 showed on a small scale how that works. Images, which the same contrastive methods can place in one space with text, are left out.

We assume the transformer of Chapter 11 and the prompting, scoring and paired error bars of Chapter 18. We ran the notebooks on one GPU with 24 GB of memory and the judge that grades answers on two, but no notebook requires a GPU. The long computations were done once and their results published with the book. Each notebook fetches them and recomputes a small part of each as a check; without a GPU it takes a cheaper path, with fewer examples or a smaller search, and its output says which. The questions were drafted and checked through a paid API, and the generator's answers and the judge's verdicts took hours of GPU time. All of these were recorded once, so the notebooks replay them and call no API.

Resources and Further Reading

The resources below accompany the sections of this chapter, and each names the section it goes with. All are freely accessible online. If you read only three, read the training overview of Sentence Transformers, the Faiss wiki and Jason Liu's essay on improving a RAG system: between them they cover how an embedder is trained, how an index is chosen, and how to decide what to fix next. Methods that build on the chapter without being taught in it, such as learned sparse retrieval, late interaction and the many ways of improving a retrieval-augmented pipeline, are collected in Section 19.7.

Courses

- Stanford CS224N: Natural Language Processing with Deep Learning opens with word vectors and a first assignment on them, the material of Section 19.1. Its pretraining lecture covers the masked-token encoders of Section 19.2, and its lecture on agents, tool use and retrieval-augmented generation the system of Section 19.5.
- Berkeley CS288 has lectures on text classification, the task of Section 19.2, on retrieval and RAG, and on experimental design, which frames the one-change-at-a-time measurements of Section 19.6.
- CMU 11-711: Advanced Natural Language Processing gives a lecture to retrieval and RAG, with readings on retrieval-based language models that extend Section 19.4 and Section 19.5.

Illustrated introductions

- Jay Alammar's The Illustrated Word2vec draws the sliding window and the negative samples of skip-gram, a picture to read beside Section 19.1.
- His The Illustrated BERT draws the input layout and the task heads of a masked-token encoder, as Section 19.2 uses them.
- The ModernBERT announcement by the model's authors explains the design of the encoder that Section 19.2 uses, including two choices the section leaves out: unpadding and its attention kernels.

Libraries and their documentation

- The Sentence Transformers documentation and its training overview describe the library that Section 19.3 checks its derivations against, with the contrastive losses, Matryoshka training and quantized vectors of that section.
- The Faiss wiki explains the inverted files, product quantizers and graphs of Section 19.4, how to name a combination of them, and how to choose one for a collection of a given size.
- Pyserini provides BM25 and other word-index baselines with reproducible settings, and BEIR evaluates retrievers on collections of many kinds, the test behind the warning in Section 19.4 that a dense retriever trained on one collection can fall below BM25 on another.

Building retrieval-augmented systems

- Jason Liu's Systematically Improving Your RAG and Eugene Yan's Patterns for Building LLM-based Systems and Products separate the retrieval and the generation of a pipeline and measure each, the decomposition that Section 19.5 and Section 19.6 carry out on the book.
- The Hugging Face cookbook's Advanced RAG builds a complete pipeline in one notebook, to set beside the pipeline of Section 19.5 and compare stage by stage.

19.1 Word Embeddings

The language model of Section 11.2 begins with a table that holds one row of numbers for every token in its vocabulary. Gradient descent filled that table along with everything else, and we never asked what its rows mean. Here is a question we could have asked. *Physician* and *doctor* are different tokens, and nothing in the training said that they are interchangeable. Do their rows end up close anyway?

Before training there is no reason why they should. Looking up a row is the same as multiplying the table by a *one-hot* vector, all zeros except for a one at the word's index. One-hot vectors carry no similarity at all: any two different words are orthogonal, and *doctor* is as far from *physician* as from *banana*. Whatever similarity the rows hold, training put there. In the 1950s the linguists Zellig Harris and J. R. Firth (Harris 1954; Firth 1957) proposed where it could come from: words that occur in similar contexts tend to mean similar things, or in Firth's phrase, "you shall know a word by the company it keeps". Physicians and doctors keep the same company. Both examine patients and write prescriptions.

The question matters beyond word lists. Later in this chapter, whether nearby vectors mean related things decides whether a search finds the passage that answers a question, and word vectors are the smallest case of that idea. This section asks which statistic of a text a learned word vector records. It is a rare case in deep learning where we can write down the answer and then check it. We train the skip-gram model of word2vec (Mikolov, Chen, et al. 2013; Mikolov, Sutskever, et al. 2013), which made word vectors cheap enough to learn from billions of words. We then work out what its scores converge to (Levy and Goldberg 2014) and check the result on a toy corpus of four distinct words and on a slice of Wikipedia. Two methods that compute vectors from the counts directly show how much the choice of method matters, and human judgments of which words are alike serve as the yardstick. The section ends with what no such vector can do: give one word two meanings.

The next three cells are setup, and a first reading can skip to Section 19.1.1. They fix what every method shares, a window of five words on each side and vectors of 100 dimensions, and name the sources of the data. As in Chapter 18, results that take long to compute are

stored: here the 23 runs of Section 19.1.4, which the environment variable `D2L_RERUN=we-grid` repeats in about ten minutes on one GPU.

19.1.1 Co-occurrence Counts and Human Ratings

The idea that a word is known by its company is called the *distributional hypothesis*. To use it we must make "company" countable, so we slide a window over a text and count how often each word occurs near each other word. We also need a yardstick for the vectors that will come out of such counts, and it is best fixed before any vector exists. The standard one is people's judgments of which words are alike.

19.1.1.1 A Slice of WikiText-103

Our text is the first three million words of WikiText-103 (Merity et al. 2016), a collection of Wikipedia articles that the site's editors rated good or featured. We drop headings, lowercase the text, split it at whitespace and keep the tokens made of letters, allowing one apostrophe as in *'s*. A line end becomes a break that no window crosses. Words seen fewer than ten times leave the stream, as in word2vec, because their rows would be trained on almost nothing.

Three million tokens use about 86,000 different words. Only 17,997 vocabulary entries remain at ten occurrences or more, and yet the words left out make up just 5% of the tokens. A frequency cutoff loses most word types and few tokens. This is Zipf's law at work (Section 8.3.1.4): the frequency of a word falls roughly as a power of its rank, so a few words make up most of a text.

19.1.1.2 The Count Matrix

Let X_{wo} be the number of times that word o occurs within $W = 5$ positions of word w. We call w the *center* word and o a *context* word. Every pair is counted from both ends, so $\mathbf{X}$ is symmetric. `cooccurrence_counts` builds it as a sparse matrix, one sparse addition per distance $d = 1, \dots, W$, and leaves out pairs that straddle a break.

Which pairs of words have the largest counts? The question is worth a guess before reading the output.

The wins, paired with itself and with four other function words: *of*, *in*, *and*, *to*. This is not the company Firth had in mind. Raw counts mostly measure how frequent two words are, not whether they belong together. Note also how empty the matrix is: only 2% of its 324 million cells hold a count.

Pointwise mutual information corrects for frequency (Section 37.6.1.4). It compares how often a pair occurs with how often it would occur if the two words were placed independently. Write $p(w, o) = X_{wo} / \sum_{w',o'} X_{w'o'}$ for the share of all pairs that are (w, o), and $p(w)$ and $p(o)$ for its row and column sums. Then

$$\operatorname{pmi}(w, o) = \log \frac{p(w, o)}{p(w)\, p(o)} \tag{19.1}$$

is positive for pairs that attract and negative for pairs that repel.

By this measure *the* and *of*, the second-largest count, are only weakly associated, with a pmi of 0.36, and *the* even repels itself (-0.27): two of them stand within five words of each other less often than their frequency predicts. *Prime* and *minister* meet in only 166 windows, but their pmi is 6.55, so they occur together about 700 times as often as chance predicts. For the 98% of pairs that never occur, the pmi is $-\infty$, a value that no model with finite outputs can reproduce. Every method below has to decide what to do about these pairs.

19.1.1.3 Human Similarity Ratings

WordSim353 (Finkelstein et al. 2002) holds 353 word pairs rated by people, and its ratings mix relatedness with similarity: *cup* and *coffee* score high. *SimLex-999* (Hill et al. 2015) holds 999 pairs rated for similarity alone. *Clothes* and *closet*, which WordSim353 rates as closely related, score low there. A closet is where clothes are kept, which makes the two related and not alike.

To score a table of vectors we compute the cosine of each rated pair, and then the Spearman correlation ρ between the cosines and the ratings. A rank correlation uses only the order of the two lists, so the scales of cosines and ratings do not matter. `spearman_eval` also reports a 95% bootstrap interval, obtained as in Section 18.5 by resampling the pairs 2,000 times.

A pair with a word outside the vocabulary cannot be scored. Dropping it shrinks the test set without warning, so we count the pairs that remain.

The slice covers 295 of the 353 WordSim353 pairs and 865 of the 999 SimLex-999 pairs. A correlation computed under another vocabulary is therefore a correlation on another test set.

What do random vectors score? Zero on average, of course, but not zero in any one draw. For n pairs without association a rank correlation has a standard deviation of about $1/\sqrt{n-1}$, which is 0.058 for 295 pairs and 0.034 for 865. Twenty random tables should spread over about twice these amounts on either side of zero.

On WordSim353 they do, from -0.10 to $+0.13$. On SimLex-999 they stay somewhat narrower, from -0.05 to $+0.04$. A method has to clear this floor before its correlation means anything; on WordSim353, a correlation of 0.1 means nothing.

19.1.2 Skip-Gram with Negative Sampling

Take the GPT of Section 11.2, remove everything between the token table and the output layer, and ask it to predict the words around a word instead of the next one. What remains is skip-gram. It keeps two tables with one row per word. The row $\mathbf{v}_w$ of $\mathbf{V}$, the *center vector*, is used when w sits in the middle of a window, and the row $\mathbf{u}_o$ of $\mathbf{U}$, the *context vector*, when o is one of the neighbors. The model scores a pair by the inner product $s(w,o) = \mathbf{u}_o^\top \mathbf{v}_w$. That GPT used one table for both ends, reading tokens in and scoring them out. Skip-gram does not tie its tables, and for a good reason. With one table, a word's score with itself would be $\|\mathbf{v}_w\|^2$, which is never negative, so the model would give every word at least even odds, $\sigma(\|\mathbf{v}_w\|^2) \geq 1/2$ in the notation below, of being its own neighbor. Yet most words of our slice never occur within five positions of themselves.

The obvious predictor is a softmax over the vocabulary, $p(o \mid w) = \exp(s(w,o))/\sum_{o'} \exp(s(w,o'))$. Its normalizer needs a score for every row: 17,997 scores for each observed pair on our slice, and millions for a full vocabulary. A GPT computes such a normalizer too, but there it is one cost among many layers. Skip-gram has

no layers, so the normalizer would be nearly all of its work, and word2vec was written to run over billions of words on ordinary processors. *Negative sampling* replaces the one large classification by a few binary ones (Mikolov, Sutskever, et al. 2013), and skip-gram trained this way is called SGNS for short. The model learns to tell the observed context word o from K noise words $o_1, \dots, o_K$ drawn from a distribution P, and we use $K = 5$. For one observed pair the loss is

$$\ell(w, o) = -\log \sigma(\mathbf{u}_o^\top \mathbf{v}_w) - \sum_{k=1}^{K} \log \sigma(-\mathbf{u}_{o_k}^\top \mathbf{v}_w), \tag{19.2}$$

where $\sigma(s) = 1/(1 + e^{-s})$ is the sigmoid. The first term pushes the score of the real pair up, and the sum pushes the scores of the noise pairs down. A pair now costs $1 + K = 6$ inner products instead of 17,997.

We call each scored pair of a center word with a context or noise word a *slot*; Figure 19.1 shows the six slots of one observed pair. `sgns_loss` computes Equation 19.2 as a binary cross-entropy and reports it per slot. At the start, when every score is zero, a slot costs $\log 2 \approx 0.693$.

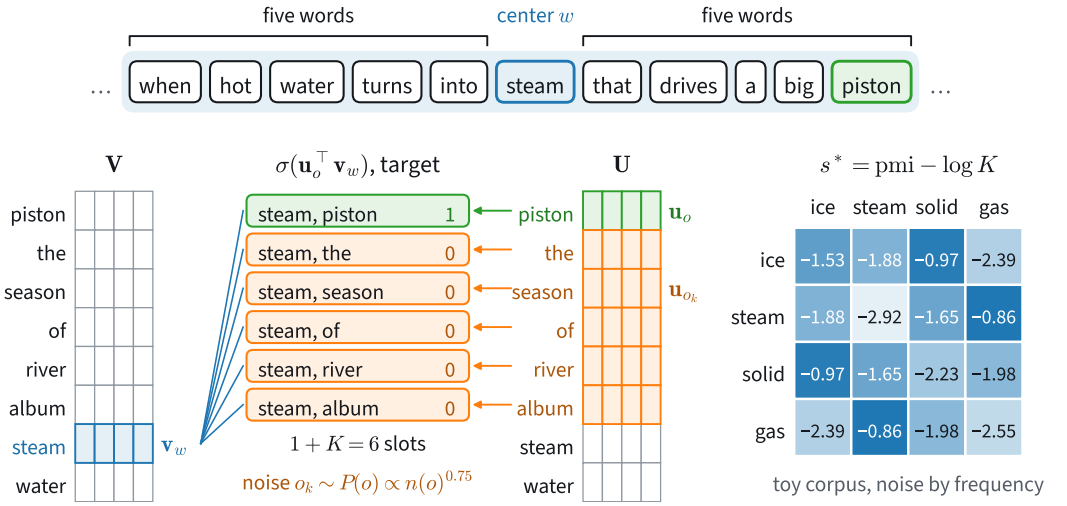

Figure 19.1: Skip-gram with negative sampling. Every word within five positions of the center word *steam* is a context word. The pair (*steam*, *piston*) is scored by the inner product of the center vector $\mathbf{v}_w$, a row of $\mathbf{V}$, with the context vector $\mathbf{u}_o$, a row of $\mathbf{U}$. Its $K = 5$ noise words, drawn with probability proportional to $n(o)^{0.75}$, fill the other slots with target 0. Right: the optimal scores of the toy corpus of Section 19.1.3, with noise drawn by frequency; that subsection derives and explains them.

19.1.2.1 The word2vec Recipe

Three choices of the word2vec recipe decide which pairs the loss sees. The first and the third are engineering that a reader may forget once the code runs. The second, a power of 0.75, looks arbitrary and is the one to remember, because it returns in the analysis below.

The first choice is *subsampling*. Pairs with *the* dominate the counts, say little about either word, and would take most of the training time. So each occurrence of a word that makes up a share $f(w)$ of the text is discarded with probability

$$\max\left(1-\sqrt{t/f(w)},\,0\right),\quad t=10^{-4}. \tag{19.3}$$

Words rarer than t are always kept, and a word that makes up 1% of the text is kept with probability $\sqrt{10^{-4}/10^{-2}}=0.1$. The decision is made per occurrence, so a frequent word stays in the vocabulary and loses most of its occurrences. The windows over the thinned stream then reach further.

The second choice is the noise distribution. Drawn by frequency, a rare word would almost never serve as a noise word, and little would push its scores down. Instead, o is drawn with probability $P_\alpha(o)\propto n(o)^\alpha$, where $n(o)$ counts the occurrences of o and $\alpha=0.75$. With $\alpha=1$ noise words are drawn by frequency, with $\alpha=0$ uniformly. The power in between flattens the frequencies: a word 100 times as frequent as another is drawn only about 32 times as often.

The third choice is the window. Near neighbors say more about a word than distant ones, so word2vec draws a width b uniformly from $1,\dots,W$ for each center word and uses the context words within b positions. A word at distance d is then used with probability $(W-d+1)/W$, so the distances 1 to 5 carry the weights 1, 0.8, 0.6, 0.4 and 0.2.

Centers have different numbers of context words, so a minibatch gives each center a row of 60 slots: one context slot for each of the $2W=10$ window positions, followed by $K=5$ noise slots for each context slot. A mask marks the empty window positions, and a masked context slot and its noise slots must not enter the loss, or the model learns to score padding. The next cell prepares one epoch and prints one row of a minibatch.

Subsampling removes half of the positions: 1.4 of the 2.8 million survive as centers. A minibatch is a block of 1,024 such rows. In the printed row, centered on *years*, the drawn window was one word wide, so the mask keeps two context slots, *era* and *francis*, and their 10 noise slots: 12 of 60.

19.1.2.2 Training

Two tables of 17,997 rows and 100 columns hold **V** and **U**. We initialize them as word2vec does, center rows small and random and context rows zero, so every score starts at zero. The word2vec program then runs plain stochastic gradient descent with a decaying learning rate; we let Adam update both tables instead. Every epoch draws a fresh subsample, fresh windows and fresh noise words. We evaluate the center table **V** and, for comparison, the sum $\mathbf{V}+\mathbf{U}$, which is what GloVe's authors use as their word vectors. The loss per slot starts from $\log 2$, and the correlations to beat are those of random vectors.

Training takes less than half a minute on one GPU. The loss per slot, averaged over an epoch, falls from 0.46 in the first to 0.37 in the fifth, and the center vectors correlate with the ratings at $\rho=0.56$ on WordSim353 and 0.18 on SimLex-999. Even the lower ends of the two intervals, 0.48 and 0.11, are far above the random floor. SimLex-999 is the harder test because a window records which words appear together, which is relatedness, while SimLex-999 asks for similarity. *Hot* and *cold* share their contexts and are not similar. The sum $\mathbf{V}+\mathbf{U}$ scores a little higher, 0.58 and 0.20. Papers differ in which table they report, so we fix **V** throughout; whether the difference is real is Exercise 4.

19.1.3 Factorizing Co-occurrence Statistics

What did the loss teach the scores? The answer is the main result of this section, and it takes only a few lines. Suppose the vectors had enough dimensions for every score $s(w, o)$ to be chosen freely. For a table of 100 columns this is a bold assumption, and we return to it. The loss, summed over the corpus, then separates into one logistic regression per pair. The pair (w, o) is a positive example X_{wo} times. It is a noise pair about $K\, n_w\, P(o)$ times, where $n_w = \sum_o X_{wo}$ counts the observed pairs with center w: each of these n_w pairs draws K noise words, and each draw is o with probability $P(o)$.

Let us solve one such problem. A single free score s that meets a positives and b negatives incurs the loss $-a \log \sigma(s) - b \log \sigma(-s)$. Since $\sigma'(s) = \sigma(s)(1 - \sigma(s))$ and $\sigma(-s) = 1 - \sigma(s)$, its derivative is

$$-a\,(1 - \sigma(s)) + b\,\sigma(s), \tag{19.4}$$

which vanishes where $\sigma(s) = a/(a + b)$, that is at $s = \log(a/b)$. The best score is the logarithm of the ratio of the two counts. In our case the ratio is $X_{wo}/(K n_w P(o))$, and since $X_{wo}/n_w = p(w, o)/p(w)$, its logarithm splits into three terms. The optimum is

$$s^*(w, o) = \log \frac{X_{wo}}{K\, n_w\, P(o)} = \mathrm{pmi}(w, o) - \log K + \log \frac{p(o)}{P(o)}. \tag{19.5}$$

At its optimum, skip-gram scores a pair by its pointwise mutual information, shifted down by $\log K$, plus an offset that depends on the noise. With noise drawn by frequency the offset vanishes, and the matrix of scores $\mathbf{V}\mathbf{U}^\top$ factorizes the shifted PMI matrix (Levy and Goldberg 2014). This is rather surprising. A model that arrived as a neural network, trained by stochastic gradient descent on billions of words, turns out to approximate a table of statistics that we could have written down from the counts. The appendix asks for the proof in full, for any noise distribution (Exercise 7 of Section 37.7).

With $\alpha = 0.75$ the offset stays, and it depends on the context word alone. A rare word is drawn as noise more often than its frequency, $P(o) > p(o)$, so the offset lowers its scores. The word2vec authors chose the 0.75 power because it worked better than 0 or 1; the optimum shows why it works (Levy et al. 2015). It counteracts the best-known weakness of PMI, which gives two rare words that meet once a very large value.

The result holds only at the optimum, and only with free scores. A table of 100 columns cannot represent an arbitrary matrix of 17,997 rows, and for the 98% of pairs with no count the optimum is $-\infty$. We first check the result where it must hold exactly, on a corpus small enough to have free scores. Then we factorize the counts directly, in two ways, and finally measure how close our trained model came.

19.1.3.1 A Toy Corpus

The toy corpus has 40 tokens of four words, *ice*, *steam*, *solid* and *gas*. With a window of one word all 16 pairs occur, so every optimum is finite. The cell minimizes the expected loss over one free score per pair by L-BFGS in float64, once with noise by frequency and once with $\alpha = 0.75$. In the first case each score should be the pmi of its pair minus $\log 5 \approx 1.609$, the matrix on the right of Figure 19.1.

Both predictions hold to 10^{-7}, the precision of the optimizer, and with $\alpha = 0.75$ only once the offset is included. The offset itself is small here, at most 0.05, because the four words occur about equally often (their rows sum to 17, 24, 17 and 20), so the 0.75 power barely changes the noise distribution. On the slice, where word counts span several powers of ten, the same offset moves the scores of rare context words by far more.

One entry can be checked by hand. *Steam* and *gas* occur together 13 times among 78 pairs, and their rows sum to 24 and 20, so their pmi is $\log(13 \cdot 78/(24 \cdot 20)) \approx 0.75$, the largest of the sixteen. Subtracting $\log 5$ gives -0.86, the two darkest cells of the figure and the largest entry of the printed table for $\alpha = 1$. Every optimal score is therefore negative. A negative score does not say that two words repel each other, only that they meet less than K times as often as chance predicts (Exercise 2).

19.1.3.2 Positive PMI and the Truncated SVD

If skip-gram approximates a known matrix, why not compute the matrix and factorize it directly? The obstacle is that the pmi of a pair that never occurs is $-\infty$, and almost all pairs never occur. The standard remedy is the *positive PMI*, $\max(\text{pmi}(w, o), 0)$, which keeps every missing pair at zero and the matrix sparse. It also drops the negative values, which say only that a pair is rarer than chance and which a small corpus estimates poorly. `ppmi` can first raise the context distribution to a power α, the counterpart of the smoothed noise (Levy et al. 2015), and we use $\alpha = 0.75$ as for skip-gram. It can also subtract a shift, and here we leave it at zero. The $\log K$ of skip-gram's optimum comes from its K noise words, and a factorization of counts draws no noise words. A shift of $\log 5 \approx 1.6$ would, moreover, set to zero every pair whose pmi lies between 0 and 1.6, the weakly associated ones. Whether that helps is a question for Exercise 2.

The best factorization of a given rank is known in closed form. By the Eckart–Young theorem (Section 33.5.2.1), the truncated SVD that keeps the k largest singular values is the best rank-k approximation in the Frobenius norm. Its error is the square root of the sum of the squared singular values left out. As word vectors we take the left singular vectors scaled by the square roots of their singular values, which splits each singular value evenly between words and contexts, as $\mathbf{V}$ and $\mathbf{U}$ split the scores. We call the method SVD-PPMI.

The cell computes the positive PMI of the slice and its rank-100 SVD, and checks the error formula on the block of the 2,000 most frequent words, where a full SVD is cheap.

Of the 6.5 million nonzero counts, 5.5 million have a positive pmi, and the residual matches the formula to rounding error. The vectors correlate with the ratings at 0.57 on WordSim353 and 0.19 on SimLex-999, within about a hundredth of skip-gram on both. They took a few seconds of linear algebra, with no learning rate to choose and no noise to draw.

19.1.3.3 GloVe

GloVe (Pennington et al. 2014) fits the logarithm of the counts directly, by weighted least squares. In our notation it minimizes

$$\sum_{w,o:\, X_{wo}>0} h(X_{wo})\left(\mathbf{u}_o^\top \mathbf{v}_w + b_w + c_o - \log X_{wo}\right)^2, \qquad h(x) = \min\left((x/x_{\max})^{0.75},\, 1\right), \tag{19.6}$$

with biases b_w and c_o and $x_{\max} = 100$. The weight h lets frequent pairs count more, up to a cap. The biases absorb the logarithms of the two words' counts, so the inner product again ends up close to a pmi, up to a constant. GloVe differs from the other two methods in several ways. It fits log counts with learned biases. Its own exponent 0.75, inside h, weights whole pairs by their count; nothing in GloVe smooths the distribution of context words, as the noise exponent of skip-gram and the context exponent of `ppmi` do. The difference to look at first, however, is the index of the sum, which runs over the nonzero counts only. A pair that never occurs never enters the loss, whereas skip-gram meets such pairs among its noise words and the SVD fits the zeros of the positive PMI.

We use the paper's optimizer settings: AdaGrad at a learning rate of 0.05, 50 passes, and the sum of the two tables as word vectors. The counts are the window counts of the other two methods, and an update is made per minibatch rather than per count. We do not tune it: word similarity has no development split, and tuning on the rated pairs would be tuning on the answers.

The loss halves between the tenth pass and the fiftieth, and the vectors correlate with the ratings at 0.29 on WordSim353 and 0.14 on SimLex-999. On WordSim353 that is half of what the other two methods reach, a gap we return to in Section 19.1.4.

19.1.3.4 Trained Scores and Shifted PMI

The toy corpus confirmed the optimum where every score is free. How close did our skip-gram model on the slice come to Equation 19.5? We compare its scores $\mathbf{u}_o^\top \mathbf{v}_w$ with the right-hand side for the 2,000 most frequent pairs. The right-hand side must use the counts that skip-gram was shown, which differ from the raw window counts in two ways. Subsampling deleted most occurrences of frequent words, so windows reach past them. The drawn widths weight distance d by $(W - d + 1)/W$, which is the same as averaging the counts of the fixed windows of width 1 to 5. At the free-score optimum every point would lie on the dashed identity line.

The points follow the line with a Pearson correlation of about 0.9 and no offset to speak of. The cloud is narrow where the target is negative and spreads widely among the strongly associated pairs: most of them score below the line, and a plume overshoots it. "Skip-gram is PMI factorization" is a statement about an optimum; a model trained for five epochs is near it for frequent pairs, not at it.

19.1.4 Evaluating Word Vectors

We have three tables from one slice: SGNS, SVD-PPMI and GloVe. Which is best? Levy et al. (2015) argued that the answer depends less on the method than it seems: settings such as the noise exponent, which one method's recipe fixed and another's left out, move the results as much as the choice of method. We test this on our slice.

19.1.4.1 Methods and Settings

Does any setting move ρ as much as the choice of method? To find out, the 23 stored runs vary both: SGNS with noise exponents $\alpha \in \{0, 0.75, 1\}$, with and without subsampling, in three seeds each; GloVe in three seeds; and SVD-PPMI, which needs no seed, with context exponents 1 and 0.75. The cell prints ρ of seed 0 with its interval and the range over the seeds. As a live check, its last line sets the stored default run of SGNS beside the one we trained above.

On WordSim353 the nine rows fall into two groups: every setting of SGNS and of SVD-PPMI lies between 0.52 and 0.59, and GloVe sits alone at 0.29. On SimLex-999 all runs lie between 0.13 and 0.21. Even GloVe's lower interval ends, 0.18 and 0.08, clear the random floor. The plot shows each method at its default settings on the left, with the interval of seed 0 and each seed as a cross. The right panel zooms in on skip-gram. It shows how far ρ moves when the noise exponent changes, measured from the default run, $\alpha = 0.75$ with subsampling, whose mean over the seeds sits on the dashed zero line. Solid lines keep subsampling and dashed lines drop it; each line is a mean over the three seeds, and its band spans them.

Is SGNS better than SVD-PPMI? On the left their intervals overlap almost entirely, and yet that does not settle it, because unpaired intervals overstate the uncertainty of a difference. Both tables are scored on the same pairs, and a pair that is hard for one tends to be hard for the other. As in Section 18.5, we therefore compare them on the same items. A rank correlation is not a mean of per-item scores, so the next cell resamples the pairs and recomputes both correlations on each resample. The seed range says how much a difference moves from run to run.

The two factorizations of PMI cannot be told apart. SGNS and SVD-PPMI differ by 0.01 on WordSim353 and by less on SimLex-999, with intervals that straddle zero. This is what Equation 19.5 leads us to expect of two factorizations of closely related matrices.

The 0.75 power helps skip-gram on WordSim353, a little. On the right of the plot the WordSim353 line peaks at 0.75 and drops by about three hundredths toward either end. In the table, 0.75 beats noise by frequency by two to four hundredths in every seed, with an interval that excludes zero, and beats uniform noise by a similar amount, at the edge of detection. On SimLex-999 it does not help: that line slopes gently downward from $\alpha = 0$, and uniform noise is ahead by one to two hundredths in every seed, again at the edge of detection. Subsampling changes ρ by an amount whose sign flips between seeds, too little for three seeds to show. On this slice its benefit is speed: an epoch has half as many centers.

The large gap is GloVe's alone. Both factorizations exceed it by about 0.3 on WordSim353, in every seed. On SimLex-999, where all three methods score low, the gap is 0.05 and its interval includes zero. The claim we set out to test therefore holds between the two methods that factorize PMI: no difference of method is detectable there, while one setting, the noise exponent, has a detectable effect. For GloVe it fails.

Why does GloVe trail? Its loss never sees a pair that does not occur, and on three million words that is 98% of the pairs. Nothing in the loss pushes down the score of a word with a context it never meets, and a rare word, with few nonzero counts, is held in place by few terms at all. The next cell splits the covered pairs of each rating set at the median count of their rarer word and scores the seed-0 tables on each half.

On WordSim353 GloVe trails in both halves: 0.21 against 0.53 and 0.54 on the pairs of rarer words, 0.40 against 0.61 on the frequent ones. The gap is wider among rare words, about 0.3 against 0.2, in the direction the second part of the argument predicts, although with half of the pairs on each side that difference is rough. What matters more is that a gap remains among frequent words. Rarity is not the whole story: the pairs that never enter the loss cost GloVe on frequent words too. On SimLex-999, where every method scores low, the halves differ by a few hundredths.

It is not the optimizer. In runs not shown here, more passes, smaller minibatches, other learning rates and the paper's distance-weighted counts all left GloVe far behind the other two methods. More text narrows the gap, and Exercise 6 measures by how much. Swivel

(Shazeer et al. 2016) was designed against this weakness: its loss gives the pairs that never occur a term of their own. Our measurement concerns three million words, and GloVe was built for billions. Its released vectors, trained on six billion tokens, are the ones we use for the last two tests of this section.

For a corpus of your own, SVD-PPMI is a good first choice. It is deterministic, takes seconds and matched SGNS on both sets, and its context exponent made no detectable difference. SGNS streams over the text and scales to corpora whose count matrix would not fit in memory; with SGNS, use the 0.75 power.

19.1.4.2 Nearest Neighbors

A correlation summarizes a thousand pairs. The nearest neighbors of a word, the rows with the largest cosine to its row, show what a table learned about one word.

Does *doctor* land next to *physician*, as the opening hoped?

It does not. *Physician* occurs only 38 times on the slice, against 205 for *doctor*, and a *doctor* there is mostly the Doctor of *Doctor Who* (Amy, Torchwood, the TARDIS) or a character in *The X-Files* (Scully, Mulder, Skinner). *Chip*, with 30 occurrences and many senses, gets lists that look like noise for every method. *Stock* shows something more interesting. Under SGNS its neighbors come from finance (*enterprises*, *financing*, *bankrupt*, *profits*), under SVD-PPMI mostly from Hollywood (*pictures*, *paramount*, *goldwyn*): one word, two senses, and the method decides which one wins its row. *Bank* sits among Swiss banks for all three methods. GloVe's lists are the noisiest overall, in line with its correlations. Nearest neighbors describe the corpus, not the language, and the articles of this slice include a good deal of television.

19.1.4.3 Analogies

Two more tests of word vectors are famous, and both are best read as cautionary tales about evaluation. The first is the analogy: *king* $-$ *man* $+$ *woman* lies close to *queen*. Such tests are usually run on vectors trained on billions of words, so we load the pretrained GloVe-6B vectors, which GloVe's authors trained on six billion tokens of Wikipedia and newswire.

For an analogy $a : b :: c : x$, the method called 3CosAdd answers with the word x whose unit vector has the largest cosine with $\mathbf{b} - \mathbf{a} + \mathbf{c}$, all three normalized. If the offset $\mathbf{b} - \mathbf{a}$ is small compared with $\mathbf{c}$, the nearest word is c itself, so the standard evaluation excludes the query words from the answers. We run five analogies with and without that exclusion.

With the query words excluded, all five answers are right: *queen*, *japan*, *biggest*, *went* and *saw*. Without the exclusion, two of the five answers are a query word: *king* for *man* : *woman* :: *king*, and *see* for *do* : *did* :: *see*. The famous analogy holds because the method forbids the answer *king*, as Linzen (2016) pointed out. An analogy accuracy means little unless it says whether the inputs were excluded.

19.1.4.4 Bias

Word vectors record the associations of their text, stereotypes included (Bolukbasi et al. 2016). The second test probes for them with a direction: the unit vector $\mathbf{g}$ along $\mathbf{he} - \mathbf{she}$, and the projection of each word's unit vector onto it. A simplified version of the repair that Bolukbasi et al. proposed removes the projection onto $\mathbf{g}$ from every word, so that no word leans either way.

Gonen and Goldberg (2019) argued that this hides the bias rather than removing it, and we can test the argument. After the removal, we find each profession's ten nearest neighbors and average their *original* projections. If the removal had erased the association, the new neighbors of a profession would lean toward *she* or *he* no more than chance allows. If it only hid it, their lean would still follow the profession's own original lean.

Before the removal, *homemaker* (-0.37) and *nurse* (-0.28) lean toward *she*, and *manager* ($+0.28$) and *captain* ($+0.21$) toward *he*. These numbers describe how the corpus of GloVe-6B uses the words: *secretary* leans toward *he* ($+0.18$), probably because in newswire a secretary is often a Secretary of State. After the removal every projection is zero by construction, and the neighborhoods barely change. The median profession keeps 9 of its 10 nearest neighbors, and the new neighbors still lean the way the word did, with a correlation of about 0.9 over the 20 professions. The association is spread over many directions, and removing one of them hides it from one probe.

19.1.5 Static Vectors and a Language Model's Table

We return to the table that opened the section. Qwen3-0.6B (A. Yang et al. 2025), loaded with `d2l.load_qwen3` as in Section 18.2, has a token table of 151,936 rows of width 1,024 among its 596 million parameters. The cell computes the table's share of the model and the nearest neighbors of four words. For the opening question it prints the cosine of *doctor* and *physician*, with the rank of *physician* among the neighbors of *doctor*.

The table holds 156 million of the 596 million parameters, or 26%: a quarter of the model is a lookup table. It is tied, so the output layer multiplies by the same matrix. The checkpoint file stores the table once for each use, so it holds more numbers than the model has parameters, and a count taken from the file overstates the size of the model.

The neighbors in Qwen's table are of a different kind from those of SGNS. *Doctor* sits next to *doctors*, *Doctor*, the Chinese word for doctor, and itself without the leading space, and the other three words likewise sit among their spellings and translations. The table has two jobs. It hands the token to the layers above, which work out its meaning from the context. Because it is tied, it also scores the token as the next one, and *doctor* and *Doctor* are predicted in the same places, so their rows end up close.

Now we can answer the question we started with. In the GloVe-6B vectors, trained on six billion tokens, *physician* is the nearest row to *doctor*, at a cosine of 0.77. In Qwen's table it comes sixth (0.65), right behind the spellings and the translation of *doctor* itself. On our slice of three million words SGNS puts it 977th of about 18,000, at 0.44: *physician* is rare there, and *doctor* keeps the company of *Doctor Who*. Training does put synonyms next to each other, given enough text in which they keep the same company.

Nothing in such a table requires the categories to be words. Any categorical variable with many values can have one: store numbers, product codes, postal codes or user ids. Guo and Berkhahn (2016) trained such *entity embeddings* with a network that predicts from tabular data, and categories that behave alike ended up with nearby rows, as words with similar company do. For a store, one row per value is what we want, since a store is the same store wherever it appears.

A word is not. Under SGNS on our slice, *bank* is closer to *river* (0.53) than to *money* (0.32), although its nearest neighbors are Swiss banks. In GloVe-6B the order is reversed (0.33 and 0.57), and in Qwen's table neither cosine is large (0.24 and 0.22). Each table places *bank* at one point, and its corpus decides where that point lies between the bank of a river and the

bank that keeps our money. A vector computed from the sentence around the word would not have to choose, and Section 19.2 computes one.

19.1.6 Summary

A word vector records how often a word occurs near other words, compared with how often it would by chance. At its optimum with free scores, skip-gram with negative sampling scores a pair by its pointwise mutual information minus $\log K$, plus an offset set by the noise distribution. A toy corpus of four distinct words confirms this to the precision of the optimizer, and a model trained on three million words of Wikipedia follows it closely for frequent pairs. A truncated SVD of the positive PMI matrix computes such a factorization in seconds and cannot be told from skip-gram on human similarity ratings, while GloVe, whose loss skips the pairs that never occur, trails on a corpus this small. Comparing word vectors takes the covered pairs, a random floor and paired differences, and analogy and bias tests need the same care about protocol. Every static table, word2vec's or a language model's, gives a word one vector, so *physician* can land next to *doctor*, given enough text, but *bank* cannot have two meanings; vectors computed from context come next.

19.1.7 Exercises

1. **Subsampling and the optimum.** Each occurrence of a word w of relative frequency $f(w) > t$ is kept with probability $r_w = \sqrt{t/f(w)}$; rarer words have $r_w = 1$.
    1. Show that the expected number of kept occurrences of w in a corpus of N tokens is $N\sqrt{tf(w)}$. Subsampling thus replaces a frequency by the geometric mean of the frequency and t. What does it do to the ratio of the counts of two frequent words?
    2. Ignore that windows reach further after deletions, so that a pair survives with probability $r_w r_o$, and keep the noise distribution P computed from the full counts, as the code does. Show that the free-score optimum on the subsampled text is $s^*(w,o) + \log r_o - \log \bar{r}_w$, where $\bar{r}_w = \sum_{o'} r_{o'} X_{wo'} / \sum_{o'} X_{wo'}$. Why does the keep rate of the center word cancel?
    3. Which scores does subsampling lower the most, and how does its effect compare with that of the noise exponent in Equation 19.5?
    4. A pair at distance 6 in the original text can enter the counts that skip-gram sees. Explain how, and say which pairs gain most from it.
2. code **The optimum for other numbers of noise words.** Rerun the toy check of Section 19.1.3 with $K = 1$, 5 and 15.
    1. Before running, predict from the printed counts which optimal scores are positive for $K = 1$ with noise drawn by frequency, and why. Then check your prediction, and check that the optimum follows Equation 19.5 for every K.
    2. The printed table of optimal scores for $\alpha = 0.75$ is not symmetric, although the counts are: *steam* and *gas* score -0.86 in one order and -0.81 in the other. Explain the two values from the offset in Equation 19.5.
    3. Delete the pair *steam–gas* from the counts, setting both of its entries to zero, and run the optimizer again. What happens to its score as the iterations proceed, and how do positive PMI and GloVe each avoid the problem?
    4. Back on the slice, compute SVD-PPMI with `shift=np.log(K)` for $K = 5$ and 15, the shift that the optimum of skip-gram contains. Compare ρ with that of the

unshifted SVD-PPMI on both rating sets, with paired intervals as in Section 19.1.4. Which entries of the matrix does the shift remove, and does removing them help?

3. code **Analogy accuracy and width.** ● Download the Google analogy set `questions-words.txt` (Apache-2.0) and train SGNS on the slice with `DIM` $\in \{25, 50, 100, 300\}$, three seeds each.
   1. Report the number of covered questions and the 3CosAdd accuracy with and without excluding the query words, with the seed range. At which width does the difference between the two protocols shrink?
   2. For the questions that fail only without the exclusion, which query word is returned? Relate the answer to the length of $\mathbf{b} - \mathbf{a}$ compared with that of $\mathbf{c}$.
4. code **Center table, context table, or their sum.** Evaluate $\mathbf{U}$, $\mathbf{V}$ and $\mathbf{V} + \mathbf{U}$ of the default run on both rating sets, with paired intervals for the differences computed as in Section 19.1.4.
   1. Which differences can you detect?
   2. Explain why the choice matters for skip-gram and does not arise for the tied table of Qwen3-0.6B.
   3. With $\mathbf{V}+\mathbf{U}$, the cosine of two words contains the terms $\mathbf{v}_w^\top \mathbf{u}_{w'}$. Use Equation 19.5 to say what these terms measure.
5. code **CBOW.** The continuous bag of words, word2vec's other model (Mikolov, Chen, et al. 2013), reverses the prediction: the mean of the context vectors of a window predicts the center word. Implement it with K noise words per window, and train it with the same budget of epochs and the same noise distribution. Compare ρ on both rating sets, with paired intervals against SGNS, and the seconds per epoch. Which updates does CBOW perform fewer of, and what does that predict for rare words?
6. code **GloVe and the size of the corpus.** ● The text of Section 19.1.4 claims that GloVe's gap narrows with more text. Test it. For the first two parts, set `N_WORDS` to 30 million and skip the cells of the grid, whose stored results belong to the three-million-word slice.
   1. Measure the share of zero entries in the count matrix of the most frequent 18,000 words.
   2. Train GloVe with the same settings and compute SVD-PPMI on the larger slice, and compare their ρ on WordSim353 with a paired interval. Does the gap shrink as the share of zeros falls?
   3. The text states that a better fit of GloVe's loss does not close the gap. Check one case: train GloVe once more on the three-million-word slice with ten times as many passes, and compare the loss and ρ with those of the 50 passes.
7. [extended] **An embedding for a categorical column.** ●● Take the house prices of Section 4.7 and one categorical column with many values, such as the neighborhood.
   1. Show that a table of width d followed by a linear layer is a linear function of the one-hot vector of rank at most d. Under a linear model, when can it differ from one-hot features at all?
   2. Fit the linear model of Section 4.7 with one-hot features and with tables of width $d \in \{2, 4, 32\}$, and then with a small MLP on top of each. Compare the k-fold validation errors of that section over three seeds.

3. Plot the rows of the width-2 table, and say whether neighborhoods with similar prices lie close together.

19.2 Pretrained Encoders

The previous chapter labeled news headlines by prompting a decoder (Section 18.3). With a few solved examples in its prompt, the decoder beat a classifier fitted to the same examples, but it read those examples again for every headline. Now suppose that the task does not stop after two hundred headlines. A support team sorts ten thousand messages an hour by topic, and over the months thousands of labeled messages pile up. Should we keep prompting, or can a model learn from the labels once and then label the stream cheaply?

The bidirectional encoder of Section 11.4 points to an answer. It learned to predict hidden bytes from both sides, and to do so it computed at every position a vector that describes the text around it. BERT (Devlin et al. 2018) trained the same kind of model on subword tokens and a few billion words. It then added a small layer for each task, the task's *head*, and trained all weights briefly on the task's labeled examples, a step called *fine-tuning*. With one head per task it beat the specialized models of its time on a whole suite of language tasks. Encoders of this kind, with about a hundred million parameters, still do much of the routine labeling of text in filters, taggers and search engines. In this section we load a released encoder, fine-tune it for three tasks, and measure on the same items when it beats a prompted decoder, and at what cost.

Which tasks should we measure? We take one that a decoder has in effect already met, and one whose rules it must pick up from its examples. Sentiment is everywhere in the text a decoder is pretrained on: SST-2 (Socher et al. 2013) holds sentences from movie reviews labeled positive or negative. *Natural language inference* is not. In MNLI (Williams et al. 2018) each item pairs a *premise* with a *hypothesis*, labeled *entailment* if the premise implies the hypothesis, *contradiction* if it rules the hypothesis out, and *neutral* otherwise. Where one label ends and the next begins is a convention of the dataset's annotators. Sorting messages by topic lies between the two. The third task, CoNLL-2003 (Tjong Kim Sang and De Meulder 2003), marks every name in a set of news sentences with its type. It needs a label per word, which a prompt can produce only by writing the tagged sentence out again.

The encoder is ModernBERT-base (Warner et al. 2024), released in 2024, and the decoder is Qwen3-1.7B, the instruct model of Section 18.3. The next four cells are setup and can be skimmed. As in the previous chapter, the expensive results were computed once and stored, here in about an hour on one RTX 4090. A run of the notebook reads them and recomputes a small piece of each as a check. The environment variable `D2L_RERUN` names results to recompute in full.

`HF_ENCODER_REVISIONS` pins the encoder to a commit, as Section 18.1 pinned the decoders.

The datasets are pinned as well, beside the four stored results.

`load_encoder` loads a pinned encoder, bare or with a head, and reports which weights go unused and which start at random.

Let us look at the answer first, on MNLI. The encoder, fine-tuned on 16,000 labeled pairs, meets Qwen3-1.7B, prompted with 8 solved pairs, on the same 2,000 validation pairs. Accuracies are means over three training seeds and over three sets of solved examples.

The encoder labels 0.84 of the pairs correctly and the decoder 0.63, and the encoder takes

about a hundredth of the time. On these numbers the choice looks easy. The comparison is not a fair one, however: the encoder learned from 16,000 labeled pairs and the decoder from 8. The rest of the section builds the encoder's row of this table and then asks what the table leaves open. How many labels does the encoder need before it passes the decoder?

19.2.1 A Released Masked-Token Encoder

19.2.1.1 Token Vectors

ModernBERT is the encoder of Section 11.4 at scale: a stack of transformer blocks without the causal mask, with subword tokens in place of bytes, 22 blocks in place of 4, and two trillion tokens of pretraining text. We begin with the smallest experiment there is, and pass it one premise and one hypothesis, without any head.

The tokenizer writes the pair as `[CLS] premise [SEP] hypothesis [SEP]`, as BERT did (Ġ marks a token that begins with a space). `[SEP]` is a separator that closes each text, and `[CLS]` is a special token at the start. BERT also marked each token as part of the first or the second text with a learned *segment embedding* (`token_type_ids`). ModernBERT has none: its tokenizer returns only token ids and an attention mask, so the separator alone marks where the hypothesis begins.

Sixteen tokens went in, and sixteen vectors of 768 numbers came out. Unlike the word vectors of Section 19.1, these depend on the whole input. The last lines of the output show it for *bank*, the word on which that section ended, in four sentences: two put the bank beside water and two put it in charge of money. After the embedding layer its vector is the same in all four (cosine 1.00), since the table holds one row per token. After the last layer the four vectors have moved apart, and they have moved apart by sense. The two banks by the water have a cosine of 0.81 and the two banks that deal in money 0.85, while every pair across the senses lies between 0.65 and 0.72.

How low can a cosine go in this space? The last line gives a floor: *bank* against *the* in the river sentence, a word that shares nothing with it but the sentence, has 0.32. So at the last layer the scale runs from about 0.3 to 1. The senses are not far apart on it, but they are cleanly separated: each same-sense pair lies above every cross-sense pair. The encoder did not have to choose between the senses of the word. The sentence told it which one was meant.

The pair also entered as one input. In every layer each token of the hypothesis can therefore attend to every token of the premise, so the two texts are compared word by word before anything is pooled. An encoder that reads both texts of a pair together is called a *cross-encoder*. The alternative, to encode each text alone and compare the two vectors, is much faster when one text must be compared with many, and the next sections build it.

19.2.1.2 Masked-Token Prediction

The checkpoint ships with its pretraining head, the weights that the load report above listed as not used: a dense layer, a GELU, a norm and a projection onto the vocabulary. With it we mask one token in each of three sentences and print the five most probable fills.

The model puts 0.92 on "Paris", splits the cup between coffee (0.61) and tea (0.21), and fills the third gap with "both" at 0.94, a word that only the token after the gap pins down. A decoder that reads from the left would have had to guess it. The head predicts words. It

knows nothing of entailment or sentiment, so each task below gets a new head, built on the pretrained dense layer and norm.

19.2.1.3 The 80/10/10 Corruption

In Section 11.4 every selected byte became the mask symbol. BERT also selects 15% of the tokens for prediction, but it replaces only 80% of them by `[MASK]`, replaces 10% by a random token and leaves 10% unchanged. The loss is computed at all selected positions. Why not mask them all? BERT gave two reasons. First, `[MASK]` never occurs in the text the encoder is later fine-tuned on. Second, if only `[MASK]` positions were ever scored, nothing in the loss would ask the vector at any other position to describe its own token, yet those are the vectors that fine-tuning reads. When any ordinary-looking token may be asked about, the model must keep a good guess of the true token everywhere. `mlm_corrupt` implements the rule and never selects a special token.

We send a million token ids through the corruption and count.

The counts match the rule to within a fraction of a percent. So 12% of all tokens show `[MASK]`, and only 1.5% are random tokens that the model must recognize as wrong. The proportions are BERT's and are not sacred: ModernBERT was pretrained with 30% of its tokens selected. Nor do the two reasons weigh as much as they sound. In BERT's own ablation, fine-tuning turned out "surprisingly robust" to the mix; masking every selected token hurt mainly when the token vectors were used without fine-tuning, as fixed features for tagging names (Devlin et al. 2018).

19.2.1.4 Successors of BERT

BERT had a second pretraining objective, *next-sentence prediction*, read from the final vector of `[CLS]`: did the second text follow the first in the source? Its successors dropped it. RoBERTa (Liu et al. 2019) also drew new masks each time a sequence was read (as calling `mlm_corrupt` once per batch does) and trained longer on far more text. RoBERTa showed that BERT had been undertrained rather than misdesigned. Two others changed the objective. In ELECTRA (Clark et al. 2020) the encoder judges, at every token, whether a small generator replaced it, so every position supplies a training signal and not 15%. T5 (Raffel et al. 2020) has a decoder write out masked spans and turns every task into text in and text out, a step toward the decoders of the previous chapter.

ModernBERT stands in RoBERTa's line. It keeps BERT's bidirectional attention, special tokens and masked-token objective, has no next-sentence prediction, and rebuilds the block along the lines of recent decoders. The details of that block (the gated feed-forward layer GeGLU, the rotary positions of Section 10.4.3, the absence of bias terms) can be forgotten here. Two lines of the configuration printed with the token vectors matter. The classification head pools by the mean, which our own head will have to respect. And an input may have 8,192 tokens, sixteen times BERT's 512. The way ModernBERT arranges its attention makes such long inputs cheaper, and by how much is easy to count.

19.2.1.5 Alternating Attention

Every third layer of ModernBERT, starting with the first, is *global*: every token attends to all others. The other layers are *local*: each token attends only to the tokens within a window of $w = 128$ positions, 64 on either side, as in the sliding windows of Section 10.5.

How much does the window save? The question becomes practical in the next section, which encodes passages of several hundred tokens. A global layer scores all T^2 pairs of positions of an input of T tokens, and a local layer about Tw pairs. With n_g global and n_l local layers, the pairs scored, as a share of what global layers alone would score, are

$$s(T) = \frac{n_g T^2 + n_l T w}{(n_g + n_l) T^2} = \frac{n_g T + n_l w}{(n_g + n_l) T}. \tag{19.7}$$

For long inputs the local term vanishes and $s(T)$ approaches $n_g/(n_g+n_l)$, so that the global layers set the cost. With ModernBERT's $n_g = 8$, $n_l = 14$ and $w = 128$ the share cannot fall below 8/22, a little over a third, and the formula gives 0.37 at $T = 8{,}192$. The cell counts the pairs from boolean window masks.

The count agrees with the formula at 8,192 tokens. At 512 tokens the window already halves the number of pairs. (The count there is a shade below the formula, because windows are cut off at the ends of the input.) On short inputs nothing is saved. When T is at most 65, a window of 64 tokens on either side covers the whole input, and the sentence pairs of this section have about 40 tokens. For the rest of this section alternating attention is idle.

19.2.2 Sentence and Pair Classification

19.2.2.1 The Pooled Head

A classifier needs one vector per input, and the encoder returns one per token. BERT used the final vector of `[CLS]`, which its next-sentence objective had trained. ModernBERT averages the final vectors over the tokens, leaving out padding. Its configuration records the choice (`classifier_pooling: mean`) and Transformers' sequence classifier follows that field, so read it rather than assume `[CLS]`. Which pooling is better cannot be settled by argument. The dense layer and norm that start our head come from the masked-token head, which was trained on the vector of one token at a time. A mean over tokens is as new to them as the vector of `[CLS]`, which that head never scored, so neither pooling starts with an advantage and only an experiment can decide (Exercise 4).

Let $\mathbf{h}_1, \dots, \mathbf{h}_T$ be the final vectors of the T tokens that are not padding. The head maps their mean to one logit per class:

$$\bar{\mathbf{h}} = \frac{1}{T} \sum_{t=1}^{T} \mathbf{h}_t, \qquad \mathbf{z} = \mathbf{W}_\mathrm{c}\, \mathrm{LN}\big(\mathrm{GELU}(\mathbf{W}_\mathrm{d} \bar{\mathbf{h}})\big) + \mathbf{b}_\mathrm{c}.$$

That is a mean, a dense layer $\mathbf{W}_\mathrm{d}$ of size 768×768, a GELU, a layer norm, and a linear map with bias $\mathbf{b}_\mathrm{c}$ to the logits. (The dropout layer before the last map is idle: its rate is zero here, as are all of ModernBERT's dropout rates.) `PooledClassifier` computes this, with first-token pooling as an option that needs the padding on the right. Its submodules carry the names of Transformers' `ModernBertForSequenceClassification`, so loading that model's weights into ours is a matter of renaming.

The same encoder serves all three tasks of this section. Only the input and the head change (Table 19.1 and Figure 19.2).

Table 19.1: One encoder, three heads. Every head starts with the dense layer, GELU and norm of the pretrained masked-token head.

task	input	vectors read	output
sentence (SST-2)	`[CLS] sentence [SEP]`	the mean over tokens	2 logits
pair (MNLI)	`[CLS] premise [SEP] hypothesis [SEP]`	the mean over tokens	3 logits
tagging (CoNLL-2003)	`[CLS]` sentence among its neighbours `[SEP]`	each word's first token	9 logits per word

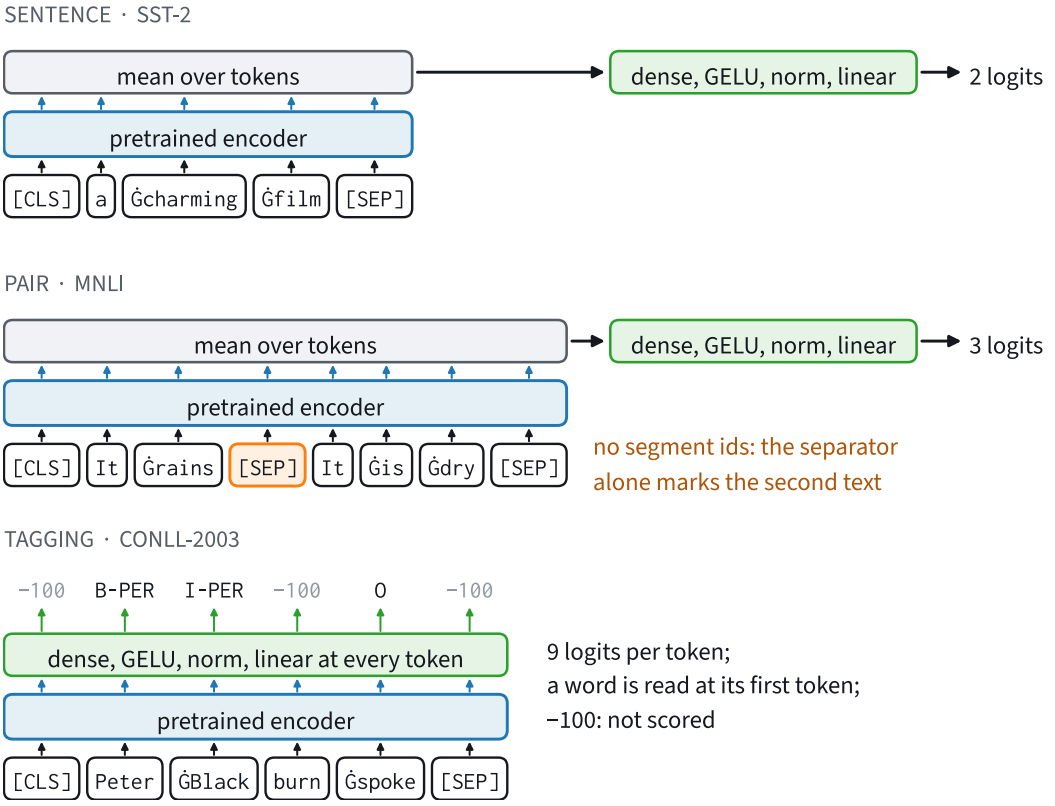

Figure 19.2: One pretrained encoder and three heads, each fine-tuned on its own task. A sentence (top) and a sentence pair (middle) are averaged over their tokens and passed through dense, GELU, norm and linear layers to two or three logits. The pair is read jointly, and the separator alone marks where its second text begins. A tagging head (bottom) applies the same layers at every token; each word's label sits on its first token, and tokens that carry -100 are not scored. Ġ marks a token that starts with a space.

We will fine-tune our own `PooledClassifier`, so we first check that it computes what the library computes. We copy the weights of Transformers' sequence classifier, with a new three-way head, into a `PooledClassifier` under the renamed keys. The load is strict, so it fails if any name does not map. Then we compare the logits of the two models on eight padded MNLI pairs, in fp32 and in bf16.

Both differences are 0.0, which is more than we asked for. The two models run the same operations in the same order on the same batch, so even bf16 agrees bit for bit. The first output line adds that the library's classifier also takes its dense layer and norm from the masked-token head, so only its final map is new.

19.2.2.2 Fine-Tuning

Fine-tuning trains every weight of the encoder and the head on the labeled examples with the cross-entropy loss, briefly and with small steps. Nothing in the recipe is deep, and all of it is worth copying. `finetune_classifier` uses AdamW (Loshchilov and Hutter 2019) with weight decay 0.01 on the weight matrices, a learning rate that rises linearly over the first 10% of the steps and then falls linearly to zero, and gradients clipped at norm 1. Warmup and clipping protect the pretrained weights from the large gradients of a new layer that starts at random.

We train in batches of 32 for two epochs, or for as many more as it takes to reach 300 optimizer steps on a small training set. For 100 sentences that is 75 passes over the data. Why the floor matters is measured below. The learning rate is chosen among 2×10^{-5}, 5×10^{-5}, 8×10^{-5} and 1.5×10^{-4} on 2,000 held-out training pairs, never on the validation items. Matrix products run in bf16 while the weights stay in fp32. Each batch is padded to its own longest example and not to the limit of 128 tokens, which would spend most of the arithmetic on padding.

The fp32 weights, their gradients and AdamW's two moment estimates take 16 bytes per parameter, about 2.4 GB for 149 million parameters. Activations come on top and grow with the batch and the length (Exercise 1).

19.2.2.3 Data and Sentence Pairs

Two details of the MNLI pair input matter, and neither raises an error when it is wrong. The separator is the only marker of the boundary, so a pipeline that drops it or swaps the texts gives the model an input it was not fine-tuned on. And a pair over 128 tokens is cut from the end of the premise (`truncation='only_first'`). Cut from the end of the pair, it could lose the "not" that decides the label.

The training sets of different sizes are nested prefixes of one permutation, and every model is scored on the same items, 2,000 MNLI validation pairs and all 872 SST-2 validation sentences. MNLI's annotators wrote one hypothesis per label for each premise, so pairs that share a premise are not independent. Our intervals therefore resample whole premises (Section 18.5).

Only 51 of the 16,000 training pairs lose the end of their premise, and no SST-2 sentence is cut. A classifier that ignores its input scores the *majority rate*, the share of the most frequent label: 0.36 on MNLI and 0.51 on SST-2. Every accuracy below should be read against these two floors.

Of the helpers in the next cell only `finetune` carries an idea: every run starts from the pretrained dense layer and norm and from a new final layer initialized from its seed.

19.2.2.4 Seeds and Sample Size

How many labeled pairs does the encoder need? The sweep fine-tunes a fresh encoder at four sizes per task, each with three seeds. A seed fixes the new layer's initial weights and the

order of the batches, and nothing else, since ModernBERT uses no dropout. Beside this grid the cell prints a second one, read from an earlier stored run of the same code that trained for two epochs at every size, the common default of a fixed number of epochs. In batches of 32, two epochs of 250 pairs are 16 optimizer steps. What can a model with a new random layer learn in 16 steps?

Both tasks chose 8×10^{-5}, a value inside the grid. With at least 300 steps (the left columns) accuracy rises steadily with the data. SST-2 climbs from 0.67 with 100 sentences to 0.93 with 8,000, and MNLI from 0.44 with 250 pairs through 0.63 and 0.76 to 0.84 with 16,000. Sentiment is learned from hundreds of examples, inference from thousands.

The right columns show what 16 steps can do, which is almost nothing. Two epochs of 250 pairs reach 0.38, hardly above the majority rate. With 1,000 pairs and 64 steps the mean is 0.47 and the three seeds lie 0.16 apart, because some runs had begun to learn the task and others had not. Given 300 steps, the same 1,000 pairs reach 0.63 and the seeds agree to within 0.02. Most of what looked like seed noise was a run too short to finish learning.

The mistake is easy to make. A fixed number of epochs turns into a handful of steps when the data are few, and nothing warns us. Mosbach et al. (2021) traced much of the notorious instability of fine-tuning BERT on small datasets to optimization, and found that training for more steps removed most of the failed runs.

Where labels are fewest the seed still matters. On MNLI the seeds never lie more than about 0.03 apart, against a median gain of 0.13 from one size to the next. At 100 SST-2 sentences, however, they lie 0.10 apart. That is more than the gain from 500 to 2,000 sentences, though only about half the gain from 100 to 500. How much of this range is the seed itself, and how much comes from 75 passes over a hundred sentences, the sweep cannot separate. Dodge et al. (2020) found such spreads for BERT on four standard tasks: the seed alone moved validation scores about as much as newer methods claimed to gain. Two fine-tuning methods compared at a few hundred examples with one seed each may differ only in their seeds, or in how long they trained.

A small range is no comfort either. With two epochs the seeds at 250 MNLI pairs agreed to within 0.05, but only because all three sat near the majority rate. Agreement among seeds shows that a result is reproducible. It does not show that the result is good.

One choice still favors the large sizes: the learning rate is chosen once per task, at the largest size. Unfortunately, choosing it for each size takes held-out labels, and a task with 250 labeled pairs has few to spare (Exercise 6).

Are the stored results what this code computes? Two live checks say so. The first retrains one entry of the grid, 1,000 MNLI pairs with seed 0.

The live run repeats the stored one, item for item. The second check loads the stored classifier, saved in bf16, which we keep for the timing below.

The stored classifier scores 0.84 and repeats the predictions it made when it was saved. Against its fp32 weights at the end of training, bf16 rounding changes the answer on a few pairs in a thousand.

19.2.2.5 The Hypothesis-Only Probe

Is 0.84 on MNLI reading comprehension? A simple test removes the premise. A model that sees only the hypothesis cannot know whether it follows from a premise it never read, so it should score the majority rate, 0.36. Gururangan et al. (2018) ran this test on the inference

datasets of the time and found scores far above chance. Annotators asked for a contradiction often wrote a negation such as "nobody" or "never", and those asked for a neutral hypothesis often added a detail that the premise did not mention. We fine-tune our encoder on 5,000 hypotheses alone, with three seeds.

The majority rate is not what we get. All three seeds reach about 0.53, some 0.17 above it, and every interval starts at 0.50 or above. The model gets more than half of the pairs right without ever reading a premise. The full model's 0.84 can therefore mix two skills, comparing the two texts and recognizing how annotators phrased each label, and its accuracy alone cannot separate them. Of the results of this section, this is the one to remember when reading benchmarks. An inference score reported without a hypothesis-only baseline does not say how much of it is reading.

19.2.3 Token Tagging

19.2.3.1 Words and Sub-Word Tokens

A pooled head averages the token vectors away. A token head classifies each of them, which is what a label per word needs. CoNLL-2003 marks every name in its news sentences as a person (PER), a location (LOC), an organization (ORG) or miscellaneous (MISC). The copy we load uses the *IOB2* scheme: the first word of a name gets `B-` and its type, the other words of the name get `I-` and the type, and all other words get `O`, nine tags in all.

There is one complication. Labels belong to words, and the tokenizer may split a word into several tokens. The usual rule, and ours, gives the word's label to its first token and -100 to the rest, so the loss skips them and the prediction for a word is read at its first token.

CoNLL-2003 comes as lists of words with their tags. We join the words with spaces, tokenize the text, and map every token to its word through the characters it covers. The tokenizer's own notion of a word would not do: it splits at punctuation, so "U.S." would count as four words.

The training set has 14,041 sentences and the validation set 3,250. In the example, "Blackburn" becomes `ĠBlack`, which carries `I-PER`, and `burn`, which is not scored.

19.2.3.2 Span F1

Accuracy per word would be a poor measure. Most words lie outside any name, and a tagger that answered `O` everywhere would look good. The shared task scores whole names instead: a predicted name counts as correct only if its type and both of its ends match a name in the annotation, a *gold* name. *Precision* is the share of predicted names that are correct, *recall* the share of gold names that are found, and *span F1* their harmonic mean. One convention needs care. An `I-` tag after an `O`, or after a tag of another type, starts a new name, as the official scorer and the library `seqeval` count it.

19.2.3.3 The Token Head

Transformers' token classifier applies the sentence head's dense layer, GELU and norm at every position, then a linear map to the nine tags. A sentence alone is not all that BERT's tagger read, however. Its authors fed each sentence together with the text around it in the same news article, the "maximal document context" (Devlin et al. 2018), so that a name could draw on what the article said about it earlier. Our copy of CoNLL-2003 does not mark where one article ends, so we place each sentence among its neighbours in the file, adding

one before and one after in turn until the window holds 256 tokens. Only the sentence in the middle carries labels; its neighbours get -100 and are read but not scored.

A window holds about 250 tokens against 22 for a sentence alone, so in each epoch a sentence is read about eleven times: once as the labeled middle of its own window and otherwise as context for its neighbours. The printed window shows what the neighbours offer. Read alone, "Texas 's lead over Seattle in the West increased to six" could be about two cities. One sentence earlier Cleveland leads the White Sox in the American League Central, and Seattle is a baseball team.

We fine-tune with the same function for two epochs. The learning rate is chosen as for the sentence tasks, among the same four rates, on 2,000 sentences carved from the training set, never on the validation items. The runs that choose it train on the other 12,041 sentences. One seed per rate decided the sweep above; here each rate is scored by the mean span F1 of three seeds. At the chosen rate the tagger is then trained on all 14,041 sentences. The cell trains seed 0 live and compares its span F1 with the three stored seeds and with `seqeval`.

The rule chose a rate of 8×10^{-5} (we return to the choice below). The tagger finds about 96% of the names, 95% of the names it predicts are right, and its span F1 of about 0.96 equals `seqeval`'s. The three stored seeds agree to the third decimal. Persons and locations are nearly solved, at about 0.98. Organizations stay a little below 0.95, and the catch-all MISC of nationalities, events and titles is at about 0.9. All of this comes from a small head on one vector per token, fine-tuned together with the encoder. Nobody wrote a rule about capital letters or a list of cities.

What goes wrong with organizations? The cell follows each of the 1,341 gold organizations of the validation set. The tagger finds about 1,280 of them. Of the sixty or so it misses, roughly half have no predicted name with the same two ends: the name was cut too short or too long, or not tagged at all. The rest are given another type, and the printed examples show why. All three come from one report on an American football player's retirement. The annotators tagged the league as an organization, and the tagger calls it a miscellaneous name; "the wonderful fans of Philadelphia" are the team's fans to the annotators and the city's to the tagger. A careful reader could make these calls either way.

19.2.3.4 Context and the Learning Rate

BERT's paper reports a span F1 of 96.4 for its base model on this validation set (Devlin et al. 2018). What do the neighbours and the choice of the learning rate contribute to ours? The stored runs answer both questions without training anything new.

The upper table is the choice of the rate. On the carved sentences the two higher rates are level, 0.941 and 0.940, and on the validation set they are level too. The lowest rate, 2×10^{-5}, is more than two points behind, and 5×10^{-5}, a common default for BERT, about half a point on the validation set. The mean over three seeds picked 8×10^{-5}, the rate the sweep chose for both sentence tasks. Since the two higher rates are level, another run of this code may pick the other one, at no cost that the validation set can see.

The lower table separates the two changes; all three rows train on the full 14,041 sentences. The better rate alone moves span F1 from 0.945 to 0.951 up to about 0.952. Reading each sentence among its neighbours adds about 0.6 points more, to 0.958, and the three seeds agree. Organizations gain most: with neighbours about 35 of them get another type, without about 50. Thirty names are right in every run with neighbours and in no run without, and seven the other way round. The printed names are ones that the sentence alone leaves open.

ATALANTA, in a headline about a transfer, could be a place; two sentences further on, the article calls it a Serie A club. Jamaica, in a list of sprint times, may be a team or a country.

Our first runs, then, fell short of BERT for two reasons. They read each sentence without the article around it, which BERT's tagger had, and they trained at a rate fixed in advance rather than chosen. The missing context cost the more of the two. That leaves about 0.6 points to BERT's 96.4, which this section does not explain. Our windows can run across the end of an article, since this copy does not mark it; the two are different models, pretrained on different text; and a single reported figure also carries the luck of its own runs.

19.2.4 Encoder or Prompted Decoder

19.2.4.1 The Prompted Decoder

We can now return to the opening question and give the decoder its turn. It labels the validation items from $k = 0$, 4 or 8 solved examples in its prompt. As in Section 18.4, each label word (`yes`, `maybe` or `no` for MNLI, `negative` or `positive` for SST-2) is appended to the prompt in turn, and the word with the highest log-probability per token wins. The choice of examples moves few-shot accuracy much as a seed moves fine-tuning, so 8 shots are scored with three disjoint sets of examples.

On SST-2 the decoder starts at 0.71 without examples and reaches about 0.94 with four or eight. It met this task all through pretraining, and a few examples suffice to tell it which task is meant. On MNLI it reaches 0.40 without examples, a little above the majority rate, and 0.62 to 0.65 with four or eight, where eight are no better than four. Which pairs MNLI calls entailment, neutral or contradiction is a convention of its annotators, and eight examples convey it only in part. The confusion counts show which part. Over the three sets of examples the decoder calls about 850 entailed pairs and about 450 contradictions neutral, and it calls about 300 neutral pairs entailed and about 400 contradictions. It takes an entailment for a contradiction, or the reverse, fewer than 200 times: nearly all of its errors are about where "maybe" begins.

The last lines check the stored scores by scoring the 8-shot MNLI items again, live. In bf16 a score depends slightly on the other items in the batch (Section 18.4), so the check sets aside *near ties*, items whose two best labels differ by at most 0.5 nats per token, and requires every other prediction to repeat. On a GPU the live batches are the stored ones, and no score moves by more than 0.0001 nats per token, the rounding of the stored values. Every prediction outside the 124 near ties repeats.

19.2.4.2 Baselines on Word Counts

Is pretraining needed at all? The classical floor is naive Bayes on word counts (Section 36.11), which treats the words of a text as independent once the class is known, so that training is counting and prediction is multiplying. A pair becomes two bags of words, with premise and hypothesis words kept apart by a prefix.

As its data grow, naive Bayes climbs from 0.53 to 0.78 on SST-2, but only from 0.38 to 0.42 on MNLI, barely above the majority rate. Word counts carry sentiment. They carry little entailment, which depends on how the words of the hypothesis relate to those of the premise, and two bags of words cannot represent that.

19.2.4.3 Cost per Example

The encoder reads about 40 tokens per MNLI pair. The decoder reads its eight solved examples again for every item, and three times over, since `score_choices` runs the prompt once for each label word. How much arithmetic is that? Every weight matrix multiplies the vector of every token, and each weight contributes a multiply and an add per token. A model with N parameters, N_{emb} of them in the embedding table, therefore spends about

$$C = 2\,(N - N_{\text{emb}})\,T \tag{19.8}$$

floating-point operations on an example of T tokens. Embedding lookups are not products. The decoder's output layer, which shares the embedding table, is applied only at the few positions that are scored. And attention's T^2 term is small at a few hundred tokens. The cost thus grows with the weights each token passes through and with the number of tokens read. `cost_per_example` evaluates Equation 19.8.

The next cell times both models on 32 MNLI items in bf16 and compares the measured ratio with the estimate.

The estimate is a product of two factors. The decoder reads 1,543 tokens per item against the encoder's 40, about 38 times as many, and each token passes through about 13 times the weights (2.8 against 0.22 GFLOPs per token). Together that makes close to 500 times the encoder's operations per example. The clock shows only about 100 times, under half a second against about 48 seconds per thousand items. Per second the decoder computes four to five times as much as the encoder. Padding, which the token count leaves out, accounts for a factor of about two. The encoder's batch is padded to 87 tokens, its longest pair, 2.2 times the 40 tokens counted per pair, and the encoder computes every padded position. The rest comes from the small matrix products of short pairs, which leave the GPU partly idle, while the decoder's long prompts fill it.

How much of the factor of 100 belongs to decoders, and how much to the way we ran this one? Two parts are ours. The three label words are single tokens, so one pass over the prompt could score all three. And a server that computes the keys and values of the shared solved examples once reads them once (Exercise 5). What remains is the query: the premise and hypothesis with a question around them, plus one label word. The output counts it at 49 tokens against the 40 of the encoder's pair, each passing through 13 times the weights, which comes to 16 times the encoder's operations. The factor we measured is about 100; the factor that caching cannot remove is 16. On SST-2, with shorter prompts and two label words, the stored timings put the decoder at about 30 times the encoder. A fine-tuned decoder would also run 13 times the weights per token, and it would give up what makes prompting attractive: no training run when the task changes.

19.2.4.4 Learning Curves and Crossing Points

The plot shows accuracy against labeled examples (left) and against seconds per thousand examples (right), both on log scales, MNLI on top. Labels cost annotators' time that eight solved examples do not, which is why the left panels measure both models against labeled examples. The bands span the encoder's seeds and the decoder's three sets of 8 solved examples; at 0 and 4 shots they are the interval of one set. The dashed line is the majority rate. On the left, look for the size at which the encoder's curve rises through the 8-shot band. On the right, each decoder point is labeled with its number of shots, and the encoder's point is the run on the largest training set.

In the panels on the right the encoder sits far to the left of the 8-shot decoder, by two decades on MNLI and by more than one on SST-2, at equal or higher accuracy. The panels on the left need more care.

Where does the encoder pass the decoder? A crossing read off a plot is easily the crossing we hoped for, so we use a strict rule instead of the eye. The rule pairs each of the three seeds with each of the three sets of examples. For each pairing the cell computes the paired bootstrap interval of the difference in accuracy, which scores both models on the same resampled items (by premise on MNLI), so that the difficulty they share cancels. A size is *passed* when

- all nine intervals exclude zero on the encoder's side, and
- the seed range and the range over the sets are both narrower than the mean gap.

The *crossing point* is the smallest size from which every larger size is passed.

On MNLI the decoder leads clearly at 250 pairs. At 1,000 the two are level: the mean gap is zero to two decimals, and the nine intervals reach 0.05 to either side of it. From 4,000 pairs on the encoder leads in every pairing, by 0.13 and then by 0.21 at 16,000, so the crossing point is 4,000. On SST-2 there is none. The decoder leads up to 2,000 sentences, and at 8,000 the remaining gap of 0.01 is within noise. The encoder catches up on sentiment but does not pass.

This is the answer to the question we began with, and it comes in two versions. On a task whose conventions eight examples cannot convey, the encoder needs about a thousand labels to draw level and a few thousand to lead. On a task the decoder largely knew before it saw an example, eight thousand labels only bring the encoder level. Where the line runs depends on how much of the task the decoder already knows. The cost does not: at every size the encoder labels an MNLI pair in about a hundredth of the time our decoder took, and with about a sixteenth of the operations even of a decoder that caches its examples.

19.2.4.5 Choice by Situation

Table 19.2 turns these measurements into advice.

Table 19.2: A fine-tuned encoder or a prompted decoder, by situation.

situation	prefer	because
no labels, or a few hundred	prompted decoder	at 250 MNLI pairs and at 100 to 2,000 SST-2 sentences the decoder was ahead
thousands of labels for a fixed task	fine-tuned encoder	on MNLI it drew level with 8 shots at 1,000 pairs and led from 4,000; on SST-2 it caught up at 8,000
many items, high throughput	fine-tuned encoder	a hundredth of our decoder's time per MNLI pair; about a sixteenth of the operations even with the examples cached
a label set that changes often	prompted decoder	a new label is a new prompt, not a new training run
a label for every word	fine-tuned encoder	one vector per token, read by a small head

situation	prefer	because
an answer that must be written or explained	decoder	an encoder head outputs one of a fixed set of labels

The support team of the opening, with thousands of labeled messages for a fixed set of topics and ten thousand new ones an hour, belongs in the second and third rows. If its topics changed every month, it would belong in the fourth.

Each task in this section got a model of its own, trained on its own labels. Search needs something else. A question must be compared with millions of passages, far too many to pair with each one in a cross-encoder, and no label set describes the questions it will be asked. It needs one vector per text, computed once, that serves every question. Whether this encoder can supply such a vector is the subject of Section 19.3.

19.2.5 Summary

A decoder that labels text from a prompt reads its solved examples again for every item, which is wasteful once the task is fixed and labels accumulate. A masked-token encoder computes one vector per token from the text on both sides, and a small head, fine-tuned with all of the encoder's weights, turns these vectors into a label per sentence, per pair or per word. Against Qwen3-1.7B with 8 solved examples, ModernBERT-base drew level on inference at about 1,000 labeled pairs and led from 4,000. It took a hundredth of the time per pair as we ran the decoder, and it would take about a sixteenth of the operations even if the decoder cached its examples. On sentiment, which the decoder largely knew already, it only caught up. Two cautions go with such numbers: a fine-tuning run on few examples needs enough optimizer steps before its seeds mean anything, and a model that never reads the premise labels more than half of MNLI correctly. A token head tagged names at a span F1 of about 0.96, nearly a point above what it reached on sentences read alone at a fixed rate; the gain came from reading each sentence among its neighbours, as BERT's authors did, and from choosing the learning rate. Prompting suits few labels and changing tasks, and a fine-tuned encoder a fixed task with thousands of labels and many items.

19.2.6 Exercises

1. code **Peak memory and batch size.** Fine-tune the MNLI classifier on 4,000 pairs for one epoch with batch sizes 8, 16, 32 and 64. Pad every batch to 128 tokens, so that the length does not vary, and record `peak_gib` from `finetune_classifier`.
    1. Fit the peak as a linear function of the batch size. Compare the intercept with the 16 bytes per parameter of the weights, gradients and AdamW moments, and the slope with an estimate of the activations kept per sequence: how many vectors of width 768 or 1,152 (the width of ModernBERT's gated feed-forward layer) per token and layer does the slope correspond to?
    2. Predict the largest batch that fits on a 24 GB card, and check it.
    3. Under autocast most saved activations are bf16 (layer norms run and save in fp32). How large would the slope be if all were kept in fp32, and which batch would then fit?
2. **The masked-token loss under 80/10/10.** Let $p = 0.15$ be the share of selected tokens, V the vocabulary size, and $\mathcal{S}$ the selected positions; the loss is $-\sum_{t\in\mathcal{S}} \log q_t(x_t)$,

where q_t is the model's distribution at position t given the corrupted input.

1. Show that the gradient of the loss with respect to the logits at an unselected position is zero. How, then, does the vector at such a position receive any gradient at all?
2. A position shows an ordinary token v whose frequency in the data is f. Compute, as functions of f, p and V, the probability that the position is scored and the probability that its target is v given that it is scored. Evaluate both for $V = 50{,}368$, once with $f = 1/V$ (tokens drawn uniformly, as in the cell that counts the shares) and once with $f = 10^{-3}$.
3. Use the result to explain why a model trained this way predicts the token it sees with high probability at most positions, and why this is useful for fine-tuning. What would the loss teach the model at a position showing v if every selected token were replaced by `[MASK]`?

3. code **What the hypothesis gives away.** Fit naive Bayes on the bags of MNLI hypothesis words alone, with the vectorizer of the naive Bayes cell and the 5,000 training hypotheses of the hypothesis-only encoder.

   1. Compare its accuracy per class with that of the hypothesis-only encoder of Section 19.2.2.5. Which class does each predict best?
   2. List the ten words with the largest ratio $p(\text{word} \mid \text{class})/p(\text{word})$ for each class. What do they say about how the hypotheses were written?
   3. On the validation pairs the full encoder gets right, how often does the hypothesis-only encoder get them right too? What does this suggest about the share of the 0.84 that needs the premise?

4. code **First token or mean.** Fine-tune `PooledClassifier` with `pooling='cls'` on 4,000 MNLI pairs with three seeds, and compare it with the stored mean-pooling runs by paired bootstrap on the same items. Before you run it, write down which result would change your mind about reading `classifier_pooling` from the configuration, and which would not. Then fine-tune both poolings once more with a freshly initialized dense layer and norm. Does the pretrained pair help either pooling?

5. **Prefix caching and break-even.** The 8-shot decoder of this section reads three copies of a prompt whose first part, the solved examples, is the same for every item.

   1. With the shared prefix cached and the three single-token label words scored from one pass, each item still costs its query and one label word, 49 tokens and 16 times the encoder's operations. Measure the length of the prefix and check that three copies of prefix, query and label word give the 1,543 tokens counted per item. Then count the encoder's padding as well, 87 tokens per pair in its batch of 32: what does the ratio of Equation 19.8 become, and how could the encoder's pairs be batched to bring it back toward 16?
   2. Qwen3-1.7B stores keys and values for 8 heads of width 128 in each of 28 layers, $2 \cdot 28 \cdot 8 \cdot 128$ numbers of two bytes per token (Section 18.3.4.2). How much memory does the cached prefix take, and how does it compare with the cache of one batch of 32 queries?
   3. Fine-tuning costs about three forward passes per example and pass over the data, since the backward pass computes two products for each one of the forward pass. Using Equation 19.8, after how many queries is fine-tuning on 4,000 pairs plus encoder inference cheaper in operations than the cached 8-shot prompt? Is the answer different if you count annotators' time for the 4,000 labels?

6. code **A learning rate for each size.** The recipe chooses the learning rate once per task, at the largest size, and trains at least 300 steps.
    1. At 250 and 1,000 MNLI pairs, choose the learning rate from the grid for that size: once on the 2,000 held-out pairs, and once on 50 pairs carved from the training set itself, training on the rest.
    2. Recompute the crossing point with the 8-shot decoder for both choices. Does the encoder pass the decoder at 1,000 pairs?
    3. Train 1,000 pairs for 1,000 steps instead of 320. Does the accuracy or the seed range change, and what does that say about the floor of 300 steps?
    4. Which of the two choices of learning rate could a team with only 250 labels make? What does the other one cost them in labels?
7. code **Extractive question answering.** Put a start logit and an end logit on every context token of a pair `[CLS] question [SEP] context [SEP]` and fine-tune for one epoch on 10,000 questions of SQuAD v1.1, whose answers are spans of the context. Predict the span with the highest sum of start and end logits whose end does not precede its start, and report exact match and token-level F1 on its validation set. Then run the tagger of Section 19.2.3 over the contexts of the questions whose answer is a name. Are the failed questions more often those whose answer the tagger misses, and what would that suggest about what the two heads read from the same token vectors?
8. code **A CRF on the token head.** The token head predicts each word's tag on its own, so it may output `I-ORG` after `B-PER`. Add a linear-chain conditional random field on top of the logits at first tokens, train it jointly by maximizing the log-likelihood of the gold tag sequence, and decode with the Viterbi algorithm. Measure the change in span F1 over three seeds against the stored seeds of the tagger with neighbours, and count the invalid tag transitions with and without the CRF.

19.3 Text Embeddings from Contrastive Training

In Section 19.2 we fine-tuned an encoder one task at a time: a small head on top of its token vectors, trained on thousands of labeled examples, decided whether one sentence entails another. Search asks for something else. Suppose a reader of this book wants to know how the book's old `load_array` helper decides whether to shuffle its data. Somewhere among the thousands of passages of the book is the paragraph that says so, and no label set describes that question, or the next one. What we want is one vector per text, computed once for every passage and once for every question, such that the passage that answers a question lies closest to it.

ModernBERT, the encoder of Section 19.2, returns one vector of 768 numbers for every token. It was pretrained to fill in hidden tokens, and nothing in that objective asks for a vector of a whole text. The obvious way to get one anyway is to average the token vectors. Make a guess before reading on: if we average the vectors of every passage of the book and of a question about it, how often will the ten nearest passages include one that answers the question?

The answer will be discouraging, and the repair has a history. Reimers and Gurevych (2019) found that averaged BERT vectors judged the similarity of two sentences worse than averaged GloVe word vectors (Section 19.1), and that training the encoder on pairs of related sentences fixed this. Their successors settled on a contrastive loss: show the encoder a question, its answer and a batch of other passages, and ask it to pick out the answer. We

first find out why the averaged vectors fail, then work out what arrangement of vectors the contrastive loss asks for, and finally train an embedder on 20,000 pairs that have nothing to do with this book and set it against a released embedder trained on far more.

Besides the raw encoder, two models appear, each fixed to one revision: Qwen3-Embedding-0.6B, a released embedder, and Qwen3-Reranker-0.6B, which reads a question and a passage together. Training this section's models takes about 13 minutes on one RTX 4090; a normal build downloads the checkpoints and their training records instead. Without a GPU the notebook searches only the passages of the documents the questions ask about, an easier problem; the text quotes the GPU run. This cell and the two after it are setup and can be skimmed: names such as the Matryoshka prefixes and the audit buckets are explained where they are used.

19.3.1 Pooled Encoder States as Text Vectors

Before any training we need a rule that turns the token vectors of a text into one vector, and a way to measure how well such vectors retrieve.

19.3.1.1 Pooling and Normalization

Three ways of turning token vectors into one are common. *CLS pooling* takes the vector at the first position, where BERT-style tokenizers place a special token `[CLS]`; BERT trained that position with a sentence-pair task. *Mean pooling* averages the vectors of all real tokens. *Last-token pooling* takes the vector of the final token, the natural choice for a decoder, whose causal attention lets only the last position see the whole text. `pool_hidden` finds the real tokens through the attention mask, so it works whether a batch is padded on the right or on the left.

Every pooled vector is then scaled to unit length, so that the dot product of two vectors is the cosine of their angle. Without this, a passage whose vector happens to be long ranks high for every question. `embed_texts` encodes texts in batches of similar length and returns the vectors in input order. A text longer than `max_len` tokens is cut, and the function prints how many were cut: a passage whose answer lies past the cut can no longer be found, and nothing later would notice.

19.3.1.2 Raw Vectors on the Book

Our collection is this book itself, without the Language Models part, cut along its section boundaries into passages of at most 512 tokens of the Qwen3 tokenizer. Section 19.4 describes the cutting, and it builds the word-counting ranker, BM25, that serves us as a floor. The questions come from the book's question set, which is split by document into train, dev and test like any benchmark and also holds questions the book cannot answer. We use the answerable dev questions. Language models drafted and checked them; no person did (Section 19.5 says how), and each was drafted from one stretch of text, its *gold span*. A passage counts as *relevant* to a question if at least half of the gold span lies in it, or at least half of the passage lies in the gold span; another span judged to answer the question counts the same way. Questions about one document are not independent, so our intervals resample documents, as in Section 18.5.

Our main measure is *Recall@k*. A question scores 1 if at least one relevant passage is among the first k retrieved and 0 otherwise, so the average over questions is the share of questions whose answer reaches a reader of the top k. Two further measures look at the order.

MRR@10 scores a question by the reciprocal of the rank of its first relevant passage, and 0 if none is among the first ten. *nDCG@10* lets a relevant passage at rank r count $1/\log_2(r+1)$. It divides the sum over the first ten ranks by its value for the best possible order, so it is 1 when the relevant passages come first. Take a question whose only relevant passage is ranked third: it scores Recall@1 $= 0$, Recall@10 $= 1$, MRR@10 $= 1/3$ and nDCG@10 $= 1/\log_2 4 = 0.5$. Recall@10 asks whether the answer arrives at all, the other two whether it arrives early. That matters as soon as whoever reads the results stops after the first few.

The next cell loads the corpus and the questions and ranks the passages with BM25, which counts the question's words in each passage, weights rare words up and involves no training.

The book has 5,324 passages, and the 220 questions ask about 32 of its documents. BM25 finds a relevant passage among its first ten for 96% of the questions. That floor is high, and the reason lies in our questions more than in BM25. A language model drafted each question while reading the passage that answers it, and it borrowed the passage's rare words: `load_array`, "unified memory". BM25 rewards exactly such words. A user who has never seen the passage tends to ask in other words and would give BM25 less to hold on to. This sets the scale for the rest of the chapter: on these questions any method has little room above counting words, and a technique that gains nothing here may simply have had nowhere to go.

Now the raw encoder, with CLS and mean pooling. Each question is matched with the ten passages of highest cosine. For the first three questions we print the heading of the best passage and of the relevant one; the second is our `load_array` question.

So the answer to the opening guess is 6%: mean pooling puts a relevant passage among the first ten for 6% of the questions, against BM25's 96%. For scale, ten passages drawn at random would contain a relevant one for about $10 \times 1.35/5{,}324 \approx 0.25\%$ of the questions. The average is about 25 times better than chance and still of little use. Our `load_array` question lands on the book's page of utility functions, one heading above the passage on training utilities that answers it. The question on saturating attention lands on the introduction of the attention chapter, not on the subsection about score variance and the $1/\sqrt{d}$ factor. The question about unified-memory machines, which the chapter on tools answers, lands on the opening of a section on attention. All three top passages open a page or a section, and the three are not exceptions. BM25 sends the 220 questions to 210 different first passages; the averaged vectors send them to only 73, so a few broad passages collect the first rank of many questions that have little in common. At best the vectors know roughly where in the book a text lives; at worst, as for the unified-memory question, not even that. They know little about what it says. No passage reached the cap of 1,024 ModernBERT tokens at which we encode passages (the model accepts 8,192), so truncation is not the cause.

19.3.1.3 Anisotropy

A first clue is how similar the raw vectors are to each other. Call the mean cosine between the vectors of distinct texts the *anisotropy* of a set of vectors: near 0 when their directions show no preference, 1 when all point the same way. For unit vectors $\mathbf{z}_1, \dots, \mathbf{z}_n$, expand the squared length of their sum:

$$\Big\| \sum_{i=1}^{n} \mathbf{z}_i \Big\|^2 = \sum_{i=1}^{n} \|\mathbf{z}_i\|^2 + \sum_{i \neq j} \mathbf{z}_i^\top \mathbf{z}_j = n + n(n-1)\,\bar{c},$$

where $\bar{c}$ is the mean cosine over the $n(n-1)$ ordered pairs. Solving for $\bar{c}$, with $\bar{\mathbf{z}}$ the mean vector,

$$\bar{c} = \frac{n\|\bar{\mathbf{z}}\|^2 - 1}{n-1} \approx \|\bar{\mathbf{z}}\|^2. \tag{19.9}$$

Thus the mean cosine is the squared length of the mean vector, up to a term of order $1/n$. Vectors that point in many directions cancel in their mean; vectors that share a direction have a mean almost as long as each of them. If the vectors do share a direction, there is an obvious repair: subtract the mean passage vector from questions and passages alike before normalizing. The opening cell already computed this *centered* variant, so that we can measure it alongside the others. The next cell also defines `align_uniform`, for two quantities we meet in Section 19.3.2.1.

We measure anisotropy on 2,000 random passages for CLS pooling, mean pooling and centered mean pooling, and check Equation 19.9 in float64.

The table settles CLS pooling first: not one of the 220 questions finds a relevant passage, no better than chance. The masked-token loss scores only the positions it hid, and the corruption rule of Section 19.2 never hides a special token such as `[CLS]`. ModernBERT has no sentence-pair task either. Nothing in its pretraining ever asked the final vector at the first position to describe the text.

Mean pooling fails for a reason that is less obvious. Raw passage vectors share one direction: the mean cosine between two unrelated passages is 0.95 with CLS pooling and 0.94 with mean pooling (the formula reproduces it to six digits). The mean vector therefore has length about $\sqrt{0.94} \approx 0.97$, and every passage vector lies in a narrow cone around it. Ethayarajh (2019) found a similar cone in the token vectors of the upper layers of BERT and GPT-2, and B. Li et al. (2020) traced its shape to word frequency: in the raw space, how common the words of a text are moves its vector more than what the text means. A cone this narrow is a tempting explanation of the failure. Centering puts it to the test.

Centering removes the cone: anisotropy drops to 0.001, and Recall@10 stays at 0.05. So the shared direction is not what hurts retrieval, however striking it looks. What remains after centering is still an average of token states trained to predict hidden tokens, and the opening showed what such an average knows: roughly where in the book a text lives. Nothing in pretraining asked a question to lie near the passage that answers it. That relation has to be taught, with pairs of texts that belong together. The shared direction will return, as something the training has to shrink.

19.3.2 Contrastive Training

Suppose we have pairs of texts that belong together, a question and the passage that answers it. A question's vector should then be closer to its own passage than to any other. Take a batch of B pairs, encode the questions as unit vectors $\mathbf{q}_1, \dots, \mathbf{q}_B$ and the passages as unit vectors $\mathbf{d}_1, \dots, \mathbf{d}_B$, with $\mathbf{d}_i$ the passage of question i, and score every question against every passage by the cosine $c_{ij} = \mathbf{q}_i^\top \mathbf{d}_j$. A softmax over the B passages is asked to point at the right one:

$$\ell = -\frac{1}{B}\sum_{i=1}^{B} \log \frac{\exp(c_{ii}/\tau)}{\sum_{j=1}^{B} \exp(c_{ij}/\tau)}. \tag{19.10}$$

There is nothing new in this loss: it is a cross-entropy whose classes are the passages of the batch. The other $B-1$ passages are the *negatives* of question i, and they cost nothing: their vectors were computed anyway, for their own questions. The *temperature* τ divides the cosines; at $\tau = 0.05$ a cosine difference of 0.1 becomes a logit difference of 2.

The loss is InfoNCE (Oord et al. 2018). The mathematics appendix proves that it bounds the mutual information I between question and passage from below, $I \geq \log B - \ell$, a bound that never exceeds $\log B$ (Section 37.7.4). With 64 candidates the loss can certify at most $\log 64 \approx 4.16$ nats, however good the model; a larger batch raises the ceiling.

Which negatives does the loss work on? Write p_{ij} for the softmax weight of passage j for question i, and δ_{ij} for 1 if $i = j$ and 0 otherwise. Differentiating Equation 19.10 with respect to one cosine gives

$$\frac{\partial \ell}{\partial c_{ij}} = \frac{p_{ij} - \delta_{ij}}{\tau B}, \qquad p_{ij} = \frac{\exp(c_{ij}/\tau)}{\sum_{k=1}^{B} \exp(c_{ik}/\tau)}, \tag{19.11}$$

the softmax-minus-target of every cross-entropy, scaled by $1/(\tau B)$. A step raises c_{ii} with weight $1 - p_{ii}$ and lowers each c_{ij} with weight p_{ij}; the weights of a row sum to one, so the push on the negatives adds up to the pull on the positive. The push is far from even: two negatives whose cosines differ by Δ receive weights in the ratio $e^{\Delta/\tau}$. The cell checks the gradient against automatic differentiation and prints that ratio.

Automatic differentiation agrees with the formula to 10^{-16}. At $\tau = 0.05$, a negative 0.1 closer to the question than another receives 7.4 times its push, and one 0.3 closer receives 403 times. A low temperature puts nearly all of its gradient on the few negatives that look most like the answer, the *hard negatives*. That helps when they are true negatives and hurts when they are not. The same weights say when a batch stops teaching: once the right passage takes almost all of the softmax, $1 - p_{ii}$ and every p_{ij} are near zero, and random negatives contribute almost nothing.

19.3.2.1 Alignment and Uniformity

What arrangement of vectors does the loss want? The gradient answers this for one batch at a time, which is too local to picture. Wang and Isola (2020) answered it for the whole data by letting the batch grow. This is the hardest step of the section, and everything we later measure about the geometry of trained embedders refers back to it. Subtract $\log B$ from the loss of one question and move the B inside the logarithm:

$$\ell_i - \log B = -\frac{c_{ii}}{\tau} + \log \frac{1}{B} \sum_{j=1}^{B} e^{c_{ij}/\tau}.$$

As B grows, with the passages drawn from the data, the average tends to $\mathbb{E}_{\mathbf{d}}\, e^{\mathbf{q}_i^\top \mathbf{d}/\tau}$; the positive is one term of B, and its share vanishes. For unit vectors, $\mathbf{q}^\top \mathbf{d} = 1 - \frac{1}{2}\|\mathbf{q} - \mathbf{d}\|^2$. Substituting this in both terms, the constants $-1/\tau$ and $+1/\tau$ cancel, and averaging over questions gives

$$\lim_{B \to \infty} \left(\ell - \log B\right) = \frac{1}{2\tau}\, \mathbb{E}\left[\|\mathbf{q} - \mathbf{d}^+\|^2\right] + \mathbb{E}_{\mathbf{q}}\Big[\log \mathbb{E}_{\mathbf{d}}\, e^{-\|\mathbf{q}-\mathbf{d}\|^2/(2\tau)}\Big], \tag{19.12}$$

where $\mathbf{d}^+$ is the passage of question $\mathbf{q}$. The first term, the *alignment*, is the mean squared distance within positive pairs. The second, the *uniformity*, is the logarithm of a Gaussian kernel averaged over all passages, small when the passages keep their distance from every question. In the large-batch limit the loss has only these two terms: one pulls pairs together, the other pushes all vectors apart.

The loss's uniformity term compares questions with passages. To compare embedders by their passages alone, Wang and Isola measure the same kernel on two independent passages $\mathbf{z}$ and $\mathbf{z}'$,

$$\mathcal{U}_t = \log \mathbb{E}\, e^{-t\|\mathbf{z}-\mathbf{z}'\|^2},$$

which also falls as the vectors spread out. The loss's own kernel has $t = 1/(2\tau) = 10$; we use their $t = 2$, so that our numbers compare with theirs. `align_uniform` computes the alignment and $\mathcal{U}_2$, over distinct pairs of passages.

Let us start with the smallest case that shows the tension between the two terms. Place four unit vectors on a circle, points 1 and 2 forming one positive pair and points 3 and 4 the other. Each point acts as a question whose passage is its partner, so the batch has four rows, and each question also meets itself among the passages, as the passage of its partner. A square, with the points at 0°, 90°, 180° and 270°, spreads them as far as possible but puts each point a quarter turn from its partner. Collapsing all four onto one point aligns them perfectly. A third configuration puts each pair on one spot and the two spots on opposite sides. Which does InfoNCE prefer? The four points are the whole data, so this batch computes the right side of Equation 19.12 with no approximation.

The square has the best uniformity, $\mathcal{U}_2 = -4.4$, and the worst alignment, 2.0, and InfoNCE punishes it hard. Each question finds itself among the negatives at cosine 1 and its partner at cosine 0. At $\tau = 0.05$ that is a logit gap of 20, and a loss 18.6 nats above $\log 4$. The collapse gives perfect alignment and the loss of a blind guess, $\log 4$. Two coincident pairs on opposite sides win at both temperatures. Each question then finds two passages at its own spot, its partner and itself, so the softmax can at best split evenly between them: a loss of about $\log 2$, which is $\log 2$ below $\log 4$. The temperature sets how many nats a bad arrangement costs: at $\tau = 0.5$ the square costs 0.87 nats instead of 18.6.

The collapse is the extreme of anisotropy, and the loss rejects it. More generally, a shared direction caps how far uniformity can fall, and the proof takes one line.

Proposition. *For unit vectors drawn from one distribution, with anisotropy a (the mean cosine between two independent draws), the uniformity $\mathcal{U}_t$ is at least $-2t(1-a)$ for every $t > 0$.*

Proof. The logarithm is concave, so $\log \mathbb{E}\, e^X \geq \mathbb{E}\, X$ by Jensen's inequality. Take $X = -t\|\mathbf{z}-\mathbf{z}'\|^2 = -t(2-2\mathbf{z}^\top\mathbf{z}')$, whose expectation is $-2t(1-a)$. ■

The uniformity $\mathcal{U}_t$ is never above 0, its worst value, and while a is near 1 it cannot go far below 0 either. The same argument applies to the term of Equation 19.12, with the mean cosine between questions and passages in place of a. Training that lowers the term must lower that mean cosine, and since alignment holds each question near its passage, this means shortening the mean vector: contrastive training reduces anisotropy because it cannot do its job otherwise. The converse fails, as centering showed; that is what the alignment term is for.

19.3.2.2 Training on Question-Answer Pairs

The book's questions are what we test on, so we train on pairs from elsewhere and measure transfer. `train_embedder` minimizes Equation 19.10 over batches of question-passage pairs with mean-pooled vectors. Questions get the prefix `query:` and passages `passage:`, the convention of the E5 embedders (Wang et al. 2022), which lets one encoder treat the two sides differently. AdamW with warmup and linear decay, clipping at norm 1 and bf16 complete the recipe. None of this is particular to embedders, and the details can be read off the code.

Duplicates are the exception, and they need care. If two pairs in a batch share a passage, that passage is the positive of one question and a negative of the other, and the loss pushes the second question away from its own answer. Such a passage is a *false negative*. `no_duplicate_batches` prevents them within the training pairs: a pair that would repeat a question or a passage already in the batch waits for a later batch.

The pairs come from Natural Questions (Kwiatkowski et al. 2019): questions that people typed into a search engine, each with a Wikipedia passage that answers it. We train on 20,000 pairs chosen by one seeded permutation. To choose the learning rate we hold out 300 later pairs whose question and passage occur nowhere in training, so that the rate that best memorizes training passages gains nothing. For each held-out question we rank 5,000 unseen passages and score MRR@10, which here is the reciprocal of the rank of the question's own passage.

Of the 20,000 training pairs, 3,236 share their passage with another pair, the duplicates the sampler keeps apart. The next cell holds helpers for encoding, ranking, scoring, mining and checkpoints.

The training run first tries three learning rates, all with seed 3, which no reported model uses, so that the reported models are not winners of a selection, and scores them on the held-out pairs. It then trains the chosen rate with seeds 0, 1 and 2, which shows how much Recall@10 moves from training noise alone, and saves the seed-0 model.

19.3.2.3 Hard Negatives and False Negatives

A random passage from Wikipedia is rarely about the subject of a given question, and by Equation 19.11 such easy negatives receive almost no gradient. The hard negatives, passages that the current model ranks high for a question although they are not its passage, are the ones the gradient works on. Why not supply them on purpose? Finding them by searching with the model itself is called *mining*. We mine with the seed-0 model: for each training question it ranks the distinct training passages, its own left out, and one hard negative is drawn uniformly from ranks 11 to 50.

Why not from the top? A passage ranked first is often a correct answer that happens not to be the labeled one, and training against it pushes the question away from an answer. We measure how often. For 500 training questions we take one mined passage from each of four rank buckets and ask Qwen3-Reranker-0.6B whether the passage answers the question. The reranker is a cross-encoder in the sense of Section 19.2: it reads question and passage together and answers yes or no. A probability of yes above 0.5 marks a passage as probably relevant. These labels come from a model, not from people.

Two variants follow at the chosen rate, seed 0. One adds the mined negative as one more candidate per question, so that every question sees 128 passages. The other, the *Matryoshka* model, trains for vectors that can be shortened, with a loss defined in Section 19.3.4, and is saved.

The next cell reads what the training run recorded: first the learning-rate check and a summary of each run, then the audit, with intervals over the held-out and the audited questions.

The learning rate 10^{-4}, the largest we tried, won with MRR@10 of 0.87 on the held-out pairs. 3×10^{-5} came within noise of it and 10^{-5} did not, so the optimum is flat at the top of the grid. One epoch, 313 steps, takes about a minute on one RTX 4090. The loss falls from about 3.2 nats over the first ten steps to 0.05 over the last ten. Is the model memorizing? Memorization cannot explain it: each pair is seen once, and the held-out pairs, whose texts never occur in training, score 0.87. The model simply picks the right passage among 64 almost every time, so by the gradient weights above, random negatives had little left to teach by the end of the epoch.

The audit shows why the top ranks are left alone. Among mined passages at ranks 1 to 5, the reranker calls 30% probably relevant: by its judgment nearly a third of the "negatives" there are answers. The share falls with every bucket, to 10%, 2% and under 1%, so mining from ranks 11 to 50 keeps false negatives, by the reranker's labels, to one or two percent.

So far no model has seen a question about the book. Whether the trained encoder retrieves anything there, and whether the mined negative helps, is the subject of the next part, where both meet the book's questions beside a released embedder.

19.3.3 Trained and Released Embedders on the Book

Our encoder has seen 20,000 pairs about Wikipedia, once. Before it meets the book's questions, let us look at the competition it will face there.

19.3.3.1 Released Embedders

Released embedders are trained on far more, in stages. E5 (Wang et al. 2022) first trains on weak pairs gathered from the web, such as titles with their articles, then on smaller labeled sets with mined hard negatives. Qwen3-Embedding (Zhang et al. 2025) had a larger Qwen3 model write its weak pairs, then trained on labeled and filtered synthetic pairs with hard negatives, and finally merged several of its checkpoints. RocketQA (Qu et al. 2021) introduced the step our audit imitates: a cross-encoder filters the mined negatives, so that false negatives are dropped rather than pushed away.

Qwen3-Embedding-0.6B starts from a pretrained decoder of the Qwen3 family and keeps its causal attention. Three conventions follow, and a model used against any of them loads and runs without complaint. The wrong pooling or padding reads the state of the wrong token. The wording of the instruction changes what the query vector encodes, in a direction that has to be measured.

- **Last-token pooling.** Under causal attention only the last position has seen the whole text.
- **Left padding.** Short texts are padded on the left, so the last position of every row holds a real token.
- **An instruction on the query side.** A question enters as `Instruct: {task}\nQuery:{query}`. Passages are encoded without it, so one passage index serves many tasks. The task is free text. The model card's default, `Given a web search query, retrieve relevant passages that answer the query`, is the one this chapter uses. The wording we first wrote for the book, `Given a question about the book, retrieve passages that answer it`, is measured against it below.

Last-token pooling is not the only way out of causal attention. Some recipes remove the causal mask instead and fine-tune the decoder with attention in both directions, so that every position sees the whole text (BehnamGhader et al. 2024; Lee et al. 2025); Section 19.7 says what each recipe changes.

19.3.3.2 Comparison on the Book

Now all models answer the same 220 questions. How far do 20,000 pairs about Wikipedia carry toward a book about deep learning? The cell also checks that the two saved checkpoints reproduce the rankings recorded at training time.

Most of the way. Contrastive training turns the encoder into a retriever: Recall@10 rises from 0.06 to 0.76 for seed 0, the three seeds span 0.73 to 0.78, and anisotropy falls from 0.94 to 0.52, as the proposition says it must. The first ranks spread out as well: the 220 questions now land on 188 different first passages, against 73 before training. The model still trails BM25, and by more in the order of its results than in what it finds: its nDCG@10 is about 0.52, BM25's 0.82, with intervals far apart. The saved checkpoints reproduce the recorded Recall@10 for at least 99.5% of the questions, although bf16 rounding lets near-tied passages swap places.

Qwen3-Embedding finds a relevant passage among its first ten for 98% of the questions or more, in each of the three ways we pose the query. At the first rank it is no better than BM25: Recall@1 is 0.76 for BM25, against about 0.70 for Qwen3-Embedding without an instruction or with the model card's task, and 0.67 with ours.

The next cell computes paired differences on the same questions, with intervals that resample documents, and marks whether each exceeds the range of the three seeds. A second table compares Qwen3-Embedding with BM25, and the three forms of the query with each other, on one measure of finding and two of order.

Contrastive training on 20,000 pairs that never mention the book lifts Recall@10 by 70 points over raw mean pooling, more than fifteen times the seed range of 4.5 points. This is the result of the section. Nothing in a pretrained encoder says which passage a question should be near, and a minute of contrastive training on someone else's questions puts it there.

The released embedder adds about 20 points more, and that gap bundles several causes. Qwen3-Embedding has a larger backbone, pretrained on far more text. It saw far more training pairs, many of them written by a language model. And it may have read this book, which has been on the web for years. The run cannot separate these causes, and the last one makes the 0.99 optimistic by an amount we cannot measure. ModernBERT's pretraining text (Warner et al. 2024) may have included the book too, but the raw encoder's 0.06 shows that such exposure alone retrieves nothing; the 0.76 measures what generic pairs transfer.

The mined hard negative raised every measure in its one run: Recall@10 by about 3 points, with an interval that reaches zero, and the other measures by 3 to 5. That is the direction the gradient weights predict, but one run against a seed spread of 4.5 points does not establish it. The comparison has a second weakness. The variant gives each question 128 candidates instead of 64, so even a clear gain could come from more negatives rather than harder ones. Settling the question takes several seeds of the variant and a control with one random extra negative per question; we have not run them.

Finally, the instruction we first wrote for the book made Qwen3-Embedding worse. Every measure of order came out lower with it: MRR@10 by about 0.03, with an interval that excludes zero, Recall@1 by 3 points and nDCG@10 by 2. Recall@10 moved by -0.014, an in-

terval that reaches zero. This runs against the model card, which reports gains of 1% to 5% from instructions and recommends writing one for the task at hand. When a measurement contradicts a technique this well established, the first suspect is our own setup.

Is the fault in instructions as such, or in ours? The format is the card's, as the library check below confirms, and the last two rows of the second table answer the question. The card's own task, a sentence about web search queries in the same format, is level with no instruction on all three measures, every interval containing zero, and ahead of our wording by 0.033 in MRR@10, an interval from 0.012 to 0.053. The fault lies in our wording. A sentence that describes the task well to a human reader pushed relevant passages down the model's ranking, and only a measurement against no instruction showed it. The card's task brings no gain here either; on questions that copy their passages' rare words there may be little left for an instruction to add.

The rest of the chapter therefore uses the card's task, which the library stores as `d2l.BOOK_TASK`. We take it because it is the card's default, not because it came out ahead here: a wording picked on these questions would carry their noise into every later measurement on them. A wording of one's own is a parameter like any other, and it has to be chosen on questions other than those it is evaluated on; Exercise 5 does this with the training questions.

The second table also settles the comparison with BM25. Without an instruction, Qwen3-Embedding finds a relevant passage within ten for about 4 points more of the questions than BM25, an interval from 1 to 6 points, and the two cannot be told apart at the first rank or by MRR@10. With the card's task the picture is the same: about 3 points more within ten, an interval from 0.5 to 6 points, and no difference at the first rank that the intervals resolve. With our first wording, BM25 put a relevant passage first more often: by 9 points of Recall@1 and by 0.065 in MRR@10, both intervals excluding zero. On questions that repeat the rare words of their passages, counting those words remains a strong way to pick the top passage.

19.3.3.3 Geometry after Training

Does training change the geometry as Equation 19.12 predicts? We measure alignment on all pairs of a dev question and one of its relevant passages, and $\mathcal{U}_2$ on the 2,000 sampled passages. The plot projects the passage vectors onto the two directions along which they extend furthest, found by an SVD without subtracting the mean, so that a shared direction stays visible as a long mean vector (the star).

Training moved pairs apart: the alignment, the mean squared distance within pairs, grows from 0.19 for raw mean pooling to 0.60. That seems to contradict the pull of the alignment term, until we compare it with how far apart passages lie in general. For unit vectors $\|\mathbf{z} - \mathbf{z}'\|^2 = 2 - 2\,\mathbf{z}^\top \mathbf{z}'$, so two random passages lie at mean squared distance $2 - 2a$, with a the anisotropy. The table sets the two distances side by side (Table 19.3).

Table 19.3: Mean squared distance between a question and its relevant passage (the alignment) and between two random passages ($2 - 2a$), and their ratio.

model	question to its passage	two random passages	ratio
raw mean pooling	0.19	$2 - 2 \times 0.940 = 0.12$	0.6
contrastive, seed 0	0.60	$2 - 2 \times 0.522 \approx 0.96$	1.6
Qwen3-Embedding, card's task	0.61	$2 - 2 \times 0.283 \approx 1.43$	2.4

Before training, a question lies farther from its own passage than two random passages lie from each other. Training moved everything apart, and unrelated passages much more than pairs: after training, two random passages lie 1.6 times as far apart as a question and its passage, and 2.4 times for Qwen3-Embedding. Retrieval depends on this ratio. The values of $\mathcal{U}_2$, -0.23, -1.82 and -2.78, lie just above the bounds $-4(1-a)$ of the proposition, -0.24, -1.91 and -2.87: in all three spaces the shared direction limits the spread. In the plot the raw vectors form a thin arc around a mean vector of length 0.97, the trained ones a much wider cap around a mean of length about $\sqrt{0.52} \approx 0.72$. Training has shortened the mean vector without removing it.

19.3.4 Smaller Vectors

So far each passage vector of Qwen3-Embedding has been 1,024 numbers. In float32 that is 4 KB per passage (our stored copy uses float16, half that), and for the book about 22 MB, which no machine notices. An index of 10^8 web passages would need about 400 GB, and an exact search reads all of it for every question. How much of the 0.99 survives with fewer bytes? We can keep fewer coordinates, or fewer bits per coordinate.

19.3.4.1 Truncation and Quantization

Truncation keeps the first k coordinates and rescales them to unit length. In a model trained with the plain loss the first coordinates are no more important than the others. *Matryoshka representation learning* (Kusupati et al. 2022) makes them so by averaging the loss over prefixes,

$$\ell_{\text{MRL}} = \frac{1}{|\mathcal{K}|} \sum_{k \in \mathcal{K}} \ell^{(k)},$$

with $\ell^{(k)}$ the loss Equation 19.10 on the first k coordinates, renormalized, and $\mathcal{K}$ a set of widths. Each prefix must then be an embedding on its own, as each doll of a Russian nesting set is a complete doll. Our Matryoshka model was trained with $\mathcal{K} = \{768, 512, 256, 128, 64\}$. Qwen3-Embedding supports such prefixes: its model card allows any width from 32 to 1,024 coordinates.

Quantization keeps all coordinates at lower precision. The simplest form, int8, stores each coordinate in one byte, with one scale per coordinate taken from the largest value in the corpus, a quarter of the float32 bytes.

Binary vectors go further and keep only the sign of each coordinate, one bit. Two of them are compared by their *Hamming distance*, the number of differing bits: one XOR and one population count per machine word. Why should signs preserve similarity? For a random direction $\mathbf{r}$, the signs of $\mathbf{r}^\top \mathbf{a}$ and $\mathbf{r}^\top \mathbf{b}$ differ with probability θ/π, where θ is the angle between $\mathbf{a}$ and $\mathbf{b}$ (Charikar 2002). An embedder's coordinates are not random directions, so the formula is not exact, but the sign agreement still falls as the angle grows.

Hamming distance discards magnitude: a coordinate where the query is nearly 0 counts as much as its largest one. *Rescoring* repairs this on the query side. It takes the top 100 passages by Hamming distance and reorders them by the dot product of the float query with the passages' signs, so the passages stay at one bit per coordinate.

The cell measures Recall@10 against bytes per vector for the plain contrastive model, the Matryoshka model and Qwen3-Embedding. Binary scores tie often; ties are put in seeded random order rather than in corpus order, which would favor passages early in the book.

For Qwen3-Embedding, int8 costs nothing we can see: Recall@10 stays at 0.99 at a quarter of the bytes. Binary vectors keep 0.96, and 0.98 with rescoring, at 1/32 of the bytes. Truncation costs more: 0.92 at 128 of 1,024 coordinates, 0.88 at 64, and below that recall collapses, to 0.68 at 32 coordinates, the smallest width the model card allows, and 0.36 at 16, below it. Compare two formats of the same size. The signs of all 1,024 coordinates fill 128 bytes, and so do 32 coordinates in float32; the first keeps 0.96, the second 0.68. At equal bytes, many coarse coordinates rank far better than a few precise ones. That is the fact to remember from this subsection; the formats themselves are details to look up when needed.

Our two models lose more to truncation. From full width to 128 coordinates the plain model falls from 0.76 to 0.69 and the Matryoshka model from 0.74 to 0.66; at 32 coordinates both are near 0.4, at 16 near 0.15. Which of the differences between the two are real? Both are single seeds, so a difference is read against the seed range of the full-width models as well as against its interval.

Binary vectors with rescoring cost Qwen3-Embedding and the Matryoshka model 1 to 2 points, with intervals that reach zero, and the plain model about 4 points, an interval that excludes zero. These are two formats of one set of trained weights on the same questions, so training noise plays no part, and the paired interval alone decides. The seed range matters only when two separately trained models are compared, as next. Even at 128 bytes per passage, Qwen3-Embedding stays far ahead of our model at full precision.

The Matryoshka model, however, is not ahead at any width. The differences run from -0.03 at 128 coordinates to $+0.02$ at 16, every interval contains zero, and every difference lies within the seed range. This should make us suspicious. Kusupati et al. (2022) found the advantage to grow as the prefix shrinks, and when an accepted method fails to show its effect, the code is the first suspect. The test is to ask both models the kind of question they were trained on: the 300 held-out pairs of Natural Questions, each question searched among the 5,000 passages that no training batch contained, at the same widths.

There the loss does what its paper reports. Down to 64 coordinates the two models are level. At 32 coordinates the Matryoshka model keeps a Recall@10 of 0.83 against 0.76, and at 16 it keeps 0.62 against 0.51: gains of about 8 and 11 points, with intervals that exclude zero, below even the shortest prefix it was trained on. The code is not at fault. On the book the same comparison gave -0.01 and $+0.02$, with intervals that exclude gains of that size. The loss works on the distribution it was trained on, and on this book its advantage did not carry over.

Why not? The two settings differ in several ways, and the easiest to test is length. Training cut every Natural Questions passage to 160 tokens, while the book's passages, cut at 512 tokens of the Qwen3 tokenizer, are encoded whole. Perhaps a short prefix never learned to summarize a long text. The next cell cuts the book's passages to their first 160 tokens and compares the two checkpoints again.

The cut reaches 4,824 of the 5,324 passages and costs both models recall at full width, since some answers lie past the first 160 tokens. The gap we were looking for does not appear. At 32 and 16 coordinates the Matryoshka model is ahead by about 2 points, with intervals that contain zero and stop short of the 8 and 11 points it gained on Natural Questions. Length is ruled out. What remains is the material itself: questions about deep learning that share rare

words with their passages, against the general-knowledge questions of Natural Questions. Which part of that difference matters we do not know; Exercise 7 proposes the next test.

In practice, then: down to 64 of its 768 coordinates, a plain contrastive model truncates as well as a Matryoshka one in both settings. Below that, Matryoshka training is what keeps recall on data like its training data, and whether it helps on other data has to be measured on one's own questions.

19.3.5 Using a Released Embedder

19.3.5.1 A Library Check

In practice a released embedder is loaded through a library such as sentence-transformers, which reads its pooling, normalization and prompts from files in its repository; the padding side we pass ourselves, as the model card asks. Does it do what we derived? The cell checks the repository's query prompt and pooling, encodes 16 passages and 4 questions both ways, and compares the library's contrastive loss, `MultipleNegativesRankingLoss` at scale $1/\tau$, with `info_nce_loss`.

The two encodings agree to a cosine of at least 0.998, the difference bf16 arithmetic leaves, and the library's loss equals Equation 19.10 to 7×10^{-6}. The library reads the conventions from the repository, and the method underneath is the one derived above. What the library cannot check is whether the task written into the instruction suits the model; that, as we saw, has to be measured.

19.3.5.2 Choosing an Embedder

Released embedders are ranked on MTEB, the Massive Text Embedding Benchmark (Muennighoff, Tazi, et al. 2023), which averages scores over many tasks and languages. An average over tasks says little about one domain: a model can rise by clustering news well, and the training data of some models overlaps the benchmark's. The reliable way to choose is the one this section followed: a few hundred questions about your own documents, a word-counting floor, and paired differences with intervals that resample documents. If you can, have the questions written by people who have not just read the answer; otherwise, as here, the floor comes out high. On the book this procedure does not crown a single winner. The released embedder finds slightly more answers, and BM25 puts the answer first at least as often. The case for the embedder rests on questions phrased in other words than their passages, which this set hardly contains. So we keep both: a released embedder, in int8 or as binary vectors with rescoring when memory is short, with BM25 beside it. Training on pairs from the domain is the next step only when such a set shows a gap, and then the training questions must come from other documents than the evaluation questions.

Contrastive training makes vectors that a scan can compare. It does not make the scan cheap, and a question that turns on an exact identifier can still be missed by every vector of this section. Section 19.4 builds the index that serves these vectors and the word index that catches what they miss.

19.3.6 Summary

Search needs one vector per text, and averaging the token vectors of a pretrained encoder does not supply a useful one. On the book's questions the average found a relevant passage

among the first ten for 6% of them, where counting words found one for 96%. The averaged vectors share one direction, but removing it does not help, because pretraining never asked a question to lie near its answer. Contrastive training asks exactly that, by making each question pick its passage out of a batch; in the large-batch limit the loss pulls pairs together and pushes all vectors apart, which forces the shared direction to shrink. A minute of such training on generic pairs lifted Recall@10 by 70 points, and a released embedder went further and kept nearly all of its recall at one bit per coordinate. Mined negatives must come from below the top ranks, where a reranker judged nearly a third of them to be answers. Every other choice, from the wording of an instruction to the width of a vector, had to be measured on our own questions. The instruction we first wrote lowered the first ranks, while the model card's own wording cost nothing and is the one the chapter uses. Matryoshka training kept its advantage on its own data but not on the book.

19.3.7 Exercises

1. **The certified information.** A model trained with batches of 256 pairs reports an InfoNCE loss of 0.1 nats.
   1. How much mutual information between question and passage does this loss certify, and what is the most any loss could certify at this batch size?
   2. Our training ended at about 0.05 nats with batches of 64. What do the two certificates say about which model is better, and why can a loss near 0 not rank models trained with different batch sizes?
2. **Uniformity from the denominator.** Derive Equation 19.12 with care.
   1. For a finite batch whose negatives are drawn independently from the passages, show that the expectation over batches of $\log \frac{1}{B-1} \sum_{j \neq i} e^{c_{ij}/\tau}$ is at most $\log \mathbb{E}_{\mathbf{d}}\, e^{\mathbf{q}_i^\top \mathbf{d}/\tau}$. Which way does the positive's own term push the finite-batch value? Does a small batch overstate or understate the uniformity term?
   2. Show that the uniformity of Equation 19.12, with the logarithm inside the expectation over questions, is at most the version with the logarithm outside, at the same kernel width, when both expectations run over independent draws (a point may be drawn twice).
   3. Evaluate both versions at $t = 1/(2\tau)$ for the three four-point configurations of Section 19.3.2.1, and check the two InfoNCE columns of the table. Explain why `align_uniform`, which averages over distinct pairs only, gives a value no higher than either for these configurations, in which every point sees the same distances. Construct a set of points for which it is higher than the version with the logarithm inside.
3. code **Temperature.** ● Train the contrastive model at $\tau \in \{0.02, 0.05, 0.1, 0.2\}$ with $B = 64$ and the chosen learning rate, with seeds 0, 1 and 2 each, and report Recall@10 on the dev questions with paired, document-clustered intervals against $\tau = 0.05$.
   1. Describe the shape of Recall@10 against τ, and explain it with the weight ratio $e^{\Delta/\tau}$ of the negatives (Equation 19.11). What does a very low temperature do to the gradient of a false negative?
   2. Which differences exceed the seed range?
4. code **Last-token pooling and padding.** Encode three questions of different lengths with Qwen3-Embedding, padded on the right.
   1. Take the hidden state at the last position of each row, as code that ignores the mask would, and show that for the two shorter questions it is the state of a padding token. Compare with `d2l.pool_hidden(..., 'last')`.

   2. Encode all dev questions this way and report the change in Recall@10 against the correct pooling, with its interval.
   3. Qwen3's padding token is the same `<|endoftext|>` that the tokenizer appends to every text. Why does the state at a padding position still differ from the state at the real end of the text, and why might the damage be smaller than you expected?
5. code **Choosing an instruction.** ● The instruction we first wrote lowered Qwen3-Embedding's order measures on the dev questions, and the model card's default task left them level with no instruction.
   1. Take 200 answerable questions from `d2l.book_qa('train')` and search the whole book for each. Compare MRR@10 without an instruction, with our first task (`OUR_TASK` of the setup cell), with the model card's default task (`CARD_TASK`, the chapter's `d2l.BOOK_TASK`) and with two wordings of your own, using paired, document-clustered intervals.
   2. Choose the best wording on these training questions alone, then evaluate it once on the dev questions. Does its advantage survive? Why would a wording chosen on the dev questions overstate it?
6. **The symmetric loss.** The symmetric variant of Equation 19.10 averages the loss of questions choosing among passages and of passages choosing among questions.
   1. Derive $\partial \ell / \partial c_{ij}$ for the symmetric loss.
   2. Let passage j answer question i as well as $\mathbf{d}_i$ does, so that $c_{ij} = c_{ii}$. With what weight is c_{ij} pushed down, in each direction, and how does that weight change as τ falls?
7. code **Why Matryoshka training did not carry over.** On held-out Natural Questions pairs the Matryoshka model kept about 8 and 11 points more Recall@10 than the truncated plain model at 32 and 16 coordinates; on the book it kept none, even with the book's passages cut to the 160 tokens of training.
   1. The questions differ: the book's share rare words with their passages. Propose a measurement on the stored checkpoints that tests whether this explains the missing gain, and run it. The rewritten questions of Exercise 9 are one starting point.
   2. Cutting the passages to 160 tokens cost both models recall at full width. Find the dev questions that lose their relevant passage to the cut, and check whether the gold span of each lies past the first 160 tokens of that passage.
   3. Add 32 and 16 to the training prefixes $\mathcal{K}$ and train again. What changes on Natural Questions at those widths, and on the book?
8. [extended] **Adapting to the book.** ●● Fine-tune the seed-0 contrastive model on pairs of a question from `d2l.book_qa('train')` and one of its relevant passages, with hard negatives mined only from passages of `train` documents.
   1. Report the gain in Recall@10 on the dev questions with a paired, document-clustered interval, against the seed range of three fine-tuning runs.
   2. Explain what would leak into the dev score if the negatives were mined from all passages of the book, and measure whether it does.
   3. Does the adapted model close the gap to Qwen3-Embedding?
9. code **Questions in other words.** Our questions borrow the rare words of their passages. Rewrite 40 dev questions so that they ask the same thing in other words, replacing every identifier and technical term that also occurs in the relevant passage by a description, by hand or with the local generator of Section 19.5.
   1. Compare BM25 and Qwen3-Embedding on the original and the rewritten questions by Recall@10 and Recall@1, with paired, document-clustered intervals. How much of BM25's 0.96 survives, and does its standing at the first rank?

2. Which kinds of question lose most, and which method suffers more?

10. code **Checking the reranker's labels.** The audit's labels come from Qwen3-Reranker-0.6B, not from people. Mine again with the stored seed-0 checkpoint, draw 30 training questions, and take one passage from ranks 1 to 5 for each.
    1. Label each passage by hand, relevant or not, before looking at the reranker's probability of yes. Report your agreement with its label (probability above 0.5), with an interval.
    2. Which kinds of passage does the reranker call answers that you would not, or the reverse? How would your labels change the choice of ranks 11 to 50?

19.4 Sparse, Dense and Approximate Retrieval

At the end of Section 19.3 we had an embedder that puts a passage answering almost any question about this book among the ten nearest. We found those passages in the simplest way there is, by comparing the question's vector with every passage's vector: for one book, a single matrix product. Two doubts remain. Would the same product serve a library, where every question reads every stored vector? And what about a question that names a function, such as `load_array`? A vector records what a passage is about, and it may prefer one that merely discusses the subject.

Search engines met both problems long before neural networks. For exact words they built the word index, which lists for every word the passages that contain it, and ranked those passages by BM25, a rule from the mid-1990s that is still the default of the Lucene search library. For size they gave up exactness: an *approximate nearest-neighbor* index looks at a small fraction of the vectors and accepts that it sometimes misses the nearest one. We have met BM25 already, as the floor of Section 19.3 that found 96% of the questions; this section opens it up.

Both old answers still hold. A word index and a vector index fail on different questions, so a good retriever keeps both, merges their rankings and lets a slower model reorder the top few. For a large collection, an approximate index gives up a little recall for a great deal of speed and memory. We build each piece and end with the retriever that the rest of this part calls.

Four setup cells come first, and a first reading can skip them. They pin the chapter's embedder, Qwen3-Embedding-0.6B, and Qwen3-Reranker-0.6B, which reads a question and a passage together. Results that take minutes to compute are stored with their settings; setting `D2L_RERUN` regenerates them.

Before building anything, we run BM25 alone and the embedder alone on the 220 answerable dev questions of the book's question set, and ask whether a passage that answers the question is among the first ten. `d2l.BookRetriever`, the retriever this section ends with, is already in the library and supplies both; `d2l.book_qa` loads the questions and `d2l.gold_chunk_ids` marks the chunks that answer each (Section 19.5 shows both). Counted over all questions, the two retrievers come out close. Do they succeed on the same questions?

They do not. The embedder succeeds on 0.99 of the questions and BM25 on 0.96, a gap of about 3 points, yet on 11 of the 220, 5%, exactly one of the two succeeds: BM25 alone on 2, the embedder alone on 9. The cell prints the first question of each kind.

The first is the case that worried us above: a question that names a function. It asks what the attention chapter's `softmax_weights` returns after multiplying the scores by `scale`, and BM25,

which matches the rare name, ranks the passage that holds the function first. The embedder reads the question as being about attention scores and their scale, which it is, and fills its first ten places with passages on that subject, two of them from the very subsection that holds the function; the chunk with the code itself is not among them. The second question asks how accuracy is "computed" where its passage says "calculated based on correctness ... for all the pixels", a paraphrase that the embedder sees through, ranking the passage first, and a word count does not. One retriever matches words and the other matches topics, and each is fooled where the other is not.

19.4.1 The Book as a Corpus

Every retrieval number in this chapter is measured on one collection. Most details of how it was built can be forgotten; two cannot, which part of the book it leaves out and how it splits the documents.

19.4.1.1 Contents and Cleaning

The corpus is this book at one commit of its sources. The Language Models part is excluded: its notebooks hold the questions, answers and results of experiments on this corpus, and a retriever that could read them would answer a question by retrieving the question. The Attic, two older natural-language chapters that this part replaces, and the front matter are left out too. Each source file becomes one document under these cleaning rules:

- only the PyTorch code of each multi-framework cell is kept, so code does not appear several times;
- slide decks, exercises and cells of little more than imports are cut;
- cross-references become the titles they point to, and citations are removed, so a chunk reads as text;
- mathematics stays in the text, but is removed from the copy that the word index reads.

Library functions, not shown, apply these rules and cut each document into the *chunks* that the retrievers rank. The split into training, dev and test questions is made by document, by a hash of its name within each chapter, so no training question was drafted from a dev or test document.

The next cell prints what the corpus's manifest records, and one chunk.

The corpus holds 232 documents, 168 for training and 32 each for dev and test. The default chunking makes 5,324 chunks of at most 512 tokens, median 364, the passages that Section 19.3 searched. The manifest also counts the directories left out, by reason, and the 19 cross-references whose targets lie outside the corpus. An id such as `sec512:chapter_transformers/kv-cache#001` names the chunking, the document and the position, so a stored result can name chunks without their text. Each chunk is read in three *views*, copies of its text prepared for one reader: `display` for a language model that answers, `dense` (code cells cut after 30 lines) for the embedder, and `sparse`, without the mathematics whose LaTeX would fill the word index with tokens such as `mathbf`.

How should a document be cut? *Section chunks* pack whole paragraphs, lists, equations and code cells under their heading, up to 512 tokens. *Fixed windows* take 256 tokens at a time, here 64 shared with the next window, wherever the boundary falls. This section retrieves section chunks; the windows are kept for Section 19.5, which compares how a language model answers from each. We cut one chapter introduction both ways.

The section chunker returns the introduction's text and its list of resources as two chunks. Three of the four windows begin in the middle of a sentence.

19.4.1.2 Measuring Retrieval

The questions and the measures are those of Section 19.3, and so is the rule that decides relevance, with chunks in place of passages: a chunk is relevant if it covers at least half of an answering span, or if at least half of the chunk lies inside one. Because the rule works both ways, it treats a short chunk inside a long span and a long chunk around a short span alike. Table 19.4 collects the measures for reference.

Table 19.4: Measures of a ranked list for one question; the reported value is the mean over questions. r is the rank of the first relevant chunk, and rel_i is 1 if the chunk at rank i is relevant and 0 otherwise.

measure	value for one question	rewards
Recall@k	1 if $r \le k$, else 0	an answer among the first k chunks
MRR@10	$1/r$ if $r \le 10$, else 0	the first relevant chunk near the top
nDCG@10	$\sum_{i \le 10} \mathrm{rel}_i / \log_2(i+1)$, divided by its value for the best order	every relevant chunk near the top

Recall@k, which the `trec_eval` tool calls success@k, matters most to a system that hands the first k chunks to a language model; nDCG@10 matters to a reader who stops early. Recall@10 also grows with the size of a chunk, so it cannot compare chunkings.

Three small questions check the definitions by hand, and our `d2l.retrieval_metrics` against `pytrec_eval`, the Python binding of `trec_eval`. Question 0 has one relevant chunk, at rank 3: Recall@1 is 0, Recall@5 is 1, MRR is $1/3$ and nDCG@10 is $1/\log_2 4 = 0.5$. Question 1 has two, at ranks 1 and 4; its nDCG@10 is worth computing before reading on. Question 2's chunk was not retrieved, and every measure is 0.

Question 1's nDCG@10 is $(1+1/\log_2 5)/(1+1/\log_2 3) = 0.877$, below 1 because its second chunk sits at rank 4 instead of 2. Both columns agree, and the cell asserts it.

19.4.2 Word Indexes and BM25

The oldest way to find a passage is printed at the back of every textbook: an index that lists, for every word, the pages on which it appears. The word index of a search engine does the same and adds a rule for which pages to read first.

19.4.2.1 The Inverted Index

Write the index as a matrix $\mathbf{W}$ with one row for every term of the vocabulary and one column for every chunk, and $W_{td} > 0$ only if term t occurs in chunk d. Stored row by row as a sparse matrix, row t lists the chunks that contain t. A chunk is a list of words; the index turns this around into a list of chunks for every word, hence the name *inverted index*. If $\mathbf{n}$ counts how often each term occurs in the question, the scores of all chunks are one sparse product, $\mathbf{n}^\top \mathbf{W}$, which touches only the rows of the question's terms: a question of ten words reads ten lists and leaves the rest of the index alone, however large the corpus.

What counts as a term needs care in a technical book. `bm25_tokenize` keeps lower-cased words and numbers, without stemming. An identifier is kept whole and also split at dots, underscores and capitals: `d2l.book_corpus` also yields `d2l`, `book` and `corpus`, and `BookRetriever` yields `book` and `retriever`. A question that names part of an identifier still matches.

19.4.2.2 The BM25 Score

Which numbers go into **W**? A word that occurs in few chunks says more than one that occurs in all of them. A chunk that uses a word five times is more about it than one that uses it once, but not five times more. And a long chunk contains many words by chance. BM25 turns each intuition into a factor:

$$W_{td} = \mathrm{idf}(t)\,\frac{\mathrm{tf}_{td}}{\mathrm{tf}_{td} + k_1\left(1 - b + b\,|d|/\overline{|d|}\right)}, \qquad \mathrm{idf}(t) = \log\left(1 + \frac{N - \mathrm{df}_t + 0.5}{\mathrm{df}_t + 0.5}\right). \tag{19.13}$$

Here tf_{td} counts term t in chunk d, $|d|$ is the length of the chunk and $\overline{|d|}$ the mean length, N is the number of chunks and df_t the number that contain t. A chunk's score sums W_{td} over the question's terms.

A few numbers show what each factor does. For a chunk of average length the fraction is $\mathrm{tf}/(\mathrm{tf} + k_1)$: at $k_1 = 1.2$ one occurrence contributes 0.45 of the idf, two 0.63, five 0.81, and no number of repetitions more than the whole idf. The parameter b scales k_1 with the length: at $b = 0.75$ a chunk twice the average length faces $1.2 \times 1.75 = 2.1$, and one occurrence contributes 0.32. Among the book's 5,324 chunks, a term in one chunk has idf $\log(1 + 5323.5/1.5) \approx 8.2$, a term in half of them $\log 2 \approx 0.69$. The 1 inside the logarithm, Lucene's choice, keeps the weight of a very common term from turning negative.

The formula looks fussier than it is: its constants are conventions, and the three intuitions are what to remember. The fraction itself is a simple curve standing in for a crude model, in which the count of a word follows one of two Poisson distributions depending on whether the document is about the word (Robertson and Zaragoza 2009). That so simple a formula is still hard to beat says that on text like this book, a passage that answers a question usually shares the question's rarest words.

We check `BM25Index` against `bm25s`, a fast BM25 library whose `lucene` variant computes Equation 19.13. We give it our tokens, so that only the scoring is compared, and score 200 training questions both ways.

The two put the same chunk first for all 200 questions, and their scores agree to 4×10^{-7} relative.

19.4.2.3 Tuning on Training Questions

$k_1 = 1.2$ and $b = 0.75$ are customary defaults, Lucene's among them. Do they suit a technical book? We search a grid of k_1, b and identifier splitting on the 5,614 training questions, never on dev: a setting chosen on the questions it is scored on reports its own luck as a gain. The rule takes the highest Recall@10, then nDCG@10, then the setting nearest the defaults. `BookRetriever` stores the choice, and the cell asserts that the two agree.

The grid hardly moves: Recall@10 lies between 0.915 and 0.934 over all 24 settings. The length normalization matters most, one to two points from $b = 0.4$ to 0.9, and splitting

identifiers moves no entry by as much as 0.004. The rule chooses $k_1 = 1.2$ and $b = 0.9$ with splitting, a stronger length normalization than the default, for chunks that run from 14 tokens to 512. A grid this flat leaves little room, and we should not expect the choice to show on dev. The next cell ranks the dev questions under the chosen and the default parameters, keeping 100 chunks per question for fusion, and times BM25.

The tuning changes nothing that the dev questions can see: both settings put a relevant chunk among the first ten for 0.96 of them. BM25 answers a dev question in about 0.2 ms on one CPU core, tokenization included, under either setting.

Both choices of this subsection, which strings count as terms and how a count becomes a weight, were made by hand. Learned sparse retrieval keeps the inverted index but lets an encoder choose the terms and their weights, including words the chunk never uses (Section 19.7).

19.4.3 Dense Retrieval, Fusion and Reranking

The word index misses paraphrases, and the embedder misses rare exact words. What does the dense search cost, how can the two lists be combined, and what does a slower model that reads question and passage together add?

19.4.3.1 The Flat Scan

Let $\mathbf{X} \in \mathbb{R}^{N \times m}$ hold the unit vectors of the N chunks, $m = 1{,}024$ coordinates each, and $\mathbf{Q} \in \mathbb{R}^{B \times m}$ those of B questions. All cosines are one product, $\mathbf{S} = \mathbf{Q}\mathbf{X}^{\top}$, followed by the ten largest entries of each row. It costs $2NmB$ floating-point operations and reads $\mathbf{X}$ once, two bytes per entry in float16, so one question performs one operation per byte read. That is far too little arithmetic for a GPU: an RTX 4090 needs about 160 operations per byte read before its arithmetic, rather than its memory, sets the pace (the roofline model of Section 13.1). A scan for one question is therefore limited by memory, while a batch of questions shares each vector it reads. The cell first checks the stored chunk vectors against 64 chunks encoded again.

The re-encoded chunks agree with the stored vectors to a cosine of 0.9998. With the 220 dev questions encoded in one batch, dense retrieval takes about 1 ms per question, and both retrievers reproduce the Recall@10 of the opening cell. How much of that is the scan? We time the scan alone, for one question and for all 220 at once, on two matrices. The book's, 11 MB, fits in the GPU's 72 MB second-level cache; a synthetic matrix of 2^{17} random unit vectors, 256 MiB, has to come from memory on every scan.

For the book the scan is negligible. One question takes about 0.05 ms, mostly the fixed cost of launching the kernels and waiting for them, and all 220 together about 0.1 ms. Nearly all of the millisecond above is the encoder's forward pass over the questions, and no index could make dense search over the book noticeably faster.

A matrix that does not fit in the cache behaves as the roofline predicts. One question reads the synthetic matrix at about 800 GB/s, four-fifths of the card's bandwidth, in 0.33 ms. A batch of 220 questions performs about 220 operations per byte, past the ridge, so now arithmetic sets the bound. The batch takes about 0.7 ms, at about half the card's peak rate: 0.003 ms per question, because each vector read serves all 220.

19.4.3.2 Fusion

Neither list contains the other, so we combine them. *Reciprocal-rank fusion* (RRF) (Cormack et al. 2009) ignores the scores and gives a chunk d the score

$$s(d) = \sum_r \frac{1}{k + \text{rank}_r(d)}, \tag{19.14}$$

summed over the rankings r that contain d. The original paper fixed $k = 60$ in a pilot experiment, found it near-optimal but not critical, and never tuned it again; we keep it. A chunk first in one list and third in the other scores $1/61 + 1/63 \approx 0.0323$, a chunk first in one list only $1/61 \approx 0.0164$: agreement beats a single first place. Rank 10 scores only 13% less than rank 1, so RRF is close to a vote among the lists with a mild preference for early ranks. Needing ranks only, it fuses a BM25 score of 9 with a cosine of 0.6 without asking what either means.

Scores themselves cannot simply be added: on their raw scales the sum would be BM25's ranking with a little noise. The weighted alternative first *z-scores* each list, subtracting its mean over the chunks and dividing by its standard deviation, then adds λ times the dense score and $1 - \lambda$ times the BM25 score, with λ chosen on training questions. The cell also computes the recall of an oracle that takes, for each question, whichever retriever finds a relevant chunk.

The weight chosen is $\lambda = 0.7$, mostly dense. Both fusions keep the embedder's Recall@10 of 0.99 and rank at least as well as the better of the two lists: nDCG@10 is 0.86 for RRF and 0.88 for the weighted sum, against 0.82 for BM25 and 0.81 for the embedder. The weighted sum is a little ahead of RRF, but only with a weight tuned on training questions; RRF needs none, which is why the retriever at the end of this section uses it. The oracle shows how much the two lists hold together: it finds a relevant chunk among the first ten for every question. Fusion finds one for every question too, but only within its first 100.

19.4.3.3 Reranking

Both retrievers so far encode question and chunk separately. Such a *bi-encoder* computes every chunk vector once, before any question arrives, but the vector of a chunk must anticipate every question anyone might ask. A cross-encoder, like the MNLI classifier of Section 19.2, reads question and chunk together as one input and scores the pair. Its attention can connect a word of the question with the sentence that answers it, at the cost of one forward pass per pair, so it can only reorder a short list that a bi-encoder found (Nogueira and Cho 2019).

Qwen3-Reranker-0.6B is a decoder used as a cross-encoder. Its prompt states an instruction, the question and the chunk, and asks for "yes" or "no". The score is the label scoring of Section 18.3.1.2 with two labels,

$$P(\text{yes}) = \frac{e^{z_{\text{yes}}}}{e^{z_{\text{yes}}} + e^{z_{\text{no}}}},$$

where z_{yes} and z_{no} are the logits of the two tokens: the probability of "yes" with every other answer ruled out. `rerank_yes_no` builds the prompt of the model card and cuts the chunk so the prompt fits into 1,024 tokens.

The reranker reads each chunk in the dense view and each question with the embedder's task, `d21.BOOK_TASK`, the sentence about web search queries that both model cards give as their default. We wrote no task of our own for it: the instruction we first wrote for the book made the embedder rank worse (Section 19.3.3), and a wording for the reranker would have to be chosen on training questions in the same way. We rerank the first 20 and the first 100 fused chunks; the scores for 100, which take minutes to compute, come stored. A reranker only permutes the chunks it is given, so reranking the first 20 leaves Recall@20 and Recall@100 where they were. A table in which reranking the first 20 raises Recall@100 has measured something else.

Reranking 20 chunks takes about a quarter of a second per question on the GPU, and 100 chunks about 1.2 s. That makes the reranker the expensive stage by far: BM25, the embedder and fusion together took about a millisecond per question, with the questions encoded in one batch. The stored scores match a live run to the printed digits.

Late interaction lies between the two designs: it stores a vector for every token of every chunk and matches them against the question's token vectors at search time (Section 19.7).

19.4.3.4 Comparing the Retrievers

The next cell prints every retriever's measures with intervals over documents, the time per question, and paired differences on the same questions. It also splits the questions in two. An *identifier question* is one whose question or reference answer contains code, such as a dotted name or a call; 80 of the 220 are. They come from only 28 documents, too few to resample, so for them a sign-flip test decides: it flips the sign of each document's mean difference at random and asks how often the total lies as far from zero as the observed one.

Over all questions the embedder finds a relevant chunk among the first ten for about 3 points more of the questions than BM25, an interval from 0.5 to 6 points, and the two rank equally well: their nDCG@10 differ by 0.01, within noise. The split shows where each is stronger. On the other questions the embedder finds 6 points more, an interval that excludes zero. On the identifier questions the two find a relevant chunk about equally often (BM25 two questions more), but BM25 ranks it higher, by about 0.09 in nDCG@10, a difference the sign-flip test rejects as chance (p 0.007). The opening cell showed why in a single question: the embedder places the passage about a function among other passages on the same subject, while the function's exact name lifts it to the top for BM25.

Fusion keeps the embedder's recall and ranks better than either list. It beats the embedder by about 0.05 in nDCG@10 and BM25 by 0.04, both intervals excluding zero, and it puts a relevant chunk first for 80% of the questions, against 76% for BM25 and 70% for the embedder. Reranking the first 20 improves the ranking again. It adds about 0.03 to fusion's nDCG@10, an interval from 0.005 to 0.05 and a fifth of the remaining distance to a perfect ranking, and lifts that 80% to 84%. The plot shows the same: the retrievers differ little in Recall@10 (left) and more in nDCG@10 (right).

Two changes gained nothing, and both had no room to gain. Tuning BM25 did not change dev Recall@10 on a single question, as the flat grid predicted. Reranking 100 chunks instead of 20 did not move nDCG@10 and took five times as long, because for all but one question the first 20 fused chunks already hold a relevant one.

"Dense retrieval beats BM25" is a claim about a corpus, a question set and a model. Our questions were drafted from the book's passages and reuse their rare words (Section 19.3), which makes counting words a very high floor. The BEIR benchmark (Thakur et al. 2021)

found dense retrievers trained on one collection often below BM25 on another. The advice that survives both is to keep the word index and fuse instead of choosing: running both and fusing them costs about a millisecond per question and covers both kinds of failure.

19.4.4 Approximate Nearest Neighbors

For the book, the flat scan needs no help, but its cost grows with the collection. The synthetic matrix of 131,072 vectors already took 0.33 ms per question on the GPU. A hundred million web passages, at 1,024 coordinates of two bytes each, hold about 200 GB of vectors; scanning them would take about a quarter of a second per question, if they fitted on the card at all. We build two approximate indexes from scratch, use a third through Faiss, a C++ library of vector indexes with a Python interface, and measure all three on a larger collection.

19.4.4.1 Inverted Files

The first index is the word index again, with clusters in place of words. k-means cuts the space into n_{list} cells, each holding the vectors nearest to one centroid, and the vectors are stored grouped by cell. A question finds its n_{probe} nearest centroids and scans only their cells. With cells of equal size it compares

$$n_{\text{list}} + n_{\text{probe}} \frac{N}{n_{\text{list}}}$$

vectors instead of N: the centroids, then the probed cells. What the index gives up is exactness: a neighbor just across the border of an unprobed cell is never seen (right of Figure 19.3). `kmeans` alternately assigns each vector to its nearest centroid and moves each centroid to the mean of its vectors (Lloyd's algorithm), starting from k-means++ seeds, which spread the first centroids apart. `IVFIndex` stores the vectors cell by cell and scans the probed cells exactly.

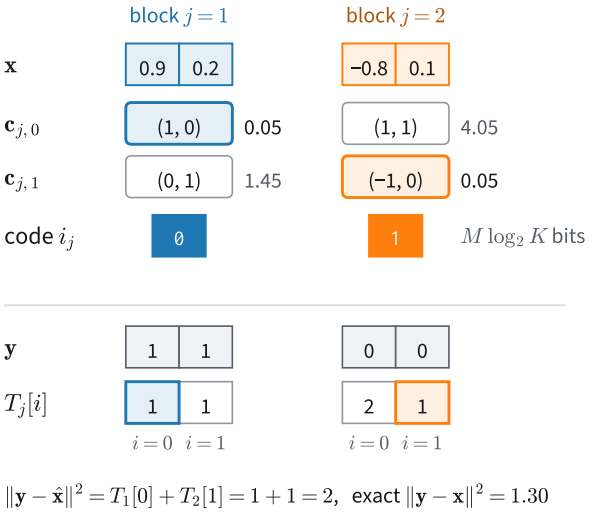
19.4.4.2 Product Quantization

An inverted file still stores every vector in full. Faiss's CPU indexes hold float32, twice the bytes of our stored float16 vectors, so a vector takes 4 KB; byte counts from here on are float32. Jégou et al. (2011) store a short code instead and compute distances from the code without decoding it. This is the cleverest idea of the section, and the step worth understanding is how a distance can be read off a code.

Split $\mathbf{x} \in \mathbb{R}^m$ into M blocks $\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(M)}$ of m/M coordinates each. For each position j, learn a codebook of K centroids $\mathbf{c}_{j,0}, \dots, \mathbf{c}_{j,K-1}$ by k-means on the blocks at that position, and replace $\mathbf{x}^{(j)}$ by the index i_j of its nearest centroid. The code $(i_1, \dots, i_M)$ takes $M \log_2 K$ bits, one byte per block at $K = 256$, and the reconstruction $\hat{\mathbf{x}}$ concatenates the chosen centroids. M codebooks of K entries name K^M reconstructions; this product of small codebooks gives the method its name.

The smallest case can be done by hand (left of Figure 19.3). Take $m = 4$, $M = 2$ and $K = 2$, with codebooks $\{(1,0),(0,1)\}$ for the first two coordinates and $\{(1,1),(-1,0)\}$ for the last two. For $\mathbf{x} = (0.9, 0.2, -0.8, 0.1)$ the first block is nearest to $(1,0)$ (squared distance 0.05 against 1.45) and the second to $(-1,0)$ (0.05 against 4.05), so the code is $(0,1)$

and $\hat{\mathbf{x}} = (1, 0, -1, 0)$. Now take the question $\mathbf{y} = (1, 1, 0, 0)$. Its first block, $(1, 1)$, lies at squared distance 1 from both centroids of the first codebook; its second block, $(0, 0)$, at 2 and 1 from those of the second. With these four numbers in a table T, the squared distance from $\mathbf{y}$ to the code is $T_1[0] + T_2[1] = 1 + 1 = 2$, read off in two look-ups without decoding anything. The exact squared distance to $\mathbf{x}$ is 1.30.



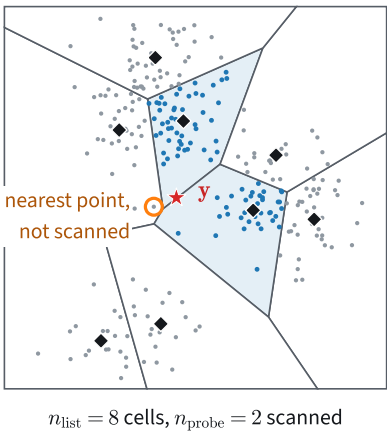


Figure 19.3: Product quantization and the inverted file. Left: the hand case with $m = 4$, $M = 2$ and $K = 2$. Each block of $\mathbf{x}$ is replaced by the index of its nearest centroid (squared distances beside the centroids), so the code is $(0, 1)$. For the question $\mathbf{y}$, the table $T_j[i]$ holds the squared distance from each block of $\mathbf{y}$ to each centroid, and the distance to the code is the sum of the two entries the code selects. Right: k-means cuts the plane into $n_{\text{list}} = 8$ cells (centroids as diamonds); the question scans the points of its $n_{\text{probe}} = 2$ nearest cells (shaded) and misses its nearest point, which lies just across a border.

The look-ups work in general, because a squared distance is a sum over coordinates and therefore over blocks. For a question $\mathbf{y}$, kept exact,

$$\|\mathbf{y} - \hat{\mathbf{x}}\|^2 = \sum_{j=1}^{M} \left\|\mathbf{y}^{(j)} - \mathbf{c}_{j,i_j}\right\|^2 = \sum_{j=1}^{M} T_j[i_j]. \tag{19.15}$$

The table $T_j[i] = \|\mathbf{y}^{(j)} - \mathbf{c}_{j,i}\|^2$ has MK entries and depends only on the question, so it is built once per question with Km multiply-adds, the cost of 256 exact distances at $K = 256$; after that each code costs M look-ups, whatever m is. Only the stored vectors are quantized, hence the name *asymmetric distance computation*. At $m = 1{,}024$, $M = 64$ and $K = 256$ a code takes 64 bytes against 4,096 in float32, plus 1 MiB of codebooks for the whole collection.

How wrong is the distance? Write $\mathbf{e} = \mathbf{x} - \hat{\mathbf{x}}$ for the quantization error. The triangle inequality bounds the error for every question at once,

$$\big|\, \|\mathbf{y} - \mathbf{x}\| - \|\mathbf{y} - \hat{\mathbf{x}}\| \,\big| \le \|\mathbf{e}\|,$$

so a vector that is quantized well is ranked well. In the hand case the error of the distance, $|\sqrt{1.30} - \sqrt{2}| = 0.27$, stays below $\|\mathbf{e}\| = \sqrt{0.10} = 0.32$. Like the distance, $\|\mathbf{e}\|^2$ is a sum over blocks, so the mean squared error of the quantizer is the sum of the distortions of its M codebooks, each minimized by its own k-means.

On average we can say more. Substituting $\mathbf{y} - \mathbf{x} = (\mathbf{y} - \hat{\mathbf{x}}) - \mathbf{e}$ gives

$$\|\mathbf{y} - \mathbf{x}\|^2 = \|\mathbf{y} - \hat{\mathbf{x}}\|^2 - 2\,(\mathbf{y} - \hat{\mathbf{x}})^\top \mathbf{e} + \|\mathbf{e}\|^2.$$

At convergence each centroid is the mean of its cell, so each block of $\mathbf{e}$ has mean zero in every cell of its codebook. Two things follow. Each block of $\hat{\mathbf{x}}$ is constant within a cell, so $\hat{\mathbf{x}}^\top \mathbf{e}$ averages to zero; and for a question independent of $\mathbf{x}$, so does $\mathbf{y}^\top \mathbf{e}$. The middle term therefore vanishes on average. Averaged over the stored vectors, the asymmetric distance is smaller than the true squared distance by the mean distortion, and by the same amount for every question. A single pair can go either way: the hand case overestimates. A shift that is the same for every vector would leave the ranking alone. What reorders neighbors is the part that changes from vector to vector: the cross term, which averages to zero but not for each vector, and $\|\mathbf{e}\|^2$. The bound limits both together: two neighbors closer together than their quantization errors can swap places.

A product quantizer compresses each vector as a low-rank approximation does (Section 33.5), but where a rank-r approximation projects every vector onto one shared subspace, the quantizer picks for each block one of finitely many points: its reconstructions form a grid, not a subspace. `ProductQuantizer` fits one codebook per block and stores each index in a byte. Its arguments follow Faiss: `m` is the number of blocks, our M, and `nbits` is $\log_2 K$.

The cell checks the hand case, then five claims on 20,000 points from a mixture of 16 Gaussians in 64 dimensions, synthetic data whose structure we know and small enough to check pair by pair, with $M = 8$ and $K = 256$: (1) the table gives the distance to the reconstruction; (2) the bound holds; (3) $\mathbf{y}^\top \mathbf{e}$ and $\hat{\mathbf{x}}^\top \mathbf{e}$ average to zero; (4) Faiss, given our codebooks, assigns our codes; (5) the distortion is the sum of the blocks' distortions.

All five hold. Table and reconstruction distances agree to 2×10^{-7} relative, the bound holds on every pair, and the means of $\mathbf{y}^\top \mathbf{e}$ and $\hat{\mathbf{x}}^\top \mathbf{e}$ lie within about one standard error of zero, where noise alone would put them. Faiss assigns our codes to every vector. The mean squared error, about 36, is the sum of eight block distortions of about 4.5; set against 64, the mean squared distance of a point from its own Gaussian's center, it says that the codes keep the cluster and lose much of the position within it.

The two indexes combine. *IVF-PQ* stores, in each cell of an inverted file, the codes of its vectors' offsets from the cell's centroid. A question probes n_{probe} cells as before and scores the codes of each with a table built for its own offset from that cell's centroid. Each vector then costs its code and an 8-byte id; the coarse centroids and the codebooks are shared by the whole collection. The offsets are shorter than the vectors, so the same codebooks quantize them with a smaller error. There is a cost, though, and it is easy to overlook. Two close vectors often share the code of a block, and then they share its reconstruction: in that block the comparison between them errs by no more than their own small difference. Plain codes give close vectors this sharing wherever they lie. Offsets give it only to neighbors in the same cell; two neighbors on either side of a border are coded from different centroids, and their errors are independent. Which effect wins depends on how many cells a question's neighbors are spread over, and we will measure both.

19.4.4.3 Navigable Small-World Graphs

The third index needs no cells. Link every vector to a few near neighbors and search by walking: start somewhere, move to whichever neighbor is closest to the question, and stop when none is closer. On a well-built graph a few dozen steps cross millions of vectors, as a short chain of acquaintances connects two strangers. The walk can also stop too early, at a vector that is closer to the question than all of its own neighbors but is not the nearest overall.

A walk that starts far from the question needs many short steps. *Hierarchical navigable small-world graphs* (HNSW) (Malkov and Yashunin 2020) therefore add layers. Every vector is on the bottom layer, and a random subset that shrinks geometrically is also on the layers above, where the links are long. A search crosses the collection on the top layer and refines its answer at the bottom.

Three knobs set the graph. Each vector keeps up to 32 links per layer here (Faiss's parameter `M`), and up to twice that at the bottom. The builder keeps *efConstruction* candidates while choosing links. A search keeps not one current vector at the bottom layer but a list of *efSearch* candidates, so it can step back from a dead end; a longer list finds more of the true neighbors and takes longer. The first two knobs can be looked up when needed; *efSearch* is the one a user turns, at search time and without rebuilding. The links are 4-byte ids, so 64 of them add 256 bytes per vector at the bottom layer, a little more with the layers above, next to the 4,096 bytes of the vector itself. A graph needs about as much memory as a flat index.

19.4.4.4 Measuring the Indexes

To see an index at work we need more vectors than the book has. The stress collection adds to the book's chunk vectors about 62,500 Wikipedia passages from Natural Questions, the pairs of search questions and passages that Section 19.3 trained on; they come from the pairs its contrastive training did not use. The same model embeds them, and 1,000 of their questions serve as timed queries. The off-topic passages enlarge the haystack without making the book's questions harder: the collection tests whether an index finds the exact nearest neighbors, not how hard retrieval is.

The collection holds 67,853 vectors, 265 MiB in float32. For every index along its knob, the next cell measures two kinds of recall. *Recall against exact search* is the share of the exact ten nearest neighbors that the index returns for the 1,000 timed questions; it measures the index. *Task recall* is the Recall@10 of the 220 dev questions searched among all 67,853 vectors; it measures what a reader of the results sees. The cell also records the median (p50) and 95th-percentile latency of one-question searches on one CPU thread, and the bytes per vector.

The inverted files have 1,024 cells, close to $\sqrt{16N}$, the count that minimizes the vectors compared at 16 probes (an exercise derives it). IVF-PQ stores 64-byte codes, built with three k-means seeds, and 32-byte ones. The rows marked "ours" give the recall of `IVFIndex` and of `ProductQuantizer` scanning all codes; their latencies are those of plain PyTorch code, and for the quantizer of a scan of every code, not of the methods.

The inverted file does what the count predicts. At 16 probes it compares about $1{,}024 + 16 \times 66 \approx 2{,}100$ vectors instead of 67,853, 33 times fewer, and runs about 35 times faster than the flat scan, about 0.4 ms against 16 ms. It loses recall: it returns 0.85 of the exact neighbors at 16 probes, our `IVFIndex` as much as Faiss's, and 0.94 at 64. The stored table agrees with this run, with the same recalls and latencies within about 10%.

Product quantization trades recall for memory. IVF-PQ stores 149 bytes per vector: the 64-byte code, the 8-byte id and, spread over this collection, 62 bytes of coarse centroids and 15 of codebooks. That is 27 times less than the flat index, but recall against exact search stalls near 0.6: 0.59 to 0.60 at 16 probes across three k-means seeds, and only 0.62 at 64. Codes of 32 bytes lose clearly more (0.52 against about 0.6, well outside the spread of the seeds). These are the swaps the bound allowed: neighbors that lie closer together than their quantization errors. One row does not fit, though. Our `ProductQuantizer`, which codes the vectors themselves and scans every code, reaches 0.69, more than IVF-PQ at any number of probes, although IVF-PQ codes the shorter offsets and should make the smaller errors.

Is the probing to blame, or the coding? Sixty-four probes still stop at 0.62, which already points at the coding. The next cell settles it. It builds IVF-PQ with 64-byte codes for 1 to 1,024 cells and probes every cell, so that no neighbor is missed for lying in an unprobed cell; one cell is plain product quantization. For each it prints recall against exact search, the mean squared error $\|\mathbf{e}\|^2$ of the codes, and the share of each question's ten exact neighbors that lie in the cell of the nearest one.

The offsets keep their promise: as the cells shrink, the mean squared error of the codes falls from 0.41 to 0.30. Recall moves the other way, from 0.70 with one cell to 0.63 with 1,024, although every cell is probed. The last column explains it. With one cell, every pair of neighbors is coded the same way, and two close vectors that share a block's code share its reconstruction: in that block their comparison errs by no more than their own small difference. At 1,024 cells only about half of a question's ten exact neighbors lie in the cell of the nearest one. The other half are coded against other centroids, and their errors become independent. A smaller error helps little once it stops being shared. Probing all 1,024 cells lifts recall only to 0.63, from 0.62 at 64 probes: what IVF-PQ loses against plain codes on this collection is lost in the coding, not in the probing.

Whatever the codes lose, the usual repair rescores the best hundred candidates with exact vectors kept on disk. (The rescoring of binary vectors in Section 19.3.4 was a cheaper cousin: it used the exact question but kept the passages at one bit.)

The graph wins at this size. HNSW returns 0.97 of the exact neighbors at $efSearch = 32$ in about 0.3 ms, and 0.998 at 256 in under 2 ms, for 272 bytes per vector beyond the vector itself, nearly all of it links, and about 15 s of building with eight threads.

Task recall drops far less, because it needs one relevant chunk among ten where recall against exact search counts all ten neighbors. IVF-Flat at 16 probes misses 15% of the exact neighbors and loses only about 0.02 of task recall. IVF-PQ64 misses 40% and loses between 0.05 and 0.09, depending on the k-means seed. Recall against exact search measures the index, and task recall what a user notices.

In the left panel HNSW lies above every other curve at every latency it reaches, and IVF-PQ, with the smallest markers, flattens out at low recall. In the right panel most curves climb to within a few points of the flat scan's 0.99 at a fraction of its latency. The last cell picks, among the one-thread searches, the fastest that returns at least 0.95 of the exact neighbors, and sets it against the flat scan.

The cell picks HNSW at $efSearch = 32$, about 50 times faster than the flat scan on the same thread. Which index is right depends on the machine and on how the questions arrive. For a CPU that answers one question at a time and has memory for the vectors, a graph is the right index. When questions arrive in batches and the vectors fit on a GPU, about ten million of them in 24 GB at float16, the exact scan is the right index. The GPU scanned all 1,000

timed questions at 0.005 ms each and returned 0.9994 of the exact neighbors; the shortfall is float16 rounding, which leaves the vectors not quite of unit length, so inner product and distance order a few near-ties differently. And when memory is the limit, IVF-PQ keeps a billion vectors in 64 GB of codes instead of 4 TB of float32.

19.4.5 The Book Retriever

Everything above now becomes the retriever that the rest of this part calls. BM25 runs over the sparse view with the parameters chosen on training questions. The embedder scans the stored chunk vectors exactly, because at 5,324 chunks no index is faster, and RRF with $k = 60$, which needs no tuned weight, fuses the two lists. The reranker is off unless the retriever is given one and a search sets `rerank_k`, as it adds about a quarter of a second to every search. With `index='hnsw'` or `'ivfpq'` a Faiss index is built on first use. The embedder is one constant shared by the retriever and later chapters.

A search returns `Hit` records: the chunk id, the final score and rank, the text and heading path, and the score of every stage, so a caller can see why a chunk was found.

We ask the retriever, with its defaults, the question of the chapter's introduction: how does the book's old `load_array` helper decide whether to shuffle? The raw encoder of Section 19.3 missed its passage. Besides the five hits, the cell prints the rank of the first relevant chunk under BM25 alone, the embedder alone, and fusion.

Fusion puts the relevant chunk first: the training utilities in the book's section of utility functions. All three rankings put it first, but with very different margins, and the difference is the identifier gap of the comparison in miniature. BM25 ranks the chunk first by a wide margin, a score of 25 against at most 15 for any other chunk, because the question names `load_array` and `DataLoader`. The embedder puts it first by 0.001 in cosine, just ahead of "A Loader for Every Epoch", a chunk about data loaders in general: the near miss that the opening of this section feared. One list alone gives a fused score of at most $1/61 \approx 0.016$. This chunk's 0.033 is the $2/61$ of two first places. The other four hits are about loading, of data or of saved weights, elsewhere in the book: on the subject, and no use for this question.

A relevant chunk among the first ten is not yet an answer. Which chunks should a language model read, in which order and how many of their tokens, and when its answer comes back wrong, did retrieval fail or the reading? Section 19.5 hands these chunks to a generator and measures each stage of the system on its own.

19.4.6 Summary

A retriever has to find the few passages that answer a question, quickly, in a collection of any size. A word index ranked by BM25, which weighs words by their rarity, and a vector index fail on different questions: on the book, exactly one of the two succeeded on 5% of the questions. On questions that involve code, BM25 ranked the relevant chunk higher. Reciprocal-rank fusion merges the two lists from their ranks alone, and a cross-encoder that reads question and chunk together reorders the top of the merged list into the best ranking we measured, for about a quarter of a second per question. When a collection outgrows the exact scan, an approximate index gives up exactness. An inverted file scans a few cells, product quantization stores a few bytes per vector and reads distances from a table, and a layered graph walks to the neighbors, about 50 times faster than a one-thread scan in our measurements. Coding each vector's offset from its cell's centroid makes the errors smaller

and still finds fewer neighbors, because close vectors in different cells no longer share their errors. Recall against exact search overstates what a reader loses.

19.4.7 Exercises

1. **Bytes and look-ups.** A collection of 10^6 passages is embedded with $m = 1{,}024$ coordinates.
   1. Compare the memory per vector of float16 storage with that of a product quantizer with $M = 64$ blocks and $K = 256$ centroids per codebook, and with $M = 128$ and $K = 16$. Include the codebooks, spread over the collection.
   2. Count the operations of one question under asymmetric distance computation: building the table and scanning every code. Below which N does building the table cost more than scanning?
   3. Compare with the multiply-adds of an exact float16 scan of the same collection. Which of the two is limited by memory bandwidth on a CPU, and why are look-ups in a table of 16,384 entries fast?
2. **Reciprocal-rank fusion by hand.**
   1. In two long lists, a chunk ranked $(1, 4)$ competes with a chunk ranked $(2, 2)$. Which wins at $k = 0$, and which at $k = 60$? What does a large k reward?
   2. BM25 ranks three chunks (a, b, c) and the embedder ranks them (c, a, b). Compute the fused order of a, b and c at $k = 0$ and at $k = 60$, and check it with `d2l.rrf_fuse`.
   3. Show that the order of RRF does not change when either retriever's scores are replaced by any strictly increasing function of them. Construct three chunks for which one outlying BM25 score changes the order of the z-scored weighted sum at $\lambda = 0.5$.
3. **The number of cells.** With N vectors in n_{list} cells of equal size, a question compares $n_{\text{list}} + n_{\text{probe}} N / n_{\text{list}}$ vectors.
   1. Show that this is smallest at $n_{\text{list}} = \sqrt{n_{\text{probe}} N}$, and find the smallest cost.
   2. At $N = 10^6$ and $n_{\text{probe}} = 16$, compare the smallest cost with the flat scan. Are the 1,024 cells of our stress index near the optimum for 16 probes?
   3. The cells of k-means are not of equal size. Which cells does a question tend to probe, and does that raise or lower the expected cost? Measure the cell sizes of the stress index and the number of vectors a question actually compares.
   4. The text blamed the low recall of IVF-PQ on neighbors that are coded against different centroids. Test the explanation: Faiss can code the vectors themselves inside the cells (set `by_residual = False` on the index returned by `faiss.extract_index_ivf` before training). At 1,024 cells, measure recall against exact search with both codings at 16 probes and with every cell probed. Predict the result first. Which coding wins, by how much, and does it fit the explanation?
4. **The bias of asymmetric distances.** The text showed that for a question independent of the data, the asymmetric distance underestimates the squared distance on average by the mean distortion.
   1. Now let the question be one of the stored vectors, $\mathbf{y} = \mathbf{x}$. What do the exact and the asymmetric distance give, and which way is the error? Why does this matter when searching for near-duplicates of stored passages?

2. Quantize the question too, and compare the expected error of this symmetric distance with that of the asymmetric one.
3. Check both answers on the Gaussian mixture of the check cell.

5. code **The knobs of the graph.** ● First predict, from how the walk stops, whether more links per layer should raise recall at a fixed *efSearch*, and what they should cost. Then, for HNSW on the stress collection, measure recall against exact search and p50 latency for *efSearch* $\in \{16, 32, 64, 128, 256, 512\}$ at 8, 16, 32 and 64 links per layer (Faiss's `M`), and record the build time and the bytes per vector for each link count. Which reaches a recall of 0.95 at the lowest latency, what does it cost in memory and build time, and where was your prediction wrong?

6. code **The switches of BM25.** On the training questions, splitting identifiers changes Recall@10 by less than 0.004 in every cell of the grid. Find the training questions whose first hit changes when splitting is turned off, at $k_1 = 1.2$ and $b = 0.9$. How many are identifier questions, and which way do they move? Explain from their tokens why the average hides them.

7. code **Chunk size and recall.** Recall@10 grows with the size of a chunk. Load the windows of 256 tokens without overlap, `d2l.book_corpus('fixed', size=256, overlap=0)`, and measure BM25's Recall@10 on the dev questions under these windows and under the section chunks, together with the number of tokens a reader of the first ten chunks would read. Which chunking "wins", and by which measure? Propose a comparison that is fair to both.

8. [extended] **A row of your own.** ●● Do one of the following.
    1. Add a learned sparse retriever, SPLADE (Formal et al. 2021) (the released checkpoint `naver/splade-v3`), or a late-interaction retriever, ColBERT (Khattab and Zaharia 2020) (`lightonai/GTE-ModernColBERT-v1`, built on ModernBERT), as a row of the comparison on the dev questions and as a point on the trade-off plot, with its index size per chunk.
    2. Design an index for a collection 10^4 times larger than the stress collection, with a budget of 100 ms per question and 16 GB of memory. Estimate its recall from the measurements of this section, and say which measurement you would make first.

19.5 Retrieval-Augmented Generation

In Section 19.4 we built a retriever that finds, for nearly every question about this book, a passage that answers it. Nobody asks a question in order to receive a ranked list, however. The obvious next step is to hand the passages to a language model and read its answer. So let us wire the retriever to a generator, Qwen3.5-9B, and ask it what happens to PyTorch modules kept in a plain Python list instead of `nn.Sequential`. The passage that answers comes back first, and its last sentence reads "Modules in a plain list stay unregistered, without any warning." The model writes four fluent sentences about registration, cites the second and third passages, and leaves out the one fact that the first passage adds: no warning is raised. So the passage was there, at the top. Did the model skip it, or did the passages it cited lead it elsewhere? Had the passage been ranked tenth and left out of the prompt, the answer might read just the same. How are we to tell these cases apart?

Systems of this kind are called *retrieval-augmented generation* (RAG), after a 2020 paper that

trained a retriever's query encoder together with a generator (Lewis et al. 2020). Today the name covers any pipeline that retrieves passages and places them in a prompt. Such a pipeline is a chain of stages: a query is formed, passages are retrieved, reordered, packed into a context and read by the generator. When the answer is wrong, any stage may be at fault, and each stage needs a different repair. One accuracy number cannot say which. The idea of this section and the next is to locate a failure by measuring each stage on its own.

The pipeline itself is quickly built. Most of the work, and most of this section, goes into the instruments: questions whose answers and source passages we know, and a grader we have reason to trust. With both in hand we measure a baseline between two bounds, a floor without passages and a ceiling with only the passages that answer. Section 19.6 then changes one stage at a time and sorts the failures by the stage that caused them.

The two cells that follow are setup, and a reader can pass over them. They pin the models: Qwen3.5-9B generates, the embedder and reranker of Section 19.4 retrieve, and a larger Qwen model, introduced with the judge below, grades. Generating and judging every answer takes GPU hours, so the answers and verdicts were recorded once. A normal run replays them and generates a few again as a live check; the environment variable `D2L_RERUN` regenerates them.

19.5.1 A Question Set over the Book

To measure a RAG system we need questions whose answers we know, and we need to know where in the corpus each answer is written. Public benchmarks give the first but not the second for our corpus, and any of them may have been in the training data of every model we use. So we build a set over the book: we know its content, every answerable question has a gold span, the stretch of book text that answers it, and we decide how it is split. The recorded model responses the set was built from are published with it (`lm-book-qa-api-cache-v1`), so its construction can be checked without any API call. The next cell registers the set and, with it, every recorded artifact of this section and the next; for now only the question set matters.

Each item holds

- a question and a reference answer;
- its *key facts*, the short statements a correct answer must contain;
- gold spans, as character ranges in the cleaned documents of Section 19.4;
- *alternative spans*, other passages of the book that answer it too;
- flags such as `identifier` (the question or reference names a function or variable of the book's code) or `general_knowledge` (answerable without the book).

Which chunks are relevant depends on how the corpus is cut, so items store spans, and `gold_chunk_ids` computes the chunks for any chunking.

The set was written and checked by models, in four steps:

1. A drafter, DeepSeek-V4.1-Flash, wrote two candidate questions per *anchor chunk*, a passage drawn from the book, each with a reference, key facts and verbatim evidence. It comes from outside the Qwen family of our generator and judge.
2. Rules removed a candidate whose evidence is not a substring of the book, whose wording assumes a context the reader lacks ("in the passage above"), that copies a run of the anchor's words (word overlap alone would then find the answer and make retrieval look easy), or that nearly repeats another.

3. A checker, Qwen3.8-27B, tested that each question stands alone and that its reference is supported, complete and unique. A search of neighboring passages collected other passages that answer it.
4. A frontier model, Claude Opus 5.5, verified every `dev` and `test` item in a fresh context.

The items were checked by models, not by people, and the choice is deliberate. Model checks are fast, cheap and recorded, so anyone can replay them. The verifier's 620 calls cost about $7, and the whole set, drafts and checks included, about $15; a person checking 480 items against their passages would need many hours. What the checks can miss is what the models share. A reference that drafter, checker and verifier misread in the same way passes every check, and the verifier may have read this public book and accept a question it can answer from memory. The checker is also the judge we use below, so a wrong reference that it passes is later used to grade answers. The protection against shared blind spots is agreement with models of other families, and Exercise 5 compares hand labels with the verifier's.

In `dev` and `test` the quotas are 120 questions answered by one passage, 40 that ask for an explanation, and 20 each of numeric, code, multi-passage (`multihop`) and unanswerable questions. `train` passed only the rules and the checker, and it carries no alternative spans, which are kept only where answers are scored. The column `closed-book correct` records whether Qwen3-4B, a smaller model than our generator, answered correctly without passages, as graded by the judge introduced below; for our own generator we measure this later.

Copying the anchor's words was the most common reason for rejection, more common than all the others together. The checker rejected 165 unanswerable and 133 code candidates but only 146 single-passage ones, although `dev` and `test` hold six times as many single-passage questions as either: a question the book does not answer, or one about its code, is the hardest kind to write well. Another 42 candidates meant to be unanswerable were answered by a neighboring passage.

On whether an item passes, verifier and checker agree on 84% of the 536 `dev` and `test` candidates that both of them checked. That sounds like agreement, but both pass most items, so they agree by default. *Cohen's* κ corrects for this. It compares the observed agreement p_o with the agreement p_e that two raters with the same pass rates would reach by chance:

$$\kappa = \frac{p_o - p_e}{1 - p_e}. \tag{19.16}$$

It is 1 for perfect agreement and 0 for agreement at chance level. Two raters who each pass about nine items in ten, independently of each other, agree on $p_e = 0.9^2 + 0.1^2 = 0.82$ of them. Two coins that each land heads nine times in ten would do as well. Against that, 84% is barely better, and κ is $(0.84 - 0.82)/0.18 \approx 0.1$; the measured value is 0.12. The per-check table shows the extreme case. On whether the answer is unique, the two agree on 96% of the items, and κ is 0.00: both call almost every answer unique, and the few that one of them doubts are not the ones the other doubts. So the items each model rejects are mostly different ones, and the set very likely still holds items that a third check would reject: the verifier alone rejected 67 items after every earlier step had passed them. Here or anywhere else, an agreement rate means little until it is set against the rate that chance alone would give, and we will hold the judge of our answers to the same test.

Here is the first `dev` item of each type with its gold span.

The questions name what they ask about ("the book's `training_memory_gib` helper"), and most need the book: the 1000 W that NVIDIA specifies for an RTX 5090 system is not common knowledge. The unanswerable question is a plausible question about attention that the book does not answer. The rule against copying is narrower than it may sound. It rejects a question that repeats a run of five words of its passage, or whose vocabulary mostly coincides with the passage's; the first item reuses the passage's words in another order and passes. We will meet the consequence when we measure retrieval.

The split is made over documents, not questions: if two questions drafted from one passage landed in `train` and `dev`, a system tuned on `train` would have seen the passage of a `dev` answer. The cell checks on every item that its anchors and spans lie in documents of its own split and that each anchor chunk serves at most one answerable evaluation item.

Whether a question has a relevant chunk depends on how the book is cut. `gold_chunk_ids` calls a chunk relevant if it overlaps a gold or alternative span by at least half of the span's characters or half of the chunk's, the rule of Section 19.4. We need it for two ways of cutting, since the next section compares them: the section chunks of Section 19.4 (`sec512`: at most 512 tokens, cut at headings), and fixed windows of 256 tokens, cut without regard to the text, either without overlap (`fix256o0`) or overlapping by 64 tokens (`fix256o64`), so that a sentence cut at one boundary appears whole in the next.

The next cell checks that every answerable item has a relevant chunk under each chunking, and shows how differently two chunkings cut one gold span.

Every answerable item has a relevant chunk under all three chunkings, as the rules demanded. The gold span of `dev-0001`, the `load_array` question of the chapter's introduction, lies in two section chunks but in five overlapping windows, so "a relevant chunk among the first five" means very different amounts of text under the two chunkings.

19.5.2 The Pipeline and Its Measurements

A pipeline over this set has five stages (Figure 19.4). The query is the question, or a rewrite of it. First-stage retrieval and the optional reranking come from Section 19.4: BM25 and dense rankings fused by reciprocal ranks, then perhaps reordered by a cross-encoder. Context assembly decides which chunks enter the prompt, in what order, within a token budget, and the generator writes an answer with numbered citations or declines. Every stage but the first can be measured without the stages after it; the query shows itself only in what retrieval does with it. That property is what will let us locate a failure.

19.5.2.1 Context Assembly and the Prompt

Recall@k, the share of questions with a relevant chunk among the first k, cannot compare chunkings, since five section chunks hold more text than five windows. *Coverage at a budget* of T tokens, `cov@T`, fixes the amount of text instead: take chunks in rank order until the next would pass T tokens, and ask whether they hold at least half of one gold span.

`assemble_context` builds the real context the same way. It skips a chunk whose embedding has a cosine above 0.95 with one already taken, since a near duplicate adds tokens and no information. It then orders the chunks by rank, in reverse (the best next to the question), or with the best at both ends (`edges`). The last order is there because language models use the start and the end of a long context better than its middle (N. F. Liu et al. 2024).

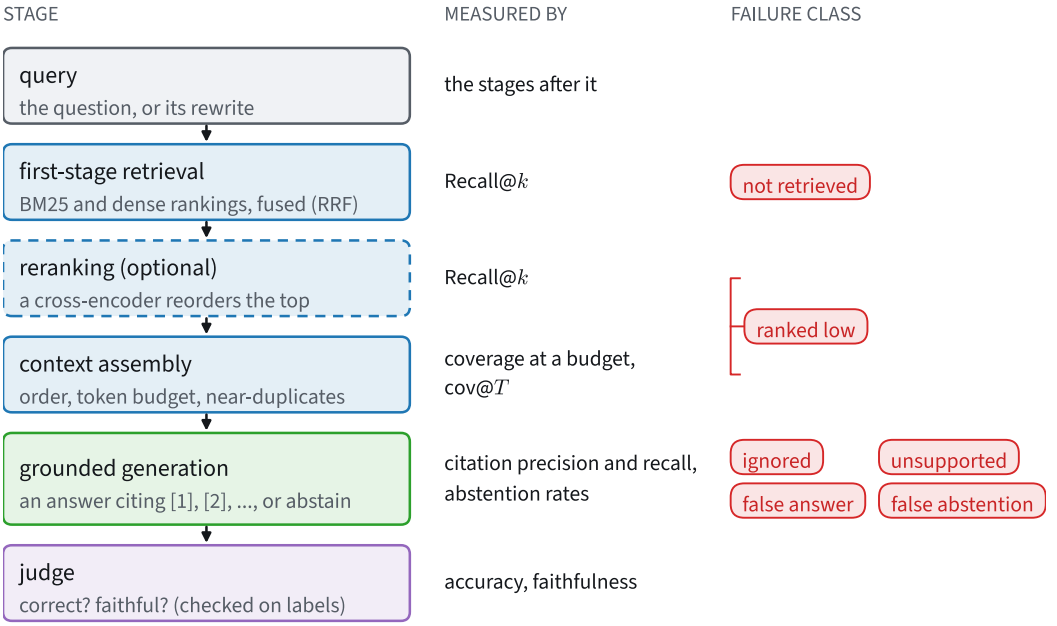

Figure 19.4: The five stages of the retrieval-augmented generator, top to bottom, with the measurement that sees each one on its own. The judge below them is not a stage but the instrument that grades the answers, giving accuracy and faithfulness. The failure classes on the right blame a wrong answer on the first stage that lost it; they are defined and counted in the next section.

The prompt is fixed. It asks for an answer from the numbered passages, each shown under its heading path, a citation after each statement, and, if the passages lack the answer, exactly the sentence "I cannot answer this from the provided passages." Without passages it becomes the closed-book prompt. The stage changes of the next section alter the context or the query and leave this prompt alone. Of all the details in this subsection, the abstention sentence matters most for the scores: it alone decides every unanswerable question.

`RAGPipeline` puts the pieces together. It is long because it carries every option that the next section switches on, and a first reading needs only `prepare` and `answer`. They run in three phases, so that the generator never generates while the embedder and reranker share its GPU. The generator writes a rewritten query if one is asked for. The retriever searches, reranks and assembles while the generator waits. Then the retriever's models leave the GPU, and the generator answers greedily, in left-padded batches of eight. Two query options, `hyde` and `decompose`, are never switched on in this chapter and can be skipped; Section 19.7 describes both.

19.5.2.2 A Judge for Free-Text Answers

Answers in free text cannot be graded by string match: "`is_train` is passed as `shuffle`" and "the data are shuffled exactly when `is_train` is true" give the same answer in different words. They need a grader that reads. `rag_judge` shows a second model, Qwen3.8-27B with thinking on, the question, the reference, the key facts, the passages and which of them the answer cites, and asks for verdicts. The first is the one accuracy rests on: an answer is *correct* if it states every key fact and nothing that contradicts the reference.

Two more verdicts ask where the answer came from, which is what a user who wants to check it relies on. An answer is *faithful* if every factual statement in it is supported by the passages in its context, whatever the reference says, and *supported* if the passages it cites suffice on their own. The three can disagree in every direction. An answer from memory can be correct and unfaithful; one that faithfully repeats an incomplete passage, faithful and wrong. The subtle case is the third: an answer that draws on passage [1] but cites only [2] is faithful and unsupported, since the support is in the context but the citation points elsewhere.

Some scores need no judge. Answers to unanswerable questions are decided by string match: a reply that contains the abstention sentence is correct, alone or after an explanation, and any reply without it, however politely it declines, counts as an answer and is incorrect. A reply with the abstention sentence to an answerable question is incorrect too. *Citation precision* is the share of cited passages that are relevant, and *citation recall* the share of relevant passages in the context that the answer cites.

19.5.3 Baseline Answers

The baseline uses section chunks, hybrid retrieval, the first five chunks in rank order within 3,000 tokens, and the fixed prompt. We answer the 240 `dev` questions with it and with three other configurations. We call each such run an *arm*, borrowing the word for the groups of a clinical trial. The *closed-book* arm gives no passages: a floor. The *oracle* arm gives only the chunks of the gold spans, as a perfect retriever would: a ceiling for retrieval. (An unanswerable question has no gold span, so there the oracle keeps the retrieved passages.) And `base-repeat` answers the same questions with the same settings in other batches, which will tell us how large a difference noise alone produces.

Generator and judge each need whole GPUs. Before loading anything we estimate what fits with `d2l.config_memory` of Section 18.1.5: generation at eight prompts of 3,300 tokens, and at four of 6,300 tokens, about the length of the largest context of the next section; the retrieval phase, with the generator idle on its GPU; and the judge.

The generator's weights take 16.7 GiB, so it gets a whole 24 GB GPU. Its cache is small. Qwen3.5-9B is a hybrid of the kind described in Section 18.1.4: only 8 of its 32 layers store keys and values, and the others carry a state of fixed size, so eight prompts of 3,300 tokens need 1.2 GiB for cache and state together. The estimate of 21.3 GiB leaves out the allocator's slack. The peaks measured in the full runs, 21.7 GiB for these batches and 22.4 GiB for the four long prompts, still fit, so the batch stays at eight. The judge, a 27B model, fits on one card because its checkpoint stores four bits per weight, with a bf16 scale for every 128 weights (W4A16: 4-bit weights, 16-bit activations), except the input embeddings and the output matrix, which stay in bf16. Those two matrices, each a vocabulary wide, take 4.7 GiB of the judge's 16.4, more than a quarter. With the cache for eight requests in flight the estimate reaches 18.8 GiB. Each 24 GB GPU therefore holds a copy of its own, and the answers are split among the copies.

The next cell loads the recorded answers and lists the four arms of this section. A normal run also generates the first recorded batch again and compares the pipeline's batched generation with the plain decoding loop `d2l.generate` of Section 18.2; a difference would mean a padding bug.

Five section chunks hold about 1,700 tokens and never reach the budget, since five chunks of at most 512 tokens hold at most 2,560. The limit of five chunks, not the budget, bounds the baseline's context. (Budgets count tokens of the corpus's tokenizer, which differ from the generator's prompt tokens.) Answers run to about 110 tokens. The live batch reproduces the recorded answers, and the two decoding loops agree token for token.

19.5.3.1 Checking the Judge

Every accuracy from here on rests on a model's verdicts. Why should we believe them? We answer in two steps: first we look at the verdicts themselves, then we check them against labels made without the judge.

The next cell loads the recorded verdicts on every answer of this section and the next, and judges twelve of them again from the judge's recorded replies, which needs neither a GPU nor a key. Thinking has a drawback here: a judge that reasons at length can run out of tokens before it gives a verdict. We therefore allow up to 12,000 new tokens, reasoning included, and ask once more, showing the reply, when a verdict comes back malformed. An answer still without a verdict is *unjudged*. It is left out of accuracy and of the failure counts, rather than blamed on the generator.

The replayed verdicts match the recorded ones, and every answer of the four arms has a verdict.

The judge itself was chosen by measurement. Two frontier models from other families, Claude Opus 5.5 and Gemini 4 Argon, labeled 200 answers of an earlier, smaller generator, Qwen3-4B, and nine Qwen candidates of three sizes judged the same answers, with thinking on and off. With thinking off every candidate was lenient, passing many answers that both labelers call wrong. With thinking on, a judge works through the key facts before it decides, which is what catches a missing fact; the smaller candidates, however, often reasoned until their replies were cut off, and agreed less with the labelers. Half of the 200 answers served

this choice, and the other 100 tested it. The chosen judge then ran with 8-bit weights; with 4-bit weights it must pass the test again. That set has a second flaw: our generator is stronger than Qwen3-4B, and its mistakes may be subtler. The same two labelers therefore also labeled 100 base answers of Qwen3.5-9B on `dev`, the *calibration set*. The next cell compares the judge, on both sets, with each labeler and with their *consensus*, the answers on which both agree. On `correct`, ten of the hundred verdicts of the calibration set are the rule's rather than the judge's, because the answers abstain.

We accept a judge whose agreement with the consensus is at least 0.8 and whose κ interval stays above 0.4, well clear of chance. On the earlier set the judge passes easily. It agrees with the consensus on 97% of the `correct` verdicts and on 94% of the `faithful` ones, with κ of 0.91 and 0.80, and it passes none of the 21 answers that both labelers call wrong. These numbers flatter, because the consensus leaves out the hard answers on which the labelers disagree. The fair comparison is with each labeler alone. There the judge reaches κ 0.89 and 0.77 on `correct`, and the labelers reach 0.81 with each other: the judge is about as reliable as a third labeler. The judge it replaced, a 4B model with thinking off, passed 14 of those 21 wrong answers, which is the leniency the selection was meant to remove.

On the answers of our own generator the same rule rejects the judge, and κ tells us little about why. The judge agrees with the consensus on 97% of the `correct` verdicts and on 98% of the `faithful` ones, yet κ on `correct` is 0.00, with an interval from 0.00 to 1.00. This is the effect we met with the checker and the verifier: Qwen3.5-9B answers well, and of the 93 answers on which the labelers agree they call only 3 wrong. With so few wrong answers, nearly all of the agreement is the agreement that the shares alone predict, and the interval says that κ could be anything. The three answers do tell us something, though. Each leaves out one key fact, and the judge passes all three: it is lenient about an omitted fact, the generator's most common mistake. The labelers agree with each other less than on the earlier set, with κ 0.47 on `correct` and 0.64 on `faithful`. As the rule prescribes, claims that rest on the judge carry its agreement rather than κ. The leniency also sets a direction. On these answers the judge errs toward passing, so the accuracies it reports are, if anything, too high. A last limit no calibration on these labels removes: the labels come from models, not from people.

A practical note for readers who want to regenerate the verdicts. This takes vLLM, an inference server that batches many requests on the GPU, here one copy of the judge's 4-bit weights on each 24 GB GPU. vLLM pins its own PyTorch, so it lives in an environment of its own (`uv venv`, then `uv pip install vllm==0.33.0`), whose `vllm` executable the variable `D2L_VLLM` names. Without such a GPU the same model, in bf16, can be called on OpenRouter for about $3 per 1,000 judgments. Other weights give other verdicts on some answers, however: on the 198 labeled answers of Qwen3-4B, the judge's 8-bit and 4-bit builds disagree on `correct` for about one answer in fifteen.

19.5.3.2 The Baseline Report

Before the averages, one answer. The chapter began by asking how the book's old `load_array` helper decides whether to shuffle its data, and the retriever of Section 19.4 ranks the passage that says so first. The next cell prints what the generator replies to that question without passages and with the baseline's five, each with the judge's verdicts.

Without passages the generator invents a plausible mechanism, a `shuffle` argument that the caller sets, and never mentions `is_train`; the judge marks the answer wrong. With the five retrieved chunks it says that `is_train` is passed to the `DataLoader` as `shuffle`, which is the book's answer, and it cites the passage it took this from. This is the system doing what it was

built for: the judge calls the answer correct, faithful and supported.

In the report each rate carries a 95% interval that resamples documents, since questions drafted from one document share its difficulty, and each difference between arms is paired over the same questions (Section 18.5, Section 36.5.2.6).

One row of the report is worth predicting before it is read. `base-repeat` sends the same 240 prompts to the same model with greedy decoding, and only the neighbors in each batch of eight differ. How many of its answers will change?

Not one of the 240 contexts changed, yet 95 of the 240 answers did: 40%. Accuracy moved by less than its noise: the difference is -0.017, with an interval from -0.04 to +0.01 that includes zero. Nothing is broken. When the padding of a prompt's batch changes, so does the shape of every matrix product, and the GPU may add the same bf16 numbers in another order; the logits move by a few rounding steps. Wherever the two likeliest tokens are nearly tied, that flips the greedy choice, and from that token on the answer takes another path. Section 18.1.5.3 met the same near-ties when it changed a batch from one prompt to two.

Greedy decoding is therefore deterministic only for a fixed batch, precision and kernel. An evaluation must batch the configurations it compares alike, or count re-batching as noise (Section 18.4). Here re-batching moves accuracy by up to about 0.04, and a change to the pipeline has to do better than that before we believe it. The judge's server batches its requests too, so the same effect reaches the verdicts: judged again with twice as many requests in flight, 5 of 54 answers changed a verdict. Every arm was judged at the same concurrency, so this noise widens the paired intervals rather than favoring one arm.

With the size of the noise known, the rest of the report reads quickly. A relevant chunk is among the first five for 97% of the answerable questions: retrieval is nearly solved here. That should not surprise us. The questions were drafted from the book's passages and, like the first example, often reuse their words, and Lee et al. (2019) observed that when the people asking already know the answer, BM25 alone retrieves well. With those chunks the generator answers 0.91 of all `dev` questions correctly, and without them 0.32, a gain of about 0.6. The closed-book score is not zero, nor should it be: the book is public, and some questions ask for general knowledge. On the 145 answerable questions that the checker marked as specific to the book, closed-book accuracy falls to 0.15, against 0.91 with retrieval. That pair of numbers is the case for retrieval. Nor do the passages merely jog the generator's memory: the baseline answers about nine in ten answerable questions correctly, both where the closed-book arm was right and where it was wrong.

The answers mostly come from their passages. The judge calls 0.93 of them faithful and finds the cited passages sufficient for 0.87. Citation precision is 0.72 and recall 0.88; precision from gold spans is strict, since a citation of a supporting passage that is not gold counts against it. The baseline abstains on 19 of the 20 unanswerable questions and on 1% of the answerable ones.

The oracle arm answers 0.93 of all questions. Its context holds a relevant chunk for every answerable question, which is why its citation precision is 1.00 by construction, and its Recall@5 and coverage are `n/a`: it bypasses the retriever. Nor are its answers more faithful: 0.94 against the baseline's 0.93, a difference whose interval runs from -0.03 to +0.04. On the answerable questions its gain over the baseline is +0.02, with an interval from -0.03 to +0.07, and cannot be told from zero. Why so little? Call a question a *hit* when its context holds a relevant chunk. Let h be the share of hits among the answerable questions, and a_1 and a_0 the accuracy on hits and on misses. Then the accuracy on the answerable questions

is

$$\text{accuracy} = h\, a_1 + (1 - h)\, a_0. \tag{19.17}$$

Accuracy is a mixture of how often retrieval succeeds and how well the generator does in each case. Here 213 of 220 contexts hold a relevant chunk, $h = 213/220$, with $a_1 = 0.93$, and $a_0 = 0.29$ on the seven misses. A perfect retriever can only turn those seven misses into hits. If the accuracy on hits stayed at a_1, it would add $(1-h)(a_1-a_0) \approx 0.032 \times 0.64 \approx 0.02$: there is no room left for retrieval to show a gain, and the oracle's +0.02 matches that estimate. The bold step is the assumption that a_1 stays put. The oracle passes only the gold chunks, about 480 context tokens against the baseline's 1,700, and so also removes passages that might distract the generator. Whether that raises the accuracy on hits, 240 questions cannot tell.

Of everything in this section, the decomposition Equation 19.17 is the result to remember. Before a single change has been tried, it says which stage to improve first, and here it points at the generator: of the 20 errors on answerable questions, 15 were made with a relevant passage in the context.

The wrong answer that opened this section is one of those fifteen: its passage was in the context, ranked first. Which stage lost each of them, and would another chunking, query or context have saved some? Section 19.6 changes one stage at a time and sorts the failures by stage.

19.5.4 Summary

When a retrieval-augmented generator answers wrongly, one accuracy number cannot say which of its stages failed, although each stage needs a different repair. Locating the failure takes instruments: questions over the corpus with known answers and gold spans, here drafted and checked by models rather than people; a judge checked against independent labels before any accuracy is read; and a measurement of each stage on its own, between a floor without passages and a ceiling with only the right ones. On this book the baseline answers 0.91 of the `dev` questions against 0.32 without passages. Retrieval is nearly solved, the decomposition $h\, a_1 + (1 - h)\, a_0$ leaves a perfect retriever almost nothing to add, and most wrong answers had a relevant passage in the context: the generator limits accuracy. Greedy decoding in bf16 also depends on the batch, which changed 40% of the answers and not accuracy.

19.5.5 Exercises

1. code **The position of the answering passage.** Take the answerable `dev` questions whose baseline context holds exactly one relevant chunk. Build contexts of five chunks with the relevant chunk at positions 1 to 5 and the other four in rank order.
   1. Predict how accuracy depends on the position, then measure it, with paired intervals against position 1. Judging needs the judge server on a 24 GB GPU of its own. With one GPU, measure instead how often the answer cites the relevant passage at each position, which needs no judge.
   2. Does the result show the dip in the middle that N. F. Liu et al. (2024) found in long contexts? Build longer contexts from more chunks of the book until it does,

or until 6,000 tokens, and report the length at which the middle positions fall behind, if any. With one GPU, again count citations of the relevant passage instead of judging.

2. code **Citation precision against support.** Citation precision from gold spans counts every cited passage that is not gold as a mistake.
   1. Collect the baseline answers that cite at least one passage outside the gold chunks. Read 20 of them with their passages and count the citations that do support their sentence.
   2. Compare citation precision with the judge's `supported` verdict per answer. On how many answers do they disagree, and on your 20, which of the two is right more often?
3. **Which stage to improve first.** A colleague's pipeline puts a relevant chunk in the context for 90% of the questions, and its accuracy is 0.7 with one and 0.2 without.
   1. Use Equation 19.17 to compute its accuracy, and its accuracy with an oracle context, assuming that the accuracy given a hit stays at 0.7. Which gains more: a perfect retriever, or raising the accuracy given a hit to 0.8?
   2. Why is "the accuracy given a hit stays at 0.7" an assumption? Name a way in which a perfect retriever would also change the accuracy given a hit, and say why the oracle arm of this section cannot tell whether it does.
   3. Suppose two configurations disagree on 10% of 240 questions. Estimate the standard error of the paired difference in accuracy, and the smallest gain a 95% interval would separate from zero. Which of the two improvements could 240 questions detect?
4. **Agreement without information.** On whether an item's answer is unique, the verifier and the checker agree on 96% of 536 items, with $\kappa = 0.00$.
   1. Write down a table of counts over the 536 items (both pass, only the verifier passes, only the checker passes, both reject) with agreement 0.96 and $\kappa = 0$. What must one of the two raters do?
   2. Show that $\kappa = 0$ exactly when the share of items that both reject equals the product of the two raters' rejection rates.
   3. A judge passes 95% of the answers, and a labeler 90%. What is the largest κ the two can reach, whatever the answers? What does this mean for comparing κ across sets of answers that a generator gets right at different rates?
5. code **Hand labels against the verifier.** Draw 20 `dev` items and 10 candidates that the frontier verifier rejected (from the recorded responses of `lm-book-qa-api-cache-v1`), with seed 0, and hide which is which.
   1. For each, read the question, the reference and the gold span, and decide yourself whether it stands alone, whether the reference is supported and complete, and whether the answer is unique.
   2. Compute your agreement with the verifier and Cohen's κ, with a bootstrap interval. What can 30 items show, and what can they not?
   3. Read the items on which you disagree. Are they errors of the model, or of yours?

19.6 Failures and Fixes in Retrieval-Augmented Generation

Suppose you have built the pipeline of Section 19.5 and are looking at the 21 `dev` questions it gets wrong. The natural impulse is to start fixing. Most people who build such systems have a favorite repair: smaller chunks, a rewritten query, more passages in the prompt, a sterner instruction to the generator. Each is plausible, and each has a paper that reports a

gain. Yet this baseline already puts a relevant chunk into the context for 213 of the 220 answerable questions, and the wrong answer that opened Section 19.5 had its passage ranked first. Which of the favorites can help a system like that, and how would we know?

In this section the measurements choose. We change one stage at a time and compare with the baseline on the same questions. We sort the wrong answers by the first stage that lost them. And we test the repair of the largest class, written down before any failure was counted, while 240 `test` questions are read only once. None of this is new: medicine has run its clinical trials this way for decades, with a control measured on the same patients and an analysis fixed before the data come in. Here the procedure will matter more than any of the repairs. A short derivation then asks whether the answers alone could teach the retriever which passages the generator can use. The section ends on the question that longer context windows keep raising: is retrieval needed at all when whole chapters fit into the prompt?

The first cells load what Section 19.5 built: its configurations, the corpus with its two retrievers, the recorded answers with the judge's verdicts, and the library's helpers for paired intervals. They hold no new idea, and a first reading can skip to Section 19.6.1. As there, a normal run replays the recorded answers and verdicts, and `D2L_RERUN` regenerates them.

19.6.1 Changing One Stage at a Time

Before we generate a single answer, we already know roughly how much a change on the retrieval side can gain. Accuracy on the answerable questions is a mixture of the accuracy on hits, the questions whose context holds a relevant chunk, and the accuracy on misses (Section 19.5). The baseline has 213 hits among 220 answerable questions, so a perfect retriever could add about 0.02, well inside the paired intervals of about ± 0.03 that 240 questions give. Retrieval has almost no room left on this book, because the questions were drafted from its passages and reuse their words (Section 19.3); on a harder collection the balance can reverse. Changes to the order or the length of the context act on how the generator reads, and the mixture does not bound them.

Chunking comes first, because it can be measured before any answer is generated. Section chunks follow the book's headings and paragraphs. Fixed windows of 256 tokens, overlapping by 64, are cut without regard to the text. Which of the two covers more? Recall@k cannot compare them fairly, since five section chunks hold more text than five windows. Coverage at a budget of T tokens, the `cov@T` of Section 19.5.2, fixes the amount of text instead: it is the share of answerable questions whose first chunks, taken in rank order up to T tokens, hold at least half of a gold span.

Section chunks cover more when the budget is tight: 0.91 of the questions at 1,000 tokens against 0.86 for windows, a gap of 0.05 whose interval excludes zero. A section holds a span whole where a window may cut it, and overlapping windows spend part of the budget on text they repeat. By 3,000 tokens both find room, and the gap shrinks to 0.01, well within noise.

Coverage says that the gold text is in the context, not that the generator uses it. For that we must generate. Each configuration that answers the questions is an arm of the experiment, as in Section 19.5. The baseline fuses the BM25 and dense rankings by reciprocal ranks and passes the first five section chunks, best first, with no reranker. The next cell answers the 240 `dev` questions with five arms that change it:

- fixed windows instead of section chunks, each question getting at most the tokens of its baseline context;

- the question rewritten by the generator as a search query, with the reranker reordering the fused top 50;
- the baseline context in reverse order, the best chunk next to the question;
- a budget of 1,500 tokens, filled in rank order without the limit of five chunks;
- the same with a budget of 6,000 tokens.

The second arm bends the rule of one change at a time, and on purpose. A rewritten query can drift from the question, so it is tested together with a guard: the reranker reads the original question and reorders what the rewrite found. The arm therefore adds two stages to the baseline, and its result belongs to the pair.

A sixth arm is a control rather than a candidate. Packing stops before the window that would pass the baseline's tokens, so fixed windows get slightly fewer context tokens than the baseline, and a loss could come from the missing tokens rather than from the cut. The control, `fixed-over`, packs windows until they pass the baseline's tokens by less than one window, and so gets slightly more context than the baseline.

No change raised accuracy measurably. The only gain, from the 6,000-token budget, is about +0.01, with an interval from -0.03 to +0.05; reversing the order and the rewrite with reranking come out about level with the baseline. On the retrieval side this is what the mixture predicted. On the generator's side it is a finding: the generator did not read measurably better for a different order or for three times the text.

The two losses teach more. Fixed windows lost 0.09. They had a little less context than the baseline, about 1,600 tokens against 1,700, but the control rules the token count out: with about 1,800 tokens, windows still lost 0.05. Coverage accounts for less than half of the loss. At budgets near the windows' own, their coverage trails by 0.02 to 0.05. A question that drops out of coverage falls at worst from the accuracy on hits to the accuracy on misses, about 0.6 lower, so such a gap could cost at most about 0.01 to 0.03. The rest is the cut itself, and coverage is blind to it: it counts half a gold span as found, and a window can hold that half and cut off the key fact in the other (Exercise 7). Chunks that follow the document's structure keep a paragraph whole, and they gave better answers.

Less context costs accuracy where coverage falls. The 1,500-token budget, about 1,300 context tokens, lost 0.06, and coverage drops from 0.97 at 2,000 tokens to 0.91 at 1,000. More context, by contrast, did nothing for accuracy: the 6,000-token budget, about 5,800 context tokens, gained nothing measurable and doubled the time per answer.

A rule fixed in advance carries the stage change with the largest `dev` gain to `test`, read once, to see whether a gain this small survives fresh questions. The cell's last line names the 6,000-token budget, ahead of the others by two verdicts in 240. But `test` has been read already. It was read once, with the verdicts of the judge's earlier 8-bit build, when the same rule named reversing the order. A test set read again after every change of the verdicts would become development data, so we do not read it again: the reversed order is the stage change that `test` was read with, at the end of the next subsection.

19.6.2 Failures by Stage

No change helped on average. Perhaps the 21 wrong answers fail in different ways, each needing its own repair, and an average over them hides that. To find out, `classify_failure` asks six questions of each wrong answer, in pipeline order, and blames the first stage that lost the answer:

1. An unanswerable question was answered: a *false answer*.
2. No relevant chunk is among the first-stage top 50: *not retrieved*.
3. A relevant chunk is in the top 50 but not in the context: *ranked low*.
4. A relevant chunk is in the context and the answer abstains: a *false abstention*.
5. A relevant chunk is in the context and the answer, faithful to the passages, is incorrect: *ignored*. The answer stays within the passages and still misses a key fact that one of them holds.
6. A relevant chunk is in the context and the answer is not faithful: *unsupported*.

The order matters more than the names: the first question that holds decides, so every wrong answer gets exactly one class. The names, in turn, describe what the answer did, not why; *ignored* says that the fact was there and did not make it into the answer, which is all the rule can see. Figure 19.4 places each class beside its stage.

Each class has its own repair (Table 19.5), written into `d21.RAG_FIXES` with the configurations of Section 19.5 before any class was counted.

Table 19.5: The failure classes, the stage each blames, and the fix written down for it before the failures were counted.

class	stage	fix written down in advance
not retrieved	first-stage retrieval	fuse a third ranking, for the rewritten question, with the BM25 and dense rankings
ranked low	reranking, assembly	rerank the top 100 and pass eight chunks
ignored	generation	quote the supporting sentences, then answer; best passages at both ends; room for 500 new tokens
unsupported	generation	drop each sentence that its cited passages do not support, as the generator judges
false answer	generation	abstain below a reranker score tuned on `train`
false abstention	generation	state the abstention rule after the passages

Why write the fixes down first? A fix chosen after reading the failures is fitted to them, and its gain on the same questions is optimistic, like any choice made on test data. With the remedies fixed in advance, the data decide only which class is largest, and the notebook takes that decision by rule. Experimental science calls this *pre-registration*: the analysis is written down before the data are seen. It is the hard discipline of this section, because it forbids the one thing we most want to do after reading a failure, which is to invent a fix for it.

The next cell counts the classes with intervals and prints five *failure cards*, records of a failure with its question, answer, ranking and verdicts. The judge's three verdicts are those of Section 19.5: an answer is correct if it states every key fact, faithful if the passages support every statement in it, and supported if the passages it cites suffice on their own. Claude Opus 5.5 also read each card and labeled its class, and the cell compares these labels, again a model's, with the rule's.

None of the 21 failures happened at first-stage retrieval, which is what the hit rate led us to expect. Ignored is the largest class, 8 failures or 0.38 of them, but its interval, [0.19, 0.57], overlaps that of unsupported, 7 failures and [0.14, 0.52]. Twenty-one failures are a small sample to divide six ways, and they cannot say which of the two classes is larger.

The last column shows what the two largest classes have in common. Five of the 8 ignored answers cite a passage that holds the answer, and so do all 7 unsupported ones. In these answers the generator found the right passage and even pointed to it. Then it left out a key fact that the passages state, or added a claim that they do not support.

How far can we trust the classes? Each of the 21 failures has a card, and the labeler agrees with the rule on 12 of them, 0.57. It calls 4 correct and blames another stage on 5. The four are answers that the labeler accepts and our grading does not. In three the judge insists on a key fact that the labeler finds stated, if clumsily. In one, an unanswerable question was declined in words other than the abstention sentence of Section 19.5, "I cannot answer this from the provided passages", which is the only reply our grading counts as declining. Of the five other attributions, three trace an unsupported answer to a relevant chunk that was ranked below the context: the answer went beyond its passages because the passage it needed was missing.

Rule and labeler disagree about whether an answer is wrong about as often as about where it went wrong. The two largest classes fare differently, which matters for what comes next. The class the rule is about to pick, ignored, is the one the labeler confirms most often: 6 of the 8 answers. Of the 7 unsupported answers it confirms only 2, and blames 3 on ranking.

Let us return to the answer that opened Section 19.5. It was picked by a fixed rule: the first `dev` answer, by question id, whose context held a relevant chunk, that the judge called incorrect, and whose card the labeler gave the same class as the rule. With two graders required to agree, the example is unlikely, though not certain, to be a judge error.

The answering passage was ranked first, and its last sentence, printed above and quoted at the start of Section 19.5, holds the missing key fact. The answer cites passages two and three and leaves out that no warning is given. The passage was neither missing nor contradicted. It was ignored. And the missing fact is the one a user needs most: nothing tells you that part of your model is not training.

The rule takes the class with the most failures, ignored, although 21 failures cannot rank it above unsupported; a rule fixed in advance decides anyway, which is what it is for. Its fix asks the generator to quote before it answers: to copy the sentences of the passages that answer the question, each with its passage number, and only then to write the answer. A fact that has been copied out should be harder to leave out. The fix also places the best passages at both ends of the context, the positions a model reads most reliably, and allows 500 new tokens instead of 300, since the quotes come first.

This is not the fix that `test` was read with. With the judge's earlier 8-bit build the unsupported class was the larger, by 11 failures to 10, so the rule picked the fix for unsupported answers, and `test` was read once, with that fix and with the reversed order. That fix checks the answer after it is written. The answer is split into sentences, and the generator is asked of each one whether the passages it cites support every fact in it, a yes or no read off the two labels' probabilities, as the reranker reads its score. A sentence the check rejects is dropped, and so is a sentence that cites nothing, since nothing can support it; an answer with no sentence left abstains. With the 4-bit judge the two classes changed places, by one failure, which is within the noise of 21 failures. We do not read `test` again for the new choice. The cell runs

the fix for ignored answers on `dev` only, and reports both fixes on `dev` and, where they were read, the earlier fix and the reversed order on `test`.

Neither fix worked. The fix for ignored answers lowered `dev` accuracy from 0.91 to 0.83, by 0.08 with an interval from -0.14 to -0.04, and the class it aimed at grew instead of shrinking, from 8 ignored answers to 17. Copying sentences out did not make the generator state the fact it needed. The larger damage came from an unexpected side: the baseline declines 19 of the 20 unanswerable questions, the fix only 7, so false answers rose from 1 to 13. Asked for quotes, the generator found sentences to quote in passages near the question and answered from them, or explained in its own words that the passages fall short, without the abstention sentence that our grading counts as declining. The fix lost 16 answerable questions that the baseline got right, 11 of them to the ignored class itself.

The fix for unsupported answers did worse. It lowered accuracy from 0.91 to 0.77 on `dev` and from 0.86 to 0.78 on `test`, by 0.15 and 0.09, and both paired intervals exclude zero. Yet it did what it was built to do: citation precision rose, by 0.02 on `dev` and 0.04 on `test`, with intervals above zero. The answers it kept cited their passages better, and fewer of them were right. It lost 36 answerable `dev` questions that the baseline got right, and the class it aimed at hardly moved, from 7 unsupported answers to 6.

Where did the 36 go? Fourteen became false abstentions: nothing of the answer was left, and an empty answer abstains. Twenty-one became ignored: what was left was faithful to the passages and lacked a key fact. The check is only half of the fix. The other half drops every sentence that cites nothing, unread, since no passage can support it. That half assumes a generator that cites what it states, and ours does not always do so. Told to cite its passages, it may state the answer in one sentence and cite the passage in the next.

The first question it lost, which the cell prints, is the `load_array` question of the chapter's introduction. The baseline's answer said in three sentences, citing none of them, that `is_train` is passed to the `DataLoader` as `shuffle`; a fourth sentence cited the passage for all of them. The fix kept the fourth sentence alone: "This behavior is defined in the function signature and implementation within the provided code [1]." It is supported, and it answers nothing. Exercise 4 asks how many of the 36 were lost to uncited sentences alone.

Both fixes were chosen from `dev` failures, so `dev` could have flattered them; they lost there anyway, and for the one read on `test`, `test` agrees. Nor do we now search for a better fix, such as one that keeps uncited sentences: one found by looking at these results would need a fresh test set to be believed. Of the results in this section, this is the one to remember. Two plausible repairs, each written down before any failure was counted and applied by rule, made the system worse, and nothing in the failures they aimed at warned us. Whether a fix works depends on its mechanism and on the habits of the model it acts on, and only a run tests the two together.

The stage change fared no better than noise. On `test` the reversed order changed accuracy by +0.004, with an interval from -0.03 to +0.04, and on `dev`, with the 4-bit judge's verdicts, by -0.008. The earlier verdicts ranked it first among the stage changes and the new ones rank the 6,000-token budget first; `test` finds nothing either way. A rule that picks the largest of near-equal numbers picks noise. We do not read `test` again for any other change: a test set read again after every change made on `dev` becomes development data.

The plot shows these results at a glance. On the left, both fixes move failures into other classes: the quoting fix into ignored and false answers, the sentence check into ignored and false abstentions. On the right are the accuracy and citation precision on `dev` of the closed

book (the arm without passages), the baseline, the reversed order and the two fixes. The crosses are `test`, read once, for the baseline, the reversed order and the fix for unsupported answers: 0.86, 0.87 and 0.78. The last two lie inside their `dev` intervals, and the baseline's lies just below its own, which runs from 0.87 to 0.95. Accuracies of two independent sets of 240 questions differ by that much from noise alone; the differences from the baseline, which pair each question with itself, agree across the two splits. Every arm is compared with the baseline, not with the others.

Beyond these fixes lies a large literature that this section does not measure, from transforming the query and retrieving again during generation to retrieval learned with reinforcement learning, compressed contexts and structured indexes (Section 19.7). Each of these methods can be judged with the procedure of this section.

19.6.3 Marginalizing over Retrieved Documents

A dense retriever is trained on pairs of a question and a relevant passage, with a contrastive loss (Section 19.3). Nobody tells it whether the generator can use the passages it finds. Could the answers alone teach it that? Our pipeline cannot even ask, because it treats retrieval as preprocessing: passages are chosen, concatenated and read. The model that gave RAG its name (Lewis et al. 2020) treats the retrieved document as a hidden variable instead, which makes the system a probabilistic model whose query encoder and generator can be trained together. This is the only proof in our two sections on RAG. It is short, and its last line answers the question just asked.

Let x be the question, $y = (y_1, \dots, y_n)$ the answer and z a document. The retriever gives each document a score s_z and the probability $p(z \mid x) = \mathrm{softmax}(\mathbf{s})_z$, and the generator reads one document at a time. *RAG-Sequence* draws one document for the whole answer:

$$p_S(y \mid x) = \sum_z p(z \mid x) \prod_{t=1}^{n} p(y_t \mid x, z, y_{<t}). \tag{19.18}$$

RAG-Token may draw a new document for every token:

$$p_T(y \mid x) = \prod_{t=1}^{n} \sum_z p(z \mid x)\, p(y_t \mid x, z, y_{<t}). \tag{19.19}$$

RAG-Sequence asks which single document explains the answer; RAG-Token lets each token be explained by whichever document supports it. For one document the two coincide. The smallest case in which they differ has two documents and two tokens. Let $p(z \mid x) = (0.6, 0.4)$, let document 1 give the two tokens the probabilities 0.9 and 0.2, and document 2 give 0.1 and 0.8. Then

$$\begin{aligned} p_S &= 0.6 \cdot 0.9 \cdot 0.2 + 0.4 \cdot 0.1 \cdot 0.8 = 0.140, \\ p_T &= (0.6 \cdot 0.9 + 0.4 \cdot 0.1)(0.6 \cdot 0.2 + 0.4 \cdot 0.8) = 0.2552. \end{aligned}$$

Each document supports half of the answer, and only RAG-Token combines the halves: the multi-passage question in its smallest form. Our pipeline combines passages too, through attention over their concatenation, with one long prompt instead of one short pass per document.

The sum over the corpus is too large, so it runs over the k documents of largest $p(z \mid x)$, the retrieved set $\mathcal{K}$. What does that drop? Write $L_z = p(y \mid x, z)$, $p_S^{(k)}$ for the sum restricted to $\mathcal{K}$, and $m_k = \sum_{z \in \mathcal{K}} p(z \mid x)$ for the retriever's mass on $\mathcal{K}$. (Implementations usually renormalize $p(z \mid x)$ over $\mathcal{K}$; Exercise 1 shows that the bound below survives.) The dropped terms are nonnegative and each L_z is at most $\max_z L_z$, so

$$0 \le p_S - p_S^{(k)} = \sum_{z \notin \mathcal{K}} p(z \mid x)\, L_z \le (1 - m_k) \max_z L_z. \tag{19.20}$$

The truncation error is at most the probability mass that the retriever puts outside the retrieved set, since no L_z exceeds 1. A retriever with peaked probabilities loses little; one that spreads its mass can lose much, however good its ranking.

How does the generator teach the retriever? We differentiate the logarithm of Equation 19.18 with respect to a score.

Proposition. Let $p(z \mid x, y) = p(z \mid x) L_z / p_S(y \mid x)$ be the posterior over documents once the answer is known. Then

$$\frac{\partial \log p_S(y \mid x)}{\partial s_z} = p(z \mid x, y) - p(z \mid x). \tag{19.21}$$

Proof. Write $\log p_S = \log \sum_{z'} e^{s_{z'}} L_{z'} - \log \sum_{z'} e^{s_{z'}}$. The derivative of the first term with respect to s_z is $e^{s_z} L_z / \sum_{z'} e^{s_{z'}} L_{z'}$, the posterior; that of the second is $e^{s_z} / \sum_{z'} e^{s_{z'}}$, the prior. ■

Let us read the result. Since the posterior is $p(z \mid x)\, L_z / p_S$, the gradient is $p(z \mid x)(L_z / p_S - 1)$: a document's score rises when it explains the answer better than the documents do on average, weighted by the retriever's probabilities, and falls when it explains it worse. No label says which document was relevant. That is a great deal to learn from answers alone. But it is learned through the generator's eyes. If the generator ignores every document, L_z is the same for all, the posterior equals the prior, and the retriever learns nothing. If it ignores one relevant passage while others explain the answer well, the ignored passage falls below the average, and its score falls. So the answer to our question is a qualified yes: the retriever learns which passages the generator uses, and those are not always the relevant ones.

The form is general. Take any marginal likelihood over a latent choice z, and differentiate its logarithm with respect to the parameters of $p(z \mid x)$. The result is an expectation under the posterior, $\nabla \log p(y \mid x) = \mathbb{E}_{p(z \mid x, y)}[\nabla \log p(z \mid x)]$, the same posterior that the E-step of Section 36.7 computes. For a softmax prior it is posterior minus prior. The cell checks the gradient against autograd, the bound for every k, the two marginalizations for one and three documents, and the case by hand.

The gradient matches posterior minus prior to rounding error, below 10^{-16}; every truncation error lies at or below its bound (at $k = 5$, 0.028 against 0.037); and the case by hand gives 0.140 and 0.2552.

19.6.4 Cost and Long Context

Our pipeline concatenates instead of marginalizing, and every passage adds prompt tokens that the generator must read. What does each stage cost in time? The last cell reports the tokens and seconds per answer of each configuration, then times retrieval and reranking one question at a time.

First-stage retrieval is cheap, about 30 ms per question. Reranking 50 chunks is not: about half a second, nearly half the time the generator spends on a baseline answer. It is easy to forget that the reranker, a model of 0.6 billion parameters, reads 50 pairs of question and chunk for every question. The baseline does without it, and the stage experiment gave no reason to add it.

The prompt is the context plus the instructions and the question, about 240 tokens more. Generation time barely moves between 1,500 and 2,100 prompt tokens, about 1.1 to 1.3 s per answer. At 6,300 tokens it doubles, to 2.6 s, partly because such long prompts run in batches of four instead of eight. The rewrite with reranking takes about 1.9 s per answer, since the generator first writes the query and the reranker then reads 50 chunks.

That leaves the question that longer context windows keep raising. If the generator can read 6,000 tokens, why not whole chapters, and no retrieval at all? On this set three times the baseline's context gained nothing measurable, and the oracle of Section 19.5 shows that the generator, given only the right passages, still gets about one question in fourteen wrong. More text does not cure a generator that ignores what it already has. The agents of Chapter 27 take a third path and retrieve only when they decide that they need to. Whether whole chapters, at equal cost, would beat retrieval on the questions that need several passages remains open. Exercise 2 sets up the experiment.

19.6.5 Summary

One accuracy number does not say what to fix in a retrieval-augmented generator, and a favorite fix is a guess; this section let measurements choose. Changing one stage at a time, with paired intervals on the same questions, raised accuracy measurably nowhere: retrieval had no room, as the share of hits predicted, and the generator did not read better for another order or for more text. Fixed windows and a smaller budget lowered it. Sorting the wrong answers by the first stage that lost them split them mostly between answers that go beyond their passages and answers that miss a fact their own context holds, and 21 failures could not say which class is larger. Both fixes written down in advance lowered accuracy. Quoting before answering, for the ignored class, lost 0.08 on `dev` and broke the abstentions on unanswerable questions. Checking each sentence against its citations, for the unsupported class and the one fix read on `test`, lost 0.15 on `dev` and 0.09 on `test`, by removing sentences that carried the answer, among them uncited ones that the check never read: a change aimed at one class can create others. The original RAG model marginalizes over retrieved documents, and its retriever learns the posterior minus the prior: the passages the generator uses, which are not always the ones that are relevant. Whether whole chapters in a long context can replace retrieval remains open.

19.6.6 Exercises

1. **The truncation error and recall.** Start from Equation 19.20.
    1. Show that the bound is tight: give scores and likelihoods for which $p_S - p_S^{(k)} = (1 - m_k) \max_z L_z$.

   2. Suppose exactly one document z^* answers each question, and the retriever is calibrated: $p(z \mid x)$ is the probability that z is z^*. Show that the expectation of $1-m_k$ over questions equals the probability that z^* is not in the top k, one minus Recall@k.
   3. The baseline's five chunks hold a relevant one for 213 of the 220 answerable questions, so Recall@5 ≈ 0.97. What would the bound promise for RAG-Sequence over five documents if the retriever were calibrated? Why is a softmax over BM25 or dense scores rarely calibrated in this sense, and how would you calibrate it on `train`?
   4. Implementations usually renormalize the retriever's probabilities over $\mathcal{K}$ and use $p_S^{(k)}/m_k$. Show that the error $p_S - p_S^{(k)}/m_k$ can take either sign, and that its absolute value obeys the same bound.
2. [extended] **Long context against retrieval.** ●● Put whole chapters into the prompt instead of five retrieved chunks.
   1. Budget the memory first. From the configuration of Qwen3.5-9B (8 full-attention layers of 32, 4 key-value heads of width 256, bf16), compute the bytes of cache per token and the cache at 32,000 tokens, and check with `d2l.config_memory` whether such a prompt fits beside the weights on a 24 GB card. Compare with Qwen3-4B, whose 36 layers all attend.
   2. For the 20 `multihop dev` questions, build contexts of about 32,000 tokens from the documents of their gold spans, filled up with other documents of the book. Compare accuracy and seconds per answer with the baseline, with paired intervals.
   3. Which wins, at what cost, and can 20 questions in this many documents decide it?
3. **Two marginalizations.** Use Equation 19.18 and Equation 19.19.
   1. Show that RAG-Sequence and RAG-Token give the same probability for an answer of one token, whatever the number of documents.
   2. Is $p_T \geq p_S$ always? Prove it, or give a counterexample with two documents and two tokens.
   3. Which kind of answer does each marginalization favor, and which of them can a greedy decoder evaluate one token at a time?
4. code **What the check removed.** The fix of the unsupported class drops every sentence that cites nothing and every cited sentence that its check rejects. Use the recorded answers in `GENS`; no generation and no judge are needed.
   1. For each of the 36 answerable `dev` questions that the fix lost, compare the baseline's answer with the fix's, sentence by sentence. How many lost only sentences that cited nothing?
   2. Which question types have the most uncited sentences in the baseline's answers? Why might a generator leave the sentence that states the answer uncited and cite the one that explains it?
   3. Write down, before running anything, a variant of the fix that keeps uncited sentences, and predict its effect. Why may its result not be read on `test`, and what would it take to believe it?
5. code **Splitting the fix.** The fix written down for the ignored class, which the rule picks with the 4-bit judge, changes three settings at once: `RAG_FIXES['ignored']`.
   1. Define three arms that each change one of them: the quoting prompt alone (`dict(d2l.RAG_BASE, prompt='quote')`), the order with the best passages at both ends alone, and room for 500 new tokens alone. Before you run them, predict which carries the loss.
   2. Generate the three arms on `dev`, judge them with the local judge, and report each

paired difference with the baseline and each arm's failure classes. Without a 24 GB GPU for the judge, compare the abstentions on the unanswerable questions, which need no judge.

3. Compare with the bundle `fix-ignored`, recorded in `GENS`. Do the three effects add up to the bundle's? What does the answer say about writing a fix down in advance as a bundle, and why may these results not be read on `test`?

6. **Failure counts from two graders.** The labeler called 4 of the 21 failures correct.
   1. From the table of rule against labeler printed in Section 19.6.2, recount the classes with those four answers taken as correct. Does the largest class change?
   2. With the bootstrap of the failure cell, or with the normal approximation to a binomial share, compute an interval for the share of the largest class among the remaining failures. Can the classes now be ranked?
   3. What would it take to decide which grader is right on the four, and why would asking a third model not settle it?
7. code **Coverage of the whole span.** Coverage counts a question as covered when its chunks hold half of a gold span.
   1. Write a variant of `d21.cov_at_budget` that requires a whole gold span, and recompute the coverage of section chunks and fixed windows at 1,000, 2,000 and 3,000 tokens. (Without a GPU, use BM25 rankings for both.)
   2. Does the gap between windows and sections grow, and does it now come closer to the windows' loss in accuracy?
   3. Gold spans can cross a section boundary too. How often do they, and what would you change in the chunker?
8. code **A smaller generator.** Replace Qwen3.5-9B by Qwen3.5-4B of the same family and keep everything else fixed.
   1. Before you run it, predict which failure class grows most and whether the gain of the oracle context over the baseline becomes measurable.
   2. Regenerate the `base`, `closed` and `oracle` arms, judge them, and report the class shares with their intervals and the paired differences with the larger generator. Without a 24 GB GPU for the judge, compare what needs no judge: abstention rates, false abstentions and citation precision.

19.7 Further Reading

The retrieval-augmented system of Section 19.5 is plain on purpose. It scores passages with BM25 and with one vector per passage, fuses the two rankings, and hands the best five passages to a generator used as released. On this book the plain design worked well, and most of its wrong answers were made with the right passage already in the context (Section 19.6). A reader who builds such a system over other documents will soon want to change something. Should the index learn which words matter? Should a passage be more than one vector? Should the generator be trained for the job, or the context be so long that nothing needs retrieving? And once retrieval works, where should the effort go next, and how would one know that it helped?

The literature has an answer to each of these questions, usually several. This notebook collects those that change one mechanism of the chapter. Each entry names the problem a method addresses, the one thing it changes, and what that change costs. The first half stays with the representation of passages; the second takes retrieval and generation together. A reader with a working system and little time should start with three entries. Context around a Chunk is the cheapest change to an index that already works. Improving the Pipeline sorts

the many methods by the failure they repair, so that the failure counts of one's own system say which to try. And Evaluating the Pipeline is the reason to trust any of them.

19.7.1 Representations of Passages

19.7.1.1 Learned Sparse Vectors

BM25 (Section 19.4) scores a passage only by the words it shares with the question, with weights fixed by counts. A question that asks about a "container of layers" misses a passage that only ever says `nn.Sequential`. Dense vectors catch such paraphrases, but they need a nearest-neighbor index and can lose an exact identifier. SPLADE (Formal et al. 2021) keeps the inverted index and learns its weights.

Its encoder ends in a masked-token head like the one of Section 19.2, which gives, at every position i of a text t, a logit w_{ij} for every vocabulary entry j. The weight of entry j for the whole text is

$$\phi_j(t) = \sum_{i \in t} \log\left(1 + \max(0, w_{ij})\right),$$

and a passage d is scored against a question q by the sparse inner product $\sum_j \phi_j(q)\,\phi_j(d)$. The logarithm compresses a large logit, so that no single term dominates the vector. It is a soft cousin of BM25's saturation, but it acts on each position's weight, not on how often the term occurs. Because the head scores the whole vocabulary, a passage can receive weight on words it never contains. This is *document expansion*, the "expansion" of "sparse lexical and expansion model", which the name abbreviates.

Training uses the contrastive loss of Section 19.3 plus a penalty on the squared batch average of each ϕ_j. A search does work for every term active in both the question and the passage, so its cost grows with the square of how often a term is active, and the penalty is a smooth estimate of that cost: it punishes a term active in many texts far more than one active in a few, and drives most weights to zero. Compared with BM25, it needs one encoder pass per question and per passage and a larger index. Pyserini, a retrieval toolkit built on Lucene, searches such models with the inverted index it uses for BM25, and `naver/splade-v3` is a released checkpoint, under a non-commercial licence.

19.7.1.2 Late Interaction

The single vector of Qwen3-Embedding-0.6B compresses a passage of hundreds of tokens into 1,024 numbers before any question is known. The reranker of Section 19.4 avoids the compression by reading question and passage together, at the cost of a forward pass per pair, which made it by far the slowest stage of retrieval. ColBERT (Khattab and Zaharia 2020) sits between the two. It encodes every passage offline into one short vector per token, $\mathbf{v}_1, \ldots, \mathbf{v}_{L_d}$, encodes the question at query time into $\mathbf{u}_1, \ldots, \mathbf{u}_{L_q}$, and lets each question token find its best match in the passage:

$$s(q, d) = \sum_{i=1}^{L_q} \max_{1 \le j \le L_d} \mathbf{u}_i^\top \mathbf{v}_j.$$

Question and passage meet only in this sum of maxima, called *MaxSim*, after both were encoded separately. This is the "late" interaction, and it lets the passage vectors be computed once. Storage grows instead. At 128 coordinates per token, a passage of 500 tokens needs 64,000 numbers, about sixty times the single vector. ColBERTv2 (Santhanam et al. 2022) clusters all token vectors and stores each one as the index of its nearest centroid plus the residual, coded with one or two bits per coordinate. That is the coarse centroid of IVF from Section 19.4, applied to tokens, with a scalar code for the residual, a simpler relative of product quantization; the paper reports an index six to ten times smaller. `lightonai/GTE-ModernColBERT-v1` is a released ColBERT model built on ModernBERT, the encoder family of Section 19.2.

On this book, where one vector per passage already finds nearly every answer, late interaction has little left to find. Its extra storage is worth having where a single vector is too coarse, a limit that the last entry of this half makes precise.

19.7.1.3 From a Decoder to an Embedder

Many of the strongest released embedders, Qwen3-Embedding among them, start from a pretrained decoder rather than an encoder. Such a decoder has usually read far more text, but its causal attention lets a token see only what comes before it, so only the last position has seen the whole text. Section 19.3 took the simplest way out and pooled the last token. Three recipes show what else can change. E5-Mistral (Liang Wang et al. 2024) keeps the decoder as it is and pools its last token too. It fine-tunes a model of seven billion parameters for a short time with the contrastive loss, on labeled pairs and on pairs that a stronger model wrote for many tasks and languages. LLM2Vec (BehnamGhader et al. 2024) removes the causal mask, so that every token attends in both directions, and first teaches the model to use that freedom by predicting hidden tokens from both sides, as an encoder does, before contrastive training. NV-Embed (Lee et al. 2025) also removes the mask, and it pools with a small attention layer in which a trainable set of vectors reads the token vectors, in place of a mean or the last token. All three are large models: a decoder of seven billion parameters spends more than ten times the operations per token of Qwen3-Embedding-0.6B, on every passage of the collection.

19.7.1.4 Context around a Chunk

A chunk cut from the middle of a section often leans on what came before it: "this layer", "the loss above". The chunks of Section 19.4 are indexed with their heading path, "Chapter > Section > Subsection", which is a context header written by a rule. Two methods give a chunk more of its surroundings.

Contextual retrieval (Anthropic 2024) shows a language model the whole document and one of its chunks, asks for a sentence or two (50 to 100 tokens) that situate the chunk, and prepends the answer before both embedding and BM25 indexing. On the authors' collections of code, fiction, arXiv papers and science papers, the share of questions whose relevant chunk was missing from the top 20 fell by about half when both the embeddings and BM25 saw the prepended context, and a reranker on top lowered it further. The cost is one generation per chunk at indexing time, each with the whole document in its prompt, which prompt caching makes affordable, and another run whenever a document changes.

Late chunking (Günther et al. 2024) needs no generation. A long-context embedder reads the whole document once, and each chunk's vector is the mean of the token vectors inside the chunk's span. Every token vector has attended to the whole document, so the chunk

vector carries what its neighbors say, without any further training. Two costs come with it: the attention work grows with the square of the document's length, and every chunk of a document must be encoded again when one paragraph changes. The method needs bidirectional attention and an embedder trained with mean pooling. Qwen3-Embedding-0.6B has neither; the ModernBERT encoder that Section 19.3 trained has both, but it saw only short passages in training, so whether its vectors of long documents hold up is the first thing to measure.

19.7.1.5 Limits of a Single Vector

How many different answers can one vector per document give? The smallest case shows the problem. Embed every document as a single number x_i and the question as a number q. The score qx_i ranks the documents by x_i when $q > 0$ and by $-x_i$ when $q < 0$, so however many documents there are, only two top-k sets can ever be returned: the k largest and the k smallest. In two dimensions the ranking of n documents changes only where the direction of $\mathbf{q}$ crosses a line perpendicular to some difference $\mathbf{x}_i - \mathbf{x}_j$, at most $n(n-1)$ times around the circle. That allows at most $n(n-1)$ rankings, while the number of possible top-k sets, $\binom{n}{k}$, grows like n^k.

Weller et al. (2026) prove a bound of this kind for any dimension, with results from learning theory. For embeddings of dimension d, the number of distinct top-k sets of documents that some query can return is limited by d. The limit shows already for top-two results, and even when free vectors are optimized directly on the test queries. On their LIMIT dataset, built from very simple queries, state-of-the-art embedders fail. The result concerns one vector per document compared by an inner product. Learned sparse vectors are single vectors too, but with the vocabulary's tens of thousands of dimensions, so the bound bites far later. Late interaction keeps a vector per token and is not covered by the argument. On this book, where every retriever of Section 19.4 finds nearly every answer within ten, the bound is not what limits retrieval.

19.7.2 Retrieval and Generation

19.7.2.1 Training for Retrieval-Augmented Generation

In Section 19.6 the generator and both retrievers stay frozen. The marginalization derived there says what training would change: when the answer's probability is a mixture over retrieved documents, the gradient with respect to a document's score is its posterior weight given the answer minus its prior weight (Equation 19.21). A document gains score when it explains the answer better than the retriever expected, and loses score otherwise. Two lines of work train the retriever through this gradient. Two others leave the retriever alone and train the generator to use what it is given.

Joint training. RAG (Lewis et al. 2020) trains the query encoder and a sequence-to-sequence generator together on question answering by this marginal likelihood. The passage encoder and its index stay fixed: re-encoding the passages during training is costly, and the authors found it unnecessary for strong performance.

Retrieval in pretraining. REALM (Guu et al. 2020) moves retrieval into masked-token pretraining: the model retrieves a passage before it fills in a blank. The retrieved passage is a latent variable, and the retriever is trained by the same gradient. REALM updates the passage encoder too, so its index goes stale and is rebuilt asynchronously every few hundred steps.

Distractors. RAFT (T. Zhang et al. 2024) fine-tunes the generator on questions shown with the relevant document among distractors, toward chain-of-thought answers that quote the relevant passage. It targets the `ignored` failures of Section 19.6, where a relevant passage was in the context and the answer missed it. The fix written down in advance for that class asks for the same quoting by prompt alone. RAFT trains the quoting into the weights instead, at the cost of a fine-tuning run per domain, with distractors drawn from one's own retriever. Its training examples without the relevant document still target the answer, which teaches answering from memory rather than abstaining, so whether RAFT keeps the abstentions intact is a question for the procedure of Section 19.6.

Reflection tokens. Self-RAG (Asai et al. 2024) trains the generator to emit special tokens that decide whether to retrieve, judge whether a passage is relevant, and judge whether the generator's own sentence is supported. A critic model labels the training data with these tokens offline. At inference their probabilities rank candidate continuations, so each answer costs several candidate generations.

19.7.2.2 Long Context and Retrieval

If a model can read a million tokens, why retrieve at all? Three findings argue against dropping retrieval. First, every question re-reads its whole context, and more context did not give better answers: in Section 19.6 about three times the baseline's context gained nothing measurable and doubled the time per answer. Second, accepting a length is not using it. Models use the start and the end of a long context better than its middle (N. F. Liu et al. 2024), and an exercise of Section 19.5 measures this effect on the book. How much of its window a model actually uses, its effective context (Hsieh et al. 2024), is measured in Section 21.5. Third, Jin, Yoon, et al. (2025) find that for many long-context models the quality of answers first rises and then falls as more retrieved passages are added. They name retrieved hard negatives, passages that look relevant and are not, as a main cause. When many passages are retrieved, placing the highest-scoring ones at both ends of the context recovers part of the loss without training (the `edges` order of `d2l.RAGPipeline` does this), and fine-tuning on retrieved contexts recovers more.

Long context wins in two cases: a small collection read by many questions, whose shared prefix can be cached, and a question that needs a whole document at once, such as a summary of its themes. Everywhere else retrieval stays, because a model's knowledge is fixed when it is trained (Husain and Clavié 2025). A collection that changes after training, or that is larger than any window, has to be searched.

19.7.2.3 Improving the Pipeline

Each stage of Section 19.5 can be improved, and the failure classes of Section 19.6 say where to start. On the book no wrong answer lacked a relevant chunk in the ranking, a few had it ranked too low to enter the context, and most had it in the context and still went wrong. Methods aimed at the query have little to fix on such a collection, and methods aimed at the context and the generator have more. On a collection where retrieval is harder the balance can reverse, and the same counts would show it.

The query. HyDE (Luyu Gao et al. 2023) asks the generator for a hypothetical answer passage and embeds that instead of the question, so the dense side compares a passage with passages. RAG-Fusion (Rackauckas 2024) asks the generator for several rewrites of the question and fuses their rankings with the reciprocal-rank fusion of Section 19.4. Step-back prompting (H. S. Zheng et al. 2024) retrieves for a more general version of the question as

well as for the question itself. And decomposition, as in least-to-most prompting (Zhou et al. 2023), splits a question into sub-questions, each of which retrieves separately. All four target relevant chunks that were not retrieved or were ranked too low. Each costs a generation before retrieval and one more search per extra query. `d2l.RAGPipeline` has HyDE and a two-question decomposition built in (`hyde=True`, `decompose=True`), which Section 19.5 leaves unmeasured.

Several rounds of retrieval. A multi-hop question needs a second passage that only the first one reveals. The multi-passage (`multihop`) dev questions of Section 19.5 are where a reader can try these methods on the book. The methods differ in what decides that another search is needed. In Self-Ask (Press et al. 2023) it is the model's own follow-up question, answered with a search. In IRCoT (Trivedi et al. 2023) it is every step of a chain of thought, each new sentence serving as the next query. FLARE (Z. Jiang et al. 2023) drafts the next sentence and retrieves only when the draft contains tokens of low probability. Adaptive-RAG (Jeong et al. 2024) routes each question in advance to no retrieval, one round or several, and CRAG (Yan et al. 2024) scores the retrieved documents afterwards and searches again when the score is low. These methods target passages that one search misses, and their latency grows with the number of rounds. In Search-R1 (Jin, Zeng, et al. 2025) and ReSearch (M. Chen et al. 2025) the decision is a policy learned by reinforcement learning from the correctness of the final answer, with no labeled search steps, so the model itself decides when and what to search. At that point the pipeline has become an agent with a search tool, the subject of Chapter 27.

The context. RECOMP (Xu et al. 2024) trains an extractive compressor that keeps the useful sentences and an abstractive one that summarizes several documents. Both learn from whether the generator then answers well, and either may return nothing when retrieval did not help. LongLLMLingua (H. Jiang et al. 2024) deletes the tokens a small language model judges unnecessary for the question. Both target the `ignored` class and the cost of long contexts; the risk is deleting the one sentence that held the answer.

The index. Some questions are answered by no single chunk: what a whole chapter covers, or which themes run through a collection. RAPTOR (Sarthi et al. 2024) clusters chunk vectors, has a language model summarize each cluster, and repeats on the summaries, so that retrieval can choose among the levels of a tree. GraphRAG (Edge et al. 2024) has a language model extract a graph of entities and their relations, summarizes groups of closely related entities in advance, and answers a global question from those summaries. Both need language-model calls over the whole collection at indexing time, repeated when it changes. This book already has both structures, written by its authors: a tree of headings and a graph of cross-references. The chunks of Section 19.4 use only the tree, as headers.

19.7.2.4 Evaluating the Pipeline

Section 19.5 grades answers against reference answers with a judge model, checks the judge against labels before reading any accuracy, and finds it about as reliable as a third labeler. Those labels were written by two frontier language models, not by people, so a blind spot that labelers and judge share goes undetected.

Three other approaches each change one thing. RAGAS (Es et al. 2024) needs no reference answers. A language model splits the answer into statements and checks each against the context (faithfulness), and it generates questions back from the answer to compare with the original one (answer relevance). These scores measure what the context supports, not whether the answer is right. ARES (Saad-Falcon et al. 2024) fine-tunes small judges on syn-

thetic data and then corrects their estimates with a small set of labels written by people, through prediction-powered inference. With $f(x)$ the judge's verdict on an answer x and y_i the label of a labeled one, the judge's average over all N answers is corrected by its average error on the n labeled answers,

$$\hat{\theta} = \frac{1}{N}\sum_{j=1}^{N} f(x_j) - \frac{1}{n}\sum_{i=1}^{n} \left(f(x_i) - y_i\right),$$

so the estimate stays unbiased however wrong the judge is, and its interval widens with the judge's errors. Section 19.5 uses its labeled set only to measure the judge's agreement, and its labels come from models. ALCE (T. Gao et al. 2023) scores citations with an entailment model, the kind of classifier that Section 19.2 fine-tunes on MNLI: the passages cited for a statement must together entail it (recall), and each cited passage must contribute (precision). Section 19.5 computes citation precision from gold chunk ids instead, which counts a correct citation of a passage outside the gold set as an error.

Every grader in this subsection, the judge of Section 19.5 included, is a model, trusted only as far as it was checked against labels from people or from stronger models. How to grade a pipeline on a new collection when neither is at hand is an open problem.

Chapter 20

Data for Language Models

By now you can download a pretrained model and measure what it does (Chapter 18). The text it learned from was prepared by someone else and, for many released models, never published; yet preparing it is a large part of the work of training a language model. It starts from billions of web pages, and every decision made before the first batch changes what the model can ever learn: what to extract from a page, what to throw away, what to read twice, and how to cut the rest into tokens.

For a long time such decisions were made by rules of thumb and seldom published. The open corpora of the last few years publish the pipeline together with the experiments behind it, so that others can check a choice about data. This chapter builds one that a single machine can hold, from a record of a web crawl to a token in a file on disk. It measures what each step changes and writes every decision into a manifest, so that the corpus can be rebuilt from hashes, audited, and corrected when a page has to be removed.

The chapter moves in three steps. The first decides which documents exist: it extracts text from pages (Section 20.1), filters the text and audits whose pages the filters remove (Section 20.2), and takes out near-copies and leaked test items (Section 20.3). These steps are measured on the documents of a quarter of one Common Crawl archive file, each set beside the text that FineWeb, a released corpus, kept from the same record. The second step decides how often a model reads each kind of text, and there the measure is a model: small proxy runs choose the domain weights (Section 20.4) and test whether text rewritten by a model can stretch a source that has run short (Section 20.5). The third cuts the text into tokens and writes the files on which Chapter 21 trains the book's reference model (Section 20.6). The second and third steps start from FineWeb-Edu as released, which holds far more text.

Streaming the token files into training batches belongs to the next chapter, and the data that teach a model to follow instructions and preferences belong to Chapter 24 and Chapter 25. We assume you know byte-level BPE (Section 8.2), why bits per byte can compare models with different tokenizers (Section 18.4.3), how a paired comparison puts an error bar on a difference (Section 18.5), and what a text embedding is (Section 19.3).

The long computations, labelling pages with a model of 27 billion parameters and training dozens of small language models, ran once on four 24 GB GPUs, and their results ship with the book. Each notebook downloads them, checks them against its configuration and repeats a small part; without a GPU it skips what needs one and says so. Common Crawl grants

no licence for the pages it archives, so the book publishes only byte ranges and hashes, from which the notebooks rebuild the documents. No notebook calls a paid service.

Resources and Further Reading

The resources below accompany the sections of this chapter, and each names the section it goes with. All are freely accessible online. If you read only three, read the FineWeb blog post, the data chapters of the Smol Training Playbook and the pipeline guide of the `tokenizers` library: between them they cover how a filter is tested by training on its output, how a mixture is planned, and how a tokenizer is assembled. The chapter has no notebook of further reading.

Courses

- Stanford CS336: Language Modeling from Scratch has lectures on data sources, filtering, deduplication, mixing and tokenization, and an assignment that turns Common Crawl into filtered, deduplicated training data, the pipeline of Section 20.1, Section 20.2 and Section 20.3.
- Stanford CS224N and CMU 11-711: Advanced Natural Language Processing each give lectures to pretraining and its data, a shorter route through the questions of this chapter.
- Chapter 6 of the Hugging Face LLM Course trains tokenizers with the `tokenizers` library. Read it before Section 20.6 if the library is new to you.

Building a web corpus

- The FineWeb blog post describes how FineWeb chose its extractor, filters and deduplication by training small models on the output of each candidate, the method behind Section 20.1 to Section 20.3 and the proxy runs of Section 20.4. Take the method; its numbers belong to its scale.
- Common Crawl's getting-started page explains how its archives are organized and fetched, and the trafilatura documentation lists the extraction options that Section 20.1 compares with FineWeb's settings.
- Datatrove is the library that built FineWeb: readers, extractors, the heuristic filters that Section 20.2 checks its own rules against, and the MinHash stages of Section 20.3.
- The FineWeb-Edu dataset card gives the rubric, the classifier and the share of documents kept, the recipe that Section 20.2 rebuilds with a newer labeller. FineWeb-2 is its multilingual counterpart, whose slices Section 20.2 and Section 20.6 use.
- datasketch implements MinHash and banding and serves Section 20.3 as an independent check, and deduplicate-text-datasets is the suffix-array deduplicator whose method that section writes out on a small sample.
- The dataset cards of the Hugging Face Hub and Datasheets for Datasets set the standard for documenting a corpus that the manifest and card of Section 20.1 follow.

Mixtures and generated text

- The Smol Training Playbook plans the data of a small model from start to finish, with chapters on mixtures, annealing and synthetic data that accompany Section 20.4 and Section 20.5.
- The reference implementations of RegMix and DoReMi are the full-scale versions of the two methods that Section 20.4 builds in miniature, and the Dolma 3 pool card lists the sources behind the released mixture that the section reads as a case study.

- The cards of Nemotron-CC-v2 and Cosmopedia describe a rephrased crawl and a corpus generated from seeds, with their generators, prompts and licences, the two kinds of synthetic data of Section 20.5.

Tokenizers

- The pipeline guide of the `tokenizers` library explains the normalizer, pre-tokenizer, model and decoder from which Section 20.6 assembles the reference tokenizer.
- SentencePiece trains the unigram and BPE models that Section 20.6 compares, and its documentation states the normalization defaults that the section turns off.
- minbpe writes byte-level BPE in a few hundred lines, a second implementation to read beside the tokenizer of Section 8.2.

20.1 Document Extraction from Web Crawls

Open a news article in a browser and you see the article. The page the server sent holds more: a navigation menu, a cookie banner, a column of related links, a footer of legal notices, and perhaps a table or a block of code inside the article itself. The models of Chapter 18 were trained mostly on such pages, and the web does not arrive as text. Something has to decide which part of each page is the document.

That something is an *extractor*, a program that turns a page's HTML into plain text, and its decision is final. A paragraph it drops is never seen by the model, however long we train. A menu it keeps is learned as if someone had written it as prose. Extraction decides what the model can ever learn, before any filter, deduplication or tokenizer has a say.

This section follows one archive file of Common Crawl, the public crawl behind nearly every open pretraining corpus, from its raw bytes to documents with a manifest that lets anyone rebuild them. On the way we compare three extractors with the text Common Crawl ships beside its archives, and we identify the language, normalize the characters and remove the email addresses of every document that survives. Our reference is FineWeb (Penedo et al. 2024), a released corpus built from the same archive file, so every record we keep has a production pipeline's text beside ours.

Everything below runs on a CPU in a few minutes; the first run also downloads 256 MiB of the archive and its 102 MB text file. Every step is deterministic given the pinned bytes and package versions, and the last cell checks every number against the registered copy. Setting `D2L_RERUN` makes a run write new copies of the named result files instead.

The registry holds no Common Crawl bytes. The entry `lm-cc-warc-256m-v1` is a *pin*: the archive's URL, the byte range we read and a SHA-256 hash for every 16 MiB block of it. The bytes come from Common Crawl's servers and stay in a local cache: Common Crawl grants no licence for the pages it archives. The book publishes only FineWeb's text for the records of our range (under FineWeb's ODC-By licence) and files of counts, offsets and hashes. The second cell pins, by revision, the datasets and models of the whole chapter.

20.1.1 Crawl Archives

Since 2008 Common Crawl has crawled the web again and again, lately every month or two and a few billion pages at a time. It publishes each crawl as tens of thousands of archive files in the WARC format (Web ARChive, a standard of the web-archiving community). A WARC file is a sequence of *records*, and every fetch leaves three of them. A `request` record holds

the HTTP request the crawler sent, a `response` record the server's whole reply, headers and body, and a `metadata` record what the crawler noted about the fetch. One `warcinfo` record at the start describes the crawl itself. Each record begins with a header that holds a unique record id, the URL, the date and the length of what follows.

From each WARC file Common Crawl derives two more. A WAT file holds the metadata and links of each page as JSON, and a WET file holds plain text in `conversion` records, each pointing back to its response through a `WARC-Refers-To` header. A WET file is about a tenth of the size of its WARC file, and it is the cheapest way to get text out of a crawl. Several early corpora used it. We will see what it keeps.

One design decision makes the format easy to sample. Each record is compressed as its own gzip member, and a gzip file may be a concatenation of members, so decompression can start at any member boundary. A client that asks the server for the first n bytes with an HTTP `Range` request gets a valid sequence of complete records followed by one member that the cut has split. That last member has to be counted and dropped, never parsed into half a record. `iter_warc` does this. It decompresses member by member, parses each record's WARC header and, for a response, the HTTP status line and headers, and counts every record type in `stats`.

`fetch_warc_range` reads the pin, requests the bytes block by block, and checks each 16 MiB block against its hash before it writes the block to the cache. A shorter prefix can therefore be verified on its own, and an interrupted download resumes at the first missing block. With `D2L_OFFLINE=1` the function uses only a verified local copy and otherwise stops with instructions for fetching one.

We start with one record. The next cell parses the first 4 MiB of the range and picks, by a rule it prints, the first successful HTML response that holds a table or a block of preformatted text and that FineWeb kept. It shows the record three ways: the HTML as a skeleton of its first 25 elements, each run of text replaced by its length; the WET text as counts; and the text FineWeb extracted from the same record. We print no text of our own from the crawl, only FineWeb's, whose licence lets us show it.

Before reading those three views, look at the record counts. The first 4 MiB hold 285 responses, and 572 records that are not documents at all: requests, metadata and the description of the crawl. A pipeline that counted records would overstate its corpus threefold.

The record is a page of the Apache HTTP Server manual on security. Its URL contains `zh-cn`, yet its text is English, and FineWeb kept it as English: a URL is no guide to a page's language. The skeleton is the boilerplate made visible. The body opens with five short links (the manual's menu bar), a line of 30 characters, a logo and a trail of five more links (the breadcrumbs) before the first heading. The WET text shows the signature of that boilerplate. A third of its 127 lines are shorter than 30 characters, with a run of six in a row, which is what a menu looks like once the layout is gone. FineWeb's text begins with the 30-character line, "Apache HTTP Server Version 2.4", and continues with the article. The menu, the breadcrumbs and, curiously, the heading "Security Tips" are gone. Our own trafilatura text agrees with FineWeb's to a character-5-gram F1 of 0.96, the harmonic mean of the shares of each text's five-character substrings found in the other. The WET text is about 3,000 characters longer than FineWeb's.

Our reader is short enough to read and too new to trust. `warcio`, the library that web archives use, serves as the oracle: on the same 4 MiB both must yield the same records, with the same ids, types, offsets, lengths and body hashes.

All 857 complete records agree. The one difference is the member the cut has split: warcio hands it to the caller as a record, cut short, and a pipeline that trusted it would store half a page. `iter_warc` counts it as truncated instead.

Now the whole range, 256 MiB, a little under a quarter of the file.

The range holds 29,195 complete records, of which 9,731 are responses, and every response has status 200: Common Crawl keeps redirects and errors in separate files. Almost all, 9,591, are HTML pages, with a median body of about 71 KB. The first twelve records show the pattern of the file: one `warcinfo` record, then a request, a response and a metadata record for each fetch, each a separate member of a few hundred bytes to tens of kilobytes.

The last line of arithmetic deserves suspicion. At 38 responses per MiB, the whole file would hold about 41,000 responses, but only if the range is representative of the file. The first 4 MiB already show why that is a real assumption: they held 285 responses, about 71 per MiB, and extrapolating from them would have predicted some 18,000 responses in the range, almost twice the number it holds.

A crawl is not the web either. It samples URLs by the crawler's own priorities, it misses pages behind logins, paywalls and `robots.txt` exclusions, and it sees only the HTML a server sends, not what JavaScript adds later in the browser. In the terms of Section 3.6, a corpus built from it is a shifted sample of what people write.

20.1.1.1 Charsets and Decoding

A response body is bytes, and an extractor wants characters. Decoding every body as UTF-8 is the obvious choice and a silent mistake. A page served in Windows-1251 or Shift-JIS and decoded as UTF-8 turns into replacement characters (U+FFFD), and a UTF-8 page decoded as Latin-1 turns into the wrong letters without any error at all. Browsers settle the question with a chain of evidence, and so does `d21.decode_body`. It tries, in order, the charset named in the HTTP `Content-Type` header, a `<meta charset>` declaration in the first 4 KiB of the page, and the statistical detector of the `charset_normalizer` package; only then does it fall back to UTF-8 with replacements. A declared charset is accepted if it decodes the body with at most one replacement character per thousand, because servers sometimes declare a charset that their pages do not use. The function returns which link of the chain decided, and every document's log records it. On our range (the extraction cell below prints the counts) the header decides for 8,606 of the 9,591 HTML pages, the meta tag for 850 and the detector for 125; 10 pages fall through to the fallback.

20.1.2 Main-Content Extraction

Most of a page's text is not its content. Menus, breadcrumbs, cookie notices, share buttons, lists of related articles and footers make up the *boilerplate*, repeated on every page of a site, and a model trained on it learns to write menus. A main-content extractor tries to keep the article and drop the rest, and its only evidence is the page's structure: which blocks are long, which consist mostly of links, which tags and class names surround them. We compare four sources of text for every HTML page.

- **WET**, Common Crawl's own conversion, keeps all visible text, one line per block. It has no main-content detection at all.
- **trafilatura** (Barbaresi, 2021) walks the document tree and scores elements by their text length, their link density and their tag and class names, falling back to older al-

gorithms when its own result looks too short. RefinedWeb (Penedo et al. 2023) and FineWeb extracted their text with it.

- **Resiliparse**, from the ChatNoir web search project, is written in C++ for speed. DCLM (Li and colleagues, 2024) compared it with trafilatura and WET text by training models on each. Both libraries gave better models than WET text, by similar margins, and DCLM chose Resiliparse because it is much faster.
- **naive** is our own, and it shows the mechanism in forty lines. It splits the page into blocks at block-level tags, counts each block's characters and the characters inside its links, and keeps a block with at least 40 characters of which at most a third is link text. A shorter block of at least 15 characters that passes the same link test is kept too if it lies within two blocks of a kept one, so that a short line between two paragraphs survives. The rule follows the link-density heuristics of earlier boilerplate removers such as jusText, and its thresholds are round numbers chosen before any measurement, not tuned.

Five hand-built pages pin down what the naive extractor keeps: an article with a menu and a sidebar, a forum thread, a table, a code block and an empty page. The table records a failure on purpose. Its cells are too short to be blocks, so the extractor keeps the sentence above the table and loses the table.

Now the real pages. The next cell runs the three extractors on every HTML response of the range in eight worker processes and joins the WET text by `WARC-Refers-To`. It also sorts each page into classes by markers in its HTML. A page is *code* if it has a `<pre>` or `<code>` block of at least three lines and *table* if a table has at least four cells. It is *math* if it holds TeX in MathML annotations, MathJax scripts or the alt text of images, and *prose* if it has none of these and at least 200 characters of paragraph text. A page may be in several classes.

Two of the counts are worth a second look. WET has no conversion record for 151 of the pages, so it is not only a cruder text of the same pages but a different set of pages; any comparison has to join by record id and count the missing ones. And mathematics is rare: 12 pages in 9,591, with code not much more common at 79. Tables, by contrast, appear on one page in six. The speeds differ by more than an order of magnitude: Resiliparse is more than ten times faster than trafilatura, and the naive extractor several times.

20.1.2.1 Code, Tables and Mathematics

How do we score an extractor without a correct answer? Labelling the main content of thousands of pages by hand is out of reach, and using one extractor as the reference would crown it by definition. We therefore measure recall against strings read from the HTML alone, with no extractor involved (`d21.structure_recall`):

- *code recall*: the share of the lines of the page's code blocks that appear in the output;
- *table recall*: the share of table cells (3 to 200 characters) found in the output;
- *math recall*: the share of the page's TeX strings found in the output;
- *prose recall*: the share of the five-character substrings of the page's paragraphs (`<p>` elements of at least 100 characters outside the navigation, header, footer, aside and form elements) found in the output.

Recall alone rewards keeping everything, so we add a *precision proxy*: the share of the output's characters on lines that occur in the page's content elements (paragraphs, code, tables, headings and list items that are not mostly links, all outside the navigation and its relatives). It is a generous proxy. A line counts as content if it appears anywhere in the content text,

so a short menu entry such as “Home” can match by accident. The bias favors WET and the naive extractor, which keep the most such lines, so it can only flatter their scores.

One weakness should be stated plainly. The definitions above, the 100-character paragraph, the 200-character prose page and the content elements behind the precision proxy, were settled while looking at pages of this same sample. They are not held out, and another sample might have suggested other thresholds.

The evaluation pages are chosen without consulting any extractor. We run the language identifier of Section 20.1.3 on the content text read from the HTML and keep the pages that are English with a score of at least 0.65. Choosing them by the language of trafilatura’s output, as the corpus will later do, would drop exactly the pages on which trafilatura returns nothing. A missing or empty output scores 0 on every measure. Many pages come from one site and share its template, so the intervals come from the clustered bootstrap of Section 18.5 with the registered domain as the cluster: a site’s hundred templated pages count as one draw, not a hundred. A class with fewer than 30 pages or 30 domains gets no interval. Since the extractors are deterministic, the bootstrap over pages and domains is the whole statement of noise.

The left panel shows recall by page class, and the extractors differ most on tables. Resiliparse finds about 0.73 of the table cells and trafilatura about 0.61, a paired difference of -0.12 with an interval from -0.18 to -0.06. The naive extractor finds only 0.24, because cells are too short to be blocks, as the fixture predicted. On prose the two libraries do not differ: each recovers a little under 0.9 of the paragraph text, and the paired interval includes 0. On code, 44 English pages are too few to separate them. Mathematics we wanted to measure and could not, with 4 English pages from 2 domains. A general crawl is the wrong place to study mathematical extraction; corpora such as FineMath start from pages selected for it.

WET recalls nearly everything, since it keeps everything, and the right panel shows what else it keeps. Its precision proxy is 0.44, against 0.60 to 0.64 for the three extractors, so more than half of WET’s characters sit on lines outside the content elements. The naive extractor is the surprise. It keeps more paragraph text than either library, about 0.1 more, because it has no notion of “the article” and keeps every dense paragraph, whether it belongs to the article or not. It loses the tables, and its precision proxy is the lowest of the three extractors. Between the two libraries the verdict is clear for this sample: Resiliparse is at least as good as trafilatura wherever we can tell them apart, and more than ten times faster. Trafilatura’s lead on code (0.92 against 0.82) is within the noise of 44 pages.

FineWeb’s text for the same records offers a second view, and it must be read carefully. It is not ground truth. FineWeb extracted it with trafilatura, so agreement with it measures closeness to FineWeb’s pipeline, and an extractor that copied trafilatura’s mistakes would score perfectly. Even our trafilatura text is not FineWeb’s. FineWeb ran trafilatura through the datatrove library, whose defaults favor precision, remove repeated lines and drop comments, while we call trafilatura with `favor_precision=False` and its own defaults, which keep comments. FineWeb also replaced email addresses and public IP addresses with fixed placeholders, so we mask addresses on both sides before comparing; otherwise every scrubbed address would count as a lost line. We join by record id, never by URL, because the same URL is fetched again in later crawls, with different content.

All 1,002 FineWeb rows of the range join by record id. They are the pages that FineWeb kept after all of its filters, about one HTML page in ten. Trafilatura agrees with them best, at an F1 of 0.92; the naive extractor and Resiliparse reach 0.76 to 0.78, and WET 0.63. The

split by class says where the disagreement lies: between a third and three fifths of WET's five-character substrings, depending on the class, occur nowhere in FineWeb's text, against 0.08 for trafilatura on prose pages. The lines printed at the end are lines FineWeb kept and an extractor lost: a row of an app's specification table, lost by both the naive extractor and Resiliparse, and a line of an event listing, lost by our own trafilatura run. Here is the reason never to read agreement as accuracy. Resiliparse recalled more of the table text than trafilatura did, yet it agrees less with FineWeb, because FineWeb's text is trafilatura's.

20.1.3 Language Identification and Normalization

Pretraining corpora are split by language before anything else, because every later rule, from quality filters to tokenizers, is tuned per language. The standard tool is the language identifier of fastText (Joulin and colleagues, 2017), which comes as a model of under 1 MB for 176 languages. It is about as simple as a classifier can be. The text is cut into words and their character n-grams, each is mapped to an embedding (the n-grams through a hash table of fixed size), the embeddings are averaged, and a linear layer with a softmax gives one score per language. Word order beyond the n-grams is ignored, which is why it is fast enough to run on billions of pages.

The score is a softmax output, and it is tempting to read it as the probability that a page is English. It is not. It is the model's preference for English over 175 other labels, and a page that is half navigation, half Python or half Spanish has no correct label among the 176. FineWeb keeps a page if its top label is English with a score of at least 0.65, and so do we. `detect_lang` replaces newlines by spaces first, since fastText reads a single line.

Common Crawl labels each WET record with the languages found by CLD2, the compact language detector of the Chrome browser, so we can check one identifier against another. The next cell crosses the two labels for the eight most common languages. It then sweeps the English threshold from 0.5 to 0.9 and counts, at each value, the English documents we keep and how many of those FineWeb kept. Three short strings at the end probe what a score is not.

The two identifiers mostly agree: the diagonal dominates for every language. The largest disagreements are telling. On 40 pages CLD2 says Japanese and fastText Chinese, which share many characters, and on 25 pages CLD2 says Chinese and fastText English. On 82 pages that CLD2 calls English, fastText's top label is a language outside the eight.

At the threshold of 0.65 we keep 3,288 English documents, and FineWeb kept 997 of them, about 30%. The rest fell to FineWeb's later stages, rules about what a good document looks like and deduplication against the rest of the crawl, the subjects of Section 20.2 and Section 20.3. The curve has a surprise of its own. Raising the threshold from 0.5 to 0.8 removes 857 of our English documents, but only 14 of those FineWeb kept. A low language score tends to mark a page that the later filters remove anyway. Only above 0.8 does the threshold start to cut pages that the full pipeline wanted.

The three strings show what a score is not. A plain English sentence scores 1.00. The same sentence as a comment in two lines of code still scores 0.98 for English: the identifier sees English words and ignores the code, and a filter would call the snippet English prose. A sentence that switches from English to Spanish halfway gets one label, Spanish, at 0.90. A score measures confidence in the top label, not the share of the text written in that language.

20.1.3.1 Unicode Normalization

The same visible text can be different sequences of code points. The letter é is one code point, U+00E9, or two, `e` followed by the combining acute accent U+0301, and a page may use either. Unicode defines *normalization forms* that map such equivalent sequences to one representative (Unicode Standard Annex 15). NFC composes canonically equivalent sequences: é becomes one code point, Korean jamo become syllables, and nothing on the screen changes. NFKC goes further and also maps *compatibility* characters to plain ones: the ligature fi to `fi`, the superscript of x^2 to `2`, the mathematical italic x to `x`, full-width letters to ASCII. It reads like a cleanup, and that is its danger. Once x^2 has become x2, a formula or a variable name means something else.

Why normalize at all? Recall from Section 8.2 that a byte-level tokenizer sees the UTF-8 bytes of a text, not its characters. A composed é is two bytes, `C3 A9`, and a decomposed one three, `65 CC 81`, so two documents that look identical give different token sequences. Bits per byte, the measure this chapter uses to compare data mixtures and tokenizers, would then be computed over different byte counts for the same text. The rule this book follows is short: apply NFC once, to every document, before any tokenizer sees it, and count bytes after it. The next cell measures what NFC and NFKC would change in the English documents of our range.

NFC changes none of the 3,288 documents (and applying it twice changes nothing, as the assertion checks): the English text of this range is already composed. NFKC changes 619 of them, 19%, rewriting 7,911 code points. Most of the rewrites are harmless. No-break spaces become spaces and the ellipsis becomes three dots. Further down the list they are not. The double prime of inches and arc-seconds becomes two primes, ™ becomes the letters TM, and full-width colons and commas in Chinese text become ASCII punctuation. ½ and ¼ become digits around a fraction slash, and mathematical bold letters become plain ones, erasing what may be the only mark of a vector. No-break spaces occur in 292 documents, and 6 documents still carry U+FFFD, decoding failures that the charset chain did not catch. This sample has no zero-width joiners, but a multilingual corpus does, and there they matter: in Devanagari the joiner selects a half-form of a consonant, and in emoji it joins a family into one symbol. A rule that strips "invisible" characters changes those texts. NFC, and nothing else, is the normalization of this chapter.

20.1.4 Personal Data, Rights and the Manifest

A crawl holds whatever people have put on public pages: their email addresses, phone numbers and home addresses, and, in forum threads, their health. A corpus repeats it, and a language model can memorize and reproduce text it has seen several times. Some of it can be removed by rule. An email address has a fixed shape, and so has an IP address, which can identify a household. FineWeb replaces both with placeholders, and so does `scrub_pii`, which parses every candidate IP address and keeps private, loopback, documentation and multicast addresses (192.168.1.1 identifies nobody). Names, street addresses and a sentence about someone's diagnosis have no fixed shape. No regular expression finds them, and model-based detectors find some of them along with many false alarms. We implement what rules can do, and it is the easy part.

How good are two regular expressions? The fixture below holds 60 strings with an address and 60 without, many of the latter chosen to look like one. We wrote it together with the rules (the case of an address at the end of a sentence came from it), so it is a specification of what the rules match and miss, not an estimate of their accuracy on web text. Its recall

of 1.0 holds by construction.

The false positives are the interesting output. Four numbers below 256 joined by dots parse as an address, and most such addresses are public, so version numbers, a kernel build, the section number of a standard and a puzzle score are all replaced. The names `logo@2x.png` and `icon@3x.webp`, which web designers give to images for high-resolution screens, look like email addresses, and so does the git address `git@github.com:org/repo.git`. Every one of them is code or documentation, exactly the text a model should learn character for character. On the 3,288 documents the rules match emails in 173 documents (421 replacements) and public IP addresses in 8 (27 replacements); these are rule matches, not checked by hand. The replacements shorten the corpus by 6,625 UTF-8 bytes, one more reason to scrub before bytes are counted.

Personal data is one kind of right attached to a page; copyright and the site's terms are others. Common Crawl is an archive. It honors `robots.txt` when it crawls, but it grants no licence for what it stores, and a page's being public does not make its text free to copy. Site owners have noticed. *Consent in Crisis* (Longpre and colleagues, 2024) audited the `robots.txt` files and terms of service behind widely used corpora. Restrictions aimed at AI crawlers spread within a single year, most of all among the actively maintained sites that supply much of the useful text.

Rights therefore enter a pipeline as engineering inputs, like any other field. Each of our documents records where it came from: the WARC file, the byte offset and length of its record, the URL and the fetch date. A licence field, an opt-out list checked at build time and a log of removals make a request enforceable. The Stack v2 (Lozhkov and colleagues, 2024), a corpus of source code, records the licence of every file and removes the repositories of developers who opt out before each release. With byte offsets in every row, a takedown request is the deletion of one row, and the next rebuild no longer contains the page. This book applies the same rule to itself: it publishes no text extracted from the crawl, only pins, ids, offsets and hashes, and the notebook rebuilds the text from Common Crawl's servers. The crawl text it prints is FineWeb's, released by its authors under ODC-By. None of this is legal advice; the law differs between countries and is changing.

Everything in this section was English, and that was a choice, not a necessity. FineWeb-2 (Penedo and colleagues, 2025) runs a pipeline of the same shape over Common Crawl for more than a thousand languages and finds that rules tuned for English fail elsewhere. Its language identifier covers far more languages than fastText's 176, its thresholds are set per language from the distribution of scores, and its filters and deduplication are adjusted per language as well. Its per-language pages return in Section 20.6, where one tokenizer meets ten languages.

20.1.4.1 The Manifest

Every number in this section came from a decision: which bytes, which charset, which extractor at which version, which threshold. A corpus that does not record its decisions cannot be rebuilt, audited or corrected after a takedown. We record them at two levels. Each document is a `d2l.Doc` holding its text, id, URL, date, language and score, its source (`src`: the WARC file, offset and length) and a log of what was done to it. The corpus as a whole is described by a *manifest*, a JSON file in the schema `d2l-corpus/1` (Table 20.1), which the rest of the chapter extends: filters in Section 20.2, deduplication in Section 20.3, and the tokenizer, shard format and splits in Section 20.6.

Table 20.1: The corpus manifest, schema `d2l-corpus/1`. This section fills the sources and four stages; later sections add stages and the last three fields.

field	holds	example in this section
`schema`, `name`	the schema version and the corpus name	`d2l-corpus/1`, `c0`
`sources[]`	`id`, `uri`, `revision` (a content hash or commit), `license`, `n_docs`, `bytes`	the WARC file, its SHA-256, 9,731 responses, 268,435,456 bytes
`stages[]`	`name`, `impl`, `version`, `params`, `n_in`, `n_out`, `drops` (reason: count), `in_hash`, `out_hash`, `tokens_out`	`extract` with trafilatura 2.1.0; `lang_id` with `min_score` 0.65
`tokenizer`	file, SHA-256, vocabulary size, special tokens	empty until Section 20.6
`format`	token dtype, end-of-document id, byte order	empty until Section 20.6
`splits`	per split: documents, tokens and shard files with their hashes	empty until Section 20.6

The documents are written as gzip-compressed JSON lines with sorted keys and no time stamp in the gzip header, so equal documents give equal bytes.

Two rules make a manifest checkable. First, every stage balances: each document that enters either leaves or is charged to exactly one reason for dropping it,

$$n_{\text{in}} = n_{\text{out}} + \sum_{r} \text{drops}_{r}, \tag{20.1}$$

and a document that several rules would drop is charged to the first of them in the stage's order. The order is therefore a parameter of the stage, since it changes the counts. Second, the manifest has one canonical byte form: sorted keys, no spaces, floats rounded to four decimals, no time stamps and no absolute paths. Its SHA-256 then names the corpus, and two builds that made the same decisions produce the same hash on any machine. A time stamp or a path such as `/home/user/data` would make every build unique and the hash useless, which is why `canonical_json` refuses absolute paths. The content of a set of documents has a hash of its own, `docs_hash`: the SHA-256 over the sorted pairs of document id and text hash. It ignores the order of the documents and changes with any byte of any text.

We now write the manifest of *c0*, the chapter's first corpus: the English documents of the range after extraction with trafilatura (FineWeb's extractor), language identification at FineWeb's threshold, NFC and the scrubbing of addresses. The cell then tests the hashes. The manifest must survive a save and a load, and the document hash must survive a permutation of the documents and change when one character of one document changes.

The funnel is steep. Of 9,731 responses, 9,286 yield text (140 are not HTML and 305 give empty output), and 3,288 of those are English at a score of at least 0.65: 5,448 have another top language and 550 score too low. Nearly three in five pages with text are in another language. NFC and the scrubber drop nothing; they only rewrite. Note that c0 is not the set of pages on which we compared extractors. c0 follows FineWeb's rule, the language of trafilatura's text, while the comparison chose pages by the language of their HTML; 2,810 pages are in both.

The registered artifact `lm-c0-docs-v1` holds one row per c0 document with everything except the text: id, URL, date, source offsets, charset, language and score, extractor and version, character count, text hash and log. `rebuild_c0` turns the rows back into documents. It reads each record from the verified range by offset and length, runs the recorded stages again, and keeps a document only if its text hashes to the recorded value. A document that hashes differently, because a newer trafilatura extracts one more line, say, goes into `.mismatches` and is reported, never kept.

All 3,288 documents come back, with no mismatch and the manifest's output hash. Deleting a row from the manifest removes the page from every later build, and that is the whole takedown procedure.

Datasheets for Datasets (Gebru et al. 2021) asks every dataset to answer questions about its motivation, composition, collection, preprocessing, uses, distribution and maintenance. Some of the answers are already in the manifest, and `to_card` writes them out as a Markdown dataset card in the format of the Hugging Face Hub.

The card states the source, its licence status, every stage with its implementation and version, and every drop count. It cannot say why the corpus exists, whose writing is in it, what it should not be used for, or who answers a takedown request. A manifest records what was done, not why or for whom, and those parts of a datasheet have to be written by a person. Audits of released corpora, such as Dodge and colleagues' study of C4 (2021), show how much of that only reading the documents reveals.

The last cell gathers every value this section reports and compares it with the registered copy, `lm-data-crawl-results-v1`. Every step is deterministic given the pins, so the comparison expects equality, and a package update that changes a single count fails here.

All values agree. The 3,288 documents of c0 are English, decoded, normalized, scrubbed and documented, and seven in ten of them are absent from FineWeb, which started from the same file with the same extractor and threshold. Its later stages removed them by judging what a good document is. What should "good" mean once the text is clean, and who checks what such a judgment throws away? Section 20.2 takes up quality.

20.1.5 Summary

A web page is mostly not its content, and the extractor that turns its HTML into text decides what a model trained on it can ever learn. Because Common Crawl compresses each WARC record on its own, a byte range is a valid sample and a corpus can be published as pins and hashes instead of text. On 256 MiB of one archive file the extractors differed most on tables: Resiliparse found about 0.73 of the cells, trafilatura about 0.61 and our link-density extractor 0.24. Agreement with FineWeb measures closeness to its trafilatura pipeline, not accuracy. A language score is a preference among 176 labels, not the probability that a text is English. NFC is the one safe normalization, and the rules that remove email and IP addresses also remove version numbers. A manifest whose stages balance and whose canonical form has a hash makes the 3,288 documents of c0 rebuildable, auditable and removable row by row.

20.1.6 Exercises

1. **Prefixes of archives.**

    1. Explain why a prefix of a WARC file can be parsed record by record without the rest of the file, why the last record of a `Range` request must be dropped, and why

neither holds for a prefix of a `.tar.gz` file.

2. code The first 4 MiB of the range held about 71 responses per MiB, the whole range 38. Count the responses in each 16 MiB block of the `index` table. Is the density stable after the first block? What does your answer imply for the estimate of 41,000 responses in the whole file, and how would you test it without downloading the file?

2. **What normalization changes.** For each of ﬁ (U+FB01), x², é written as e followed by U+0301, 𝑥 (U+1D465) and the zero-width joiner in क्ष, say whether NFC, NFKC, both or neither change it, and check your answers with `unicodedata`. For each change made only by NFKC, give one text in which it changes the meaning.

3. **The order of the rules.** A stage drops documents by the ordered rules $R_1, \dots, R_m$, and a document is charged to the first rule that fires. Rule R_j fires on a document with probability p_j, independently of the others, and costs c_j to evaluate; evaluation stops at the first rule that fires.

   1. Show that the expected fraction charged to R_j is $p_j \prod_{i<j}(1 - p_i)$, so the drop counts of the manifest depend on the order, while n_{out} does not.
   2. Show that the expected cost per document is smallest when the rules are sorted by increasing c_j/p_j. (Hint: swap two adjacent rules.)
   3. code The `lang_id` stage charges `not_en` (the top label is not English) before `low_score` (the top label's score is below 0.65, whatever the label). Write the two counts of the other order in terms of the funnel's 5,448 and 550 and one number that the funnel does not give. Name that number and compute it from the c0 rows of `pages`, which record every page's top label and score.

4. **A threshold for purity.** ● A corpus holds N_ℓ documents in each language ℓ. An identifier gives an English document the label `en` with probability a and a score at least t with probability $F_1(t)$, decreasing in t; a document in language $\ell \neq$ English is labelled `en` with probability e_ℓ and then scores at least t with probability $F_\ell(t)$.

   1. Write the expected numbers of English and non-English documents kept at threshold t, and the purity of the kept set.
   2. Find the threshold that keeps the most English documents subject to a purity of at least $1-\epsilon$, and show that it is the smallest t at which the purity constraint holds when the purity increases with t.
   3. Take $N_{\text{en}} = 3{,}800$ and 5,500 other documents, $a = 0.97$, $e_\ell = 0.01$ for all other languages, $F_1(t) = 1 - t^4$ and $F_\ell(t) = 1 - t$. Compute the best threshold for $\epsilon = 0.01$ and compare it with 0.65.

5. **What the document hash detects.** `docs_hash` hashes the sorted pairs of id and text hash.

   1. Show that it does not depend on the order of the documents and that it changes when one byte of one text changes, and check both on c0.
   2. What happens when two documents share an id, or when a document is duplicated? Would the exclusive or of per-document hashes, which is also independent of order, detect a duplicated document?
   3. Construct a change to the corpus that leaves `docs_hash` unchanged but changes what a tokenizer reads. What must the manifest record besides the hash to rule it out?

6. code **FineWeb's settings.** Our trafilatura text agrees with FineWeb's at an F1 of 0.92,

and the text blamed the gap on settings. Predict how the F1, the table recall and the precision proxy change, then rerun trafilatura on the 1,002 joined pages with datatrove's settings (`favor_precision=True`, `deduplicate=True`, `include_comments=False`) and measure them with domain-clustered intervals. Which part of the gap remains, and what could explain it?

7. code **Loss on one class, by hand.** Pick one page class (tables, code, or a class of your own such as recipes or forum threads) and draw 20 pages of it from the range at random. For each page, mark by hand which parts of the rendered page are content, and measure each extractor's recall and precision against your labels. Do your labels agree with the automatic measures of this section? Where they disagree, which measure is wrong?

8. [extended] **A card from the manifest alone.** Write a full dataset card for c0 in the order of *Datasheets for Datasets*, using only the manifest and the c0 rows. List every question of the datasheet that you could not answer, and for each say what would have to be added to the manifest, or which documents someone would have to read, to answer it.

20.2 Quality Filtering

The previous section turned a quarter of one Common Crawl archive file into 3,288 English documents and ended on a puzzle: about seven in ten of them are not in FineWeb, although FineWeb was built from the same file. Something judged them not worth keeping. Anyone who has looked through a crawl will not need convincing that such a judgment is necessary. Next to manuals and news articles sit product catalogues, lists of links, pages of keywords written for search engines, articles run through a program that swaps words for synonyms, and advertisements for love spells. A model trained on all of it learns all of it.

Two kinds of filter make the judgment. The older kind is a set of rules, written by people who had read many bad pages: too few words, too many repeated lines, too few lines that end in a full stop. The newer kind is a classifier. A large language model reads a sample of a few hundred thousand pages and scores each one under a written rubric, a small model learns to predict the score, and a threshold on the prediction decides for the billions of pages that no large model will ever read. FineWeb-Edu (Penedo et al. 2024) was built this way, with a rubric that asks how useful a page would be for teaching at school. Other open corpora of the same years also select with a cheap classifier, though not always one trained on a large model's scores: DCLM's learns to tell instruction data from random web pages, and Nemotron-CC combines several.

Both kinds of filter remove most of the web, and both apply a definition of quality that somebody wrote down. The rules define it by surface statistics. The classifier inherits it from a rubric and from the model that applied the rubric, that model's taste included. The two pages printed below show both definitions at work. One advertises "death spells" and passes every rule we implement. The other is a software company's guide to hiring engineers, plain and informative, and our classifier removes it. Faced with the second page, the natural instinct is to adjust the threshold. The better question is what the filter means by quality, and whose pages it removes.

This section builds both kinds of filter, trains a classifier on labels written by Qwen3.8-27B, chooses its threshold, and audits what it removes by country, kind of site and language. It

ends where the audit points: a filter keeps what its annotator likes, and only training runs, of the kind that Section 20.4 sets up, can say whether that is what a model needs.

Most of what this notebook computes is cheap: the rules run on eight CPU processes, a 0.6B-parameter model scores perplexity, an embedder encodes the crawl documents, and linear classifiers train in seconds, so a build takes a few minutes on one GPU. Two steps are expensive, and a build reads their results from registered files: labelling 22,000 documents with Qwen3.8-27B took about an hour on four GPUs, and the review of 200 removed documents a few minutes more. The vectors of the labelled documents and of the audit stream are registered too, with the released FineWeb-Edu classifier's scores. Without a GPU the notebook reads every registered result and scores perplexity on a small sample only. Setting `D2L_RERUN` to names from `ARTIFACTS` regenerates those files under new names, and the last cell compares whatever this run computed with the registered results.

The registry adds seven files. The 22,000 labelled documents and the audit stream are FineWeb text, which its ODC-By licence lets us host with attribution, and every cell that prints their text prints the attribution too. Nothing derived from our own crawl text is hosted. The flags of the crawl documents hold ids, reason codes and scores; their vectors, computed from text we may not redistribute, are cached on the machine that computed them; and the review file holds document ids and the judge's one-sentence rationales.

The first cell computes how much of this dump FineWeb-Edu keeps, from the row counts of the two datasets, and prints the two pages. Both come from the audit stream, a sample of FineWeb's output introduced below, and both are chosen by rule, not by us. The first is the page with the lowest score from our classifier among the pages that pass every rule and have at least 1,500 characters. The second is the page with the lowest score among those our classifier removes and the review at the end of the section would keep.

FineWeb-Edu keeps about one FineWeb document in fourteen. The first page shows why rules alone cannot make that cut. It is long, its sentences end in full stops, it uses enough common English words and repeats no line, so it passes every rule; only a reader, human or model, notices that it sells spells and prints a phone number twice (masked here). The second page shows the opposite failure. It opens with a sales pitch for an interview platform and then turns into a guide to hiring software engineers, coherent and useful to the right reader. A rubric that asks for material to teach schoolchildren gives it almost nothing, and the classifier that learned the rubric removes it. Keep both pages in mind. Everything below is a way of deciding between pages like these, at the scale of billions.

20.2.1 Filters Without Labels

The oldest filters need no labelled data at all. Either people write down what a bad page looks like, or a language model of clean text says how surprising a page is.

20.2.1.1 Heuristic Rules

Rules came first because they cost almost nothing and say why they fired. DeepMind's Gopher models were trained on text filtered by two families of them (Rae et al. 2021). The *quality* rules bound simple statistics of a document: between 50 and 100,000 words, a mean word length between 3 and 10 characters, few # symbols and ellipses, at most 90% of lines starting with a bullet and at most 30% ending with an ellipsis, at least 80% of words containing a letter, and at least two of eight common English words such as *the*, *of* and *with*. The

repetition rules catch pages that say the same thing many times: duplicated lines and paragraphs, and too many characters inside the most frequent 2-, 3- and 4-grams or inside 5- to 10-grams that occur more than once. C4 (Raffel et al. 2020) added a rule about sentences: once short lines, JavaScript warnings and cookie notices are set aside, a document needs at least five sentences, and none of its lines may contain "lorem ipsum" or a curly brace.

FineWeb (Penedo et al. 2024) kept both families and added rules of its own, chosen by training small models on the output of each candidate filter: too few lines ending in terminal punctuation, too many lines under 30 characters, too many characters in duplicated lines, and too many line breaks per word. Its paper reports that the first three together remove about 22% of the tokens and that it dropped C4's rule that removes every line without terminal punctuation, which alone removed about 30%. Our thresholds are those of datatrove, the code that produced the corpus, and Table 20.2 lists the fifteen rules with their reason codes.

Table 20.2: The heuristic rules, in the order `heuristic_filters` applies them. The thresholds are those of datatrove 0.10.1, the code FineWeb ran.

family	source	reason codes	what it catches
Gopher repetition	Rae et al. (2021), Table A1	`gopher_dup_text`, `gopher_top_ngram`, `gopher_dup_ngram`	repeated lines and paragraphs; text dominated by one phrase or by repeated 5- to 10-grams
Gopher quality	Rae et al. (2021)	`gopher_words`, `gopher_word_len`, `gopher_symbols`, `gopher_bullets`, `gopher_ellipsis`, `gopher_alpha`, `gopher_stop_words`	fragments and walls of text, keyword lists, tables of numbers, hashtag clouds, text without English function words
C4	Raffel et al. (2020), as FineWeb ran it	`c4_quality`	fewer than five sentences, placeholder text, code
FineWeb	Penedo et al. (2024)	`fw_line_punct`, `fw_short_lines`, `fw_dup_chars`, `fw_list_ratio`	menus, lists of links, navigation, repeated lines

Each rule has a stable reason code, and `heuristic_filters` returns, in this order, the codes of every rule that fires; an empty list keeps the document. A stage that removes documents charges each one to the first rule that fires, the charging rule of Section 20.1, so the manifest can say how many documents each rule removed while the cells can still count every rule that fired.

Each rule comes with a fixture, a short hand-written document that fires that rule and no other. A plain paragraph about a river valley fires nothing, and each fixture changes it just enough to break one rule: a sentence repeated four times, every sentence turned into a bullet, a run of year numbers inserted. A threshold that drifts, or a new rule that overlaps an old one, fails this table at once.

Our rules are a reimplementation, and the code FineWeb actually ran is datatrove's. A ta-

ble computed once with datatrove 0.10.1, in an environment of its own, compares the two on 2,000 of our crawl documents, for each family of filters and for the whole sequence as FineWeb ran it.

The two implementations decide alike on more than 99% of the documents for the repetition, C4 and FineWeb families, and on about 96% for the Gopher quality rules and for the whole sequence. The disagreements have ordinary causes. The largest, 58 documents that datatrove removes for too few alphabetic words and we keep, comes from the word tokenizer: datatrove and our regular expression split text into words differently, so a document near the 80% threshold can fall on either side. C4's 11 come from sentence splitting, which datatrove does with NLTK's sentence splitter and we do at a full stop followed by a space. In the sequence, 27 documents fail our line-punctuation rule and pass datatrove's, because datatrove's C4 filter deletes lines before FineWeb's rules see the text, and because datatrove accepts many more characters as terminal punctuation. We keep our implementation, which is short enough to read, and the table records where it departs from FineWeb's.

Now the rules on two corpora. The first is c0, the crawl documents of Section 20.1, which no quality filter has touched. The second is the *audit stream*: 20,000 documents of FineWeb's output for the same dump, every 45th row of one of its files, without the rows of our archive file. FineWeb has already applied these rules to the stream, so a rule that still fires there marks a place where our implementation and FineWeb's disagree. The cell also applies the rules to 500 documents in each of six languages from FineWeb-2, FineWeb's multilingual successor, which filtered each language with rules adapted to it.

On c0 the rules remove 2,256 of 3,288 documents, about 69%; on the stream they remove 317 of 20,000, or 1.6%. The column `first` says which rule each removal is charged to: duplicated text leads with 571 documents, followed by too few alphabetic words (403) and too few words (322). The column `fired` tells a different story. The line-punctuation rule fires on 1,150 documents and the duplicated-character rule on 937, but both come late in the order, so their documents are usually charged to an earlier rule. The pairs that fire together most often, alphabetic words with line punctuation and line punctuation with short lines, describe one kind of page: a column of short lines without full stops, such as a menu, a list of links or a table of products. The drop counts of a manifest therefore depend on the order of the rules, while the set of documents kept does not.

On the stream, FineWeb's four rules never fire, which is what a faithful reimplementation should give. What does fire are the word-based Gopher rules (alphabetic words 108 times, word count 104), the same rules on which the parity table found differences: most of the stream's 1.6% are documents near a word-count threshold that the two tokenizers count differently.

The six languages show what English rules do elsewhere. German and Swahili lose 96% and 93% of their documents, almost all to the stop-word rule, which asks for two of eight English function words; without that rule they would lose 28% and 16%. Chinese, Japanese and Thai lose every document. These scripts do not separate words with spaces, so a run of characters between two punctuation marks counts as one "word", a page has few long words and many punctuation tokens, and the word-count or alphabetic-word rule fires on every page. Hindi does put spaces between words and loses every document too, but the cause lies in our code, not in the rules. Our word pattern uses Python's `\w`, which does not count the vowel signs of Devanagari as word characters, so each word breaks into fragments of one or two letters and the mean word length falls below 3. Datatrove's word tokenizer keeps the signs with their letters, so the 100% for Hindi measures our reimplementation, not the

rules as FineWeb ran them. Every one of these documents had already passed FineWeb-2's own filters for its language. A removal rate of 100% on Thai measures the rules, not the Thai web.

20.2.1.2 Perplexity Filters

A different cheap filter replaces the rules by a language model. CCNet (Wenzek et al., 2020) trained a small n-gram model on Wikipedia in each language, scored every crawled paragraph with it, and split the crawl into thirds of low, medium and high perplexity; the low third resembles Wikipedia most. The idea is appealing: a model of clean text should find clean text predictable. We test it with a small released decoder, Qwen3-0.6B-Base, as the model of clean text. The cell computes each document's mean negative log-likelihood per token over its first 512 tokens, for 3,000 stream documents, and prints the ten most and the ten least predictable.

The median document costs about 2.9 nats per token. The most predictable documents are not the best ones. They are a forum's boilerplate ("Please be mindful of our community standards") and a run of fluent, generic explainers: "Operating systems are the software that manages ...", "In today's digital age, a strong online presence is crucial ...", "Greetings, readers! I am excited to delve into the topic of ...". Much of this reads as if a language model had written it, and a language model finds such text predictable for the obvious reason. The least predictable documents are mostly spun text ("As have a peek at these guys you can see regarding the a lot more than pokies"), together with a few honest informal pages, such as a comment on a garden blog and a site of railway photographs. Perplexity measures resemblance to the reference model's training data. Very low values flag boilerplate and machine-written prose, very high values flag spun text and also unusual but genuine writing, and neither end is a definition of quality.

20.2.2 Classifiers on Model Labels

The rules and the perplexity filter define quality by statistics that are easy to compute and far from what we care about. The classifier recipe moves the definition into words. Somebody writes a rubric, a large model applies it to a sample of documents, a small model learns to predict the large model's score from a document, and a threshold on the small model's prediction selects the corpus. The large model reads perhaps half a million documents; the small one reads billions. FineWeb-Edu is the best-known instance. Llama-3-70B-Instruct scored 450,000 FineWeb documents under an additive rubric, a regression head on a frozen encoder of 109M parameters learned the scores, and the corpus keeps the documents whose rounded prediction is at least 3. DCLM (Li et al., 2024) instead trained a fastText classifier to separate instruction-style text and well-rated answers from a forum of explanations from random web pages, and kept the top tenth of its pool by that classifier's score. Nemotron-CC (Su et al., 2024) combines several classifiers and sorts documents into quality buckets, which a mixture can weight separately instead of cutting at one threshold.

The rubric is the definition. FineWeb-Edu's asks whether "the page has a high educational value and could be useful in an educational setting for teaching from primary school to grade school levels", and awards points one at a time: a first for "some basic information relevant to educational topics", a third if the extract "is appropriate for educational use and introduces key concepts relevant to school curricula", a fifth only if it "is outstanding in its educational value". A page about hiring engineers earns at most the first point, however well it is written. `EDU_RUBRIC` holds the released prompt word for word; the extract it scores

is a document's first 1,500 characters.

The released protocol asks the model to write a justification of up to 100 words and then "Educational score: N". Generating a hundred words per document is the slow part, and parsing them is fragile, so we skip it. `edu_label_scores` starts the model's answer with the text `Educational score:` and reads, from one forward pass, the probabilities of the six digits as the next token. The label is the most probable digit, and the *expected score* $\sum_d d\,p(d) / \sum_d p(d)$ keeps the model's uncertainty as a number between 0 and 5. One detail matters more than it looks. The released format puts two spaces before the digit, so a model may write a second space and then the digit. With `extra_space` the probability of digit d is $p(d) + p(\text{space})\,p(d \mid \text{space})$; for Qwen3.8-27B that second path holds about 15% of the probability, and ignoring it would change about one label in a hundred.

The labeller is Qwen3.8-27B in RedHat's W4A16 build, with weights stored in 4 bits and activations computed in 16 (Section 28.3), which fits on one 24 GB RTX 4090 where the 54 GB of its bf16 weights would not. A vLLM server holds one copy per GPU, and `edu_label_scores_served` sends it the same token ids that `edu_label_scores` would feed a local model. Each server takes one request at a time. That is slower than it needs to be, and it is deliberate. A server that batches concurrent requests changes the order of its floating-point additions with the batch, so the probabilities of a prompt depend on which other prompts share its batch, and a near tie can flip its label. One request at a time, every server returns the same bits for the same prompt (Section 29.3 explains why). A build reads the labels, checks the provenance stored with them, and prints the pilot's check: 32 prompts scored again on another server, in reverse order.

The check agrees to the last printed digit. The labels were made once, in three parts that `D2L_RERUN` can regenerate: `edu-label-pilot` labels the 2,000 test rows, and `edu-label-0` and `edu-label-1` the 18,000 training and 2,000 validation rows. Four servers, one per RTX 4090, labelled all 22,000 rows in about an hour. The pilot does one more thing. It asks the model for a justification-first answer on each test row, under the released protocol, and counts what the model writes between the colon and the digit: 1,970 of the 2,000 answers use one space and 30 use two, which fixed `SCORE_PREFIX` with one space and kept the correction for a second. The same answers are a second annotation of the test rows by the same model, which the label-noise ceiling below needs.

Our labels come from a newer model than FineWeb-Edu's. The 22,000 documents are a sample of the released annotations, so each one also carries the score that Llama-3-70B-Instruct gave it in 2024 under the same prompt. Comparing the two is easy and easy to misread. Agreement with one labeller cannot show which labels are better: where two labellers disagree, either may be wrong, and a third model would only add a third opinion. Here the comparison is descriptive. It tells us how the two models use the scale, and whether they order documents alike; exercise 5 compares the filters that the two labellers produce.

The two models use the scale very differently. Llama-3-70B gives a score of 3 or more to about 9% of the documents, Qwen3.8-27B to about 1.4%; at 2 or more the shares are 31% and 6%. The cross-tabulation shows a shift of about one point. Of the 1,610 documents that Llama scored 3, Qwen scored 837 as 1, 634 as 2 and 138 as 3. Yet the two order documents alike: the Spearman correlation of Qwen's expected score with Llama's score is about 0.76, with a narrow interval. The binary agreement at the threshold, a Cohen's kappa of 0.24, is low because the two cut their scales at different places; cutting Qwen's expected score so that it keeps Llama's share raises the kappa to 0.65. The disagreement is mostly one of scale, not of ranking.

We keep the rubric's own cut, a score of 3 or more on Qwen's scale, as this section's definition of "educational". On the stricter scale that makes a stricter filter than FineWeb-Edu's, and the threshold cells below say how much it keeps.

The second protocol measures something else, the stability of one model's labels. Asked to justify first, the same Qwen3.8-27B gives the same score on only half of the test rows, mostly by moving 1s to 0s, yet agrees on the binary decision at 3 with a kappa of 0.66. Its scores run lower: 1.05% of the rows reach 3, against 1.80% under the digit protocol. The next cell fixes Qwen's scores as the training labels and splits the rows.

The small model is a frozen embedder with a linear head. `embed_docs` encodes each document's first 512 tokens with Qwen3-Embedding-0.6B and pools as in Section 19.3: it takes the vector of the last token, pads on the left so that the last token is always a real one, and adds no instruction, which Qwen's embedders reserve for queries. The vectors have unit length and are stored in 16 bits.

The vectors of the 22,000 labelled documents and the 20,000 stream documents are registered, together with the released classifier's scores for the same documents. The crawl documents' vectors cannot be hosted, so a build computes them once and caches them locally. Two live checks guard the registered vectors: 64 test documents are embedded again, by `embed_docs` and by the sentence-transformers library, and both must match the registered vectors to a cosine of 0.999.

Both match to a cosine of 0.9998 or better. The other line of the output matters as well: 29 of the 64 texts are longer than 512 tokens, so our classifier, like the released one, judges a long document by its beginning.

On fixed vectors the classifier is a linear model and trains in seconds. `fit_quality_head` fits either a regression on the score, as the released classifier does, or a logistic regression on the binary label "score at least 3", the two-class case of the softmax regression of Section 3.1. Both use full-batch AdamW, starting from zero weights and the best constant. `HashedBagClassifier` is the model of fastText (Joulin et al., 2017), the classifier that DCLM used, written in PyTorch. The word unigrams and bigrams of a document are hashed into a table of about a million embeddings, their vectors are averaged, and the average is mapped to a logit. It needs neither a GPU nor a pretrained model, which makes it the path for a reader without either.

The next cell trains the two heads on the training rows and the bag on their texts, and reads the released classifier's registered scores. Each classifier gets its own threshold t^*, the one with the best F1 on the validation rows; the test rows serve only for the final numbers. Choosing the threshold on the test labels would report the best of 400 tries as if it were a single one. The validation and test rows are the released classifier's own hold-out, which we reproduced from its training code (a stratified 90/10 split with seed 42; the reproduced hold-out gives the confusion matrix on the classifier's card up to rounding), so the comparison is out of sample for the released classifier too.

The thresholds already say something. The regression head's t^* is about 1.6, far below the label's 3. Each document has one label, but a linear head on a frozen vector cannot tell every document apart, and under squared loss it predicts the mean score of the documents it confuses with one another. With only 1.4% of the labels at 3 or more, a group of such documents hardly ever has a mean near 3. The head's predictions bunch between 0 and 2, and its threshold has to be read on that scale. The released classifier, trained on Llama's more generous scale, gets a threshold of about 2.9 against Qwen's labels. The last line checks

the released classifier live on the 2,000 test rows: its scores differ from the registered ones by at most 0.016.

The table compares the four classifiers on the test rows. The second half of it has an F1 and an AUC against each labeller's binary label, and an interval for the F1 against Qwen's.

The test rows hold only 36 positives among 2,000, so every F1 carries an interval about 0.12 wide on either side, and the table has to be read with it. Against Qwen's labels the regression head reaches an F1 of 0.44 and the logistic head 0.56; their intervals overlap, and we do not rank them. The hashed bag is clearly worse, at 0.26. The area under the ROC curve, which asks only whether positives score above negatives, is easier to read: the three embedding classifiers all reach about 0.98, the bag 0.90. The trained part of our heads is 1,025 numbers on top of a frozen 0.6B-parameter embedder; the bag's 67 million parameters are almost all its hash table; the released classifier's 109 million are a frozen encoder and a small head. The embedder is the slow part, a few milliseconds per document on a GPU and several times the released classifier's smaller encoder.

The comparison that matters is our head against the released classifier. The paired bootstrap over test rows gives an F1 difference of -0.02 with an interval from -0.14 to $+0.09$, and no difference in accuracy. On Qwen's labels, a classifier trained on Llama's labels does as well as one trained on Qwen's, which is what a shared ranking predicts: each threshold absorbs its labeller's scale. On Llama's labels the released classifier is ahead (an F1 of 0.54 against 0.42), as it should be on the labels it learned.

20.2.2.1 Label Noise and the F1 Ceiling

How high could any classifier score on these labels? The labels are noisy, and a classifier that knew the truth would still be marked wrong wherever the labeller was. Two short derivations make this precise.

Write π for the share of positive labels, TPR for the share of positives that the classifier keeps (its recall), and ρ for the share of all documents it keeps, the *retained fraction*. The kept positives make up a share $\pi\,\mathrm{TPR}$ of all documents, so the precision is $\pi\,\mathrm{TPR}/\rho$, and the harmonic mean of precision P and recall R simplifies to

$$\mathrm{F1} = \frac{2PR}{P+R} = \frac{2\,(\pi\,\mathrm{TPR}/\rho)\,\mathrm{TPR}}{\mathrm{TPR}\,(\pi+\rho)/\rho} = \frac{2\pi\,\mathrm{TPR}}{\pi+\rho}. \tag{20.2}$$

The F1 depends on the threshold only through the recall and the retained fraction. At a fixed recall it falls as the filter keeps more, and the best a filter can do is to keep exactly the positives, $\rho = \pi$ with $\mathrm{TPR} = 1$.

Now let each document have a true label y^*, positive with probability π^*, and let the labeller flip it with probability η in either direction, independently of the document. A classifier that predicts y^* perfectly keeps the true positives, and a share $1-\eta$ of them carries a positive label, so its precision against the labels is $1-\eta$. Its recall is the share of positive labels that belong to true positives:

$$R_{\max} = \frac{\pi^*(1-\eta)}{\pi^*(1-\eta) + (1-\pi^*)\,\eta}, \qquad \mathrm{F1}_{\max} = \frac{2\,(1-\eta)\,R_{\max}}{(1-\eta) + R_{\max}}. \tag{20.3}$$

No classifier does better against these labels: the flips do not depend on the document, so nothing in the document can predict them. The recall is where a rare class suffers. Its denominator adds the negatives flipped to positive, $(1-\pi^*)\eta$, to the true positives, $\pi^*(1-\eta)$, and when positives are 1% of the documents, a flip rate of 0.5% already makes a third of the positive labels flipped negatives that no classifier can find.

To use the ceiling we need η. Two annotations of the same documents that flip independently, symmetrically and at the same rate disagree with probability $d = 2\eta(1-\eta)$, so $\eta = (1-\sqrt{1-2d})/2$, and the observed share of positives, $\pi^*(1-2\eta)+\eta$, then gives π^*. The same model makes a prediction that can be checked before any estimate: both annotations have the same expected share of positives. We have two candidates for the second annotation, and the check applies to both. Llama's labels fail it by a wide margin, 9.1% positive against Qwen's 1.4%, a difference of scale rather than of noise. Qwen's own justification-first answers on the test rows fail it as well, less obviously: 1.05% positive against 1.80% under the digit protocol. The ceiling that the cell computes from them is therefore the value under a symmetric model that our data do not support, and we read it beside a number that needs no model of the noise: the F1 of one protocol scored against the other. The symmetric estimate is also optimistic. Errors that both protocols of one model share are invisible to it, so the true ceiling is lower. A classifier above the ceiling would therefore be a warning sign: it would mean that the flips do depend on the document, and that the classifier has learned its labeller's systematic errors.

The cell checks the identity at 50 thresholds and the ceiling against a simulation of a million documents, then estimates η and the ceiling.

The identity holds to rounding error, and the closed form agrees with the simulation at three noise levels. The two protocols disagree on 19 of the 2,000 test rows, which under the symmetric model gives $\eta \approx 0.005$ and a ceiling F1 of about 0.80, with an interval from 0.68 to 0.89. The disagreements themselves reject that model. In 17 of the 19, the digit protocol scores 3 or more and the justification-first protocol less; if the two directions were equally likely, a split at least this uneven would occur less than once in a thousand. The number that needs no noise model comes from the cross-tabulation of the two protocols printed earlier: 36 positives under the digit protocol, 21 under the justification-first protocol, 19 under both. One protocol scored against the other therefore reaches an F1 of $2 \cdot 19/(36+21) \approx 0.67$, which says how well Qwen3.8-27B reproduces its own labels when it is asked a second way. All four classifiers are below the 0.80, and their F1 values, 0.26 to 0.56, are below the 0.67 as well, although the logistic head's interval, which reaches 0.68, does not exclude it. Label noise thus accounts for part of the classifiers' errors, and with 36 positives no estimate of it is precise. An exercise asks for the ceiling under asymmetric noise.

20.2.3 Choosing a Threshold

A threshold turns a score into a decision, and the right one depends on what the corpus is for. On the validation rows, t^* maximizes the F1, which weighs precision and recall alike. Read through Equation 20.2, every threshold is also a retained fraction, and the retained fraction is what a pretraining run cares about: multiplied by the size of the crawl, it gives the tokens left to train on. A run limited by data, which would otherwise repeat its tokens (Section 21.6), should keep more and accept a lower precision. A run limited by compute, which will never read all of its data anyway, can afford a high threshold and spend its steps on the best documents. The cell plots precision, recall and F1 against the retained fraction on the test rows, converts each classifier's t^* into the shares of stream documents and tokens

it keeps, and sweeps the regression head's cut.

Look at the retained shares first. FineWeb-Edu's own rule, the released classifier's rounded score at least 3, keeps 7.1% of our stream's documents and about 10% of its tokens, close to the 7.26% of documents that FineWeb-Edu kept of the whole dump. Our head at t^* keeps about 3% of the documents and about 5% of the tokens, roughly half of FineWeb-Edu's tokens. This is the strict scale at work: a score of 3 is several times rarer on Qwen's scale than on Llama's, and a filter that looks for it keeps less. The token shares exceed the document shares because the kept documents are longer than average.

The sweep shows the trade. A cut at 1.5 keeps 5% of the documents and finds 92% of the educational test rows, at a precision of 0.27; t^* keeps 3% at a recall of 0.67; a cut at 2.0 keeps 0.3% at a precision of 0.64 but finds only a fifth of the positives. At 2.5 and above the head keeps nothing at all, for the reason we met with t^*: its predictions never reach the label's own threshold. Of a trillion tokens of such a dump, t^* keeps about 50 billion. A run that needs more tokens moves the cut down and accepts that most of what it adds is, by the rubric, not educational.

The manifest therefore stores the score, not the decision. `lm-c1-docs-v1` records each crawl document's predicted score to three decimals, and the threshold is a parameter of its stage, so Section 20.4 can weight bands of the score as separate sources without labelling anything again.

20.2.4 Auditing Removals

A filter that removes 97% of the documents will remove some kinds of pages more than others, and an audit asks which. It has two parts, a table of removal rates by group, each with an interval, and a reading of removed documents. We form three groupings. The country-code domain (.uk, .au, .in and others, against .com) is a proxy for the variety of English, and a weak one: much British writing lives on .com, and a .in domain says where a site is registered, not who wrote it. The host class sorts hosts, by rules on their names, into edu_gov, wiki, forum, news, blog, shop and other. The six FineWeb-2 languages enter under the rules only, because the classifier was trained on English and has nothing to say about Thai. All of it is measured on FineWeb's output, so the audit cannot see what FineWeb's own filters and deduplication removed before the stream was drawn.

The intervals need care. Documents from one site are alike: they share templates, authors and topics, and a filter tends to decide them alike. A bootstrap that resamples documents treats 3,000 pages of one site as 3,000 samples and reports an interval far too narrow. `audit_removals` resamples whole registered domains within each group, a *cluster bootstrap*, and marks groups with fewer than 100 documents or fewer than 10 domains as too few to report.

The cell applies three decisions to the stream: the rules alone, our classifier alone at t^*, and both. For each group it reports the removal rate and its difference to the reference group, .com for the country codes and "other" for the host classes, with a cluster-bootstrap interval. It repeats the audit on two halves of the stream, split by registered domain so that no site appears in both, and keeps a finding only if its sign is the same in both halves. The claim under test is the one an audit exists for: that the combined filter removes some group at a rate that differs from the reference by more than the interval, and that the classifier contributes to the difference beyond the rules. That second part is read from the classifier-alone arm. On FineWeb's output the rules remove so little that the classifier-alone and combined arms nearly coincide.

Why should anyone care which groups lose more? A filter keyed on a classifier's score is a covariate shift by construction: it changes the distribution of the inputs a model trains on, in the direction of whatever the classifier was trained to prefer (Section 3.6). Gururangan et al. (2022) found that the filter used for GPT-3, a classifier trained to tell curated text from random web pages, preferred articles from the newspapers of American high schools in larger, wealthier and more urban areas. Dodge et al. (2021) found that C4's list of banned words removed disproportionately much text in African-American and Hispanic-aligned English, and text that mentions gay and lesbian people. Neither filter was designed to do this. Both did it because their notion of quality was learned from text that was not drawn evenly from the people who write.

The overall rates frame everything else: the rules remove 1.6% of the stream, the classifier 97.2%. Two groups pass every test. The classifier removes .au pages at a rate 1.9 points higher than .com pages, with an interval from 0.9 to 2.7 points and the same sign in both halves, and shop hosts at a rate 2.6 points higher than other hosts. A difference of two points matters more than it seems, because what reaches the corpus is what the filter keeps: about 3% of .com pages against about 1% of .au pages, 6 of the 544, so Australian sites enter the corpus at roughly a third of the rate of .com sites. Six pages are few, so the third is a rough figure; the interval on the difference is the measured statement. The shops are the rubric working as written, since product pages teach little. The rules have one finding of their own: they remove news pages 1.4 points less often than other pages, in both halves. The other country codes show differences whose intervals include zero, and .ie, .ng, .ph and the wiki hosts are too few to report. These data cannot say why .au differs. The country code is a weak proxy, and the finding is a reason to read .au removals, not a conclusion about Australian English.

Rates say how much each group loses, not whether the losses are mistakes. For that, someone has to read removed pages. We draw 100 documents that our classifier removed and the rules kept, all with a score within 0.3 of t^*, where a mistake is most likely, and 100 that the rules removed, whatever the classifier decided. The labels do not come from people. They come from Qwen3.8-27B again, this time as a judge with its reasoning switched on, under a two-line rubric that asks a different question from the training rubric: would a reader want this page in a general-purpose training corpus? The reasoning has no budget. A budget of, say, a thousand tokens can stop the model in mid-thought and force a verdict it has not reached, so each reply may use up to 12,000 tokens of the 16,384-token context; in practice the replies were short, and none was cut off. Unlike the labeller, the judge takes ten requests per server at a time, which makes the review faster but not reproducible to the bit: batching changes the arithmetic, as we saw above, so a regenerated review can change the verdicts of pages near a tie. The review is not independent of the filter it checks, since the same model wrote the training labels, and a human reading of the same 200 pages would be the stronger test. The cell reports the share of each arm labelled "drop", the *removal precision*, with a Wilson interval, and prints five of the pages.

The two arms differ sharply. Of the classifier's removals near its threshold, the judge would have dropped about 1 in 10 (interval 6 to 19 in 100); of the rules' removals, about 70% (interval 60% to 78%). Near its threshold the classifier mostly removes pages that a general corpus would keep, like the hiring guide that opened the section. The rules mostly remove pages that nobody would miss, such as the product description of a pair of jeans, though not always: an encyclopedia entry on Erisichthon of Greek mythology and a massage therapist's professional profile were removed by rules and judged worth keeping. The classifier is doing what it was trained to do. It looks for pages that teach schoolchildren, and by that

rubric the pages it removes are removed correctly; the judge's rubric is broader. The gap between 0.11 and 0.70 is the gap between two definitions of quality, and choosing between them is a decision about the corpus, not about the classifier.

The last comparison puts our classifier and the released one side by side on the whole stream, each at its own threshold.

They keep 2.9% and 3.6% of the documents and agree on 96.7% of them, but most of that agreement is on documents both remove. Cohen's kappa, which discounts the agreement expected by chance, is about 0.47. Two classifiers with the same test F1 select noticeably different corpora.

20.2.5 The Filter in the Pipeline

The filters enter the corpus of Section 20.1 as two stages of its manifest. The `heuristics` stage removes documents and charges each one to the first rule that fires. The `edu_score` stage removes nothing. It attaches the score and records the threshold, the head's SHA-256 and the embedder's revision as parameters, so a later stage, or a reader, can apply any threshold and know exactly which model produced the scores. The flags file `lm-c1-docs-v1` holds, for each crawl document, its id, its reason codes and its score, and no text.

The rules keep 1,032 of the 3,288 crawl documents, and 20 of those score at or above t^*, about 2%, in line with the stream. The last cell compares every number this run computed with the registered results, and the manifest and the head's weights with their registered copies.

Every filter in this section removes documents because they differ from something: from English function words, from a reference model's training data, from what Llama or Qwen think a schoolteacher would use. What survives leans toward the annotator's taste. The audit can show where it leans, but not whether a model trained on the result is better or worse for it. That takes training runs with everything but the data held fixed, the method of Section 20.4, whose web text is FineWeb-Edu as released, filtered by the labels of Llama-3-70B.

20.2.6 Summary

A quality filter decides which part of the web a model learns from, and it follows a definition of quality that somebody wrote down: rules over surface statistics, or a rubric that a large model applies and a small classifier learns. The Gopher, C4 and FineWeb rules remove about two thirds of our crawl documents and match FineWeb's code on about 96% of them. They remove every Chinese, Japanese and Thai document, whose words are not separated by spaces, and our word pattern removes every Hindi one. The documents of lowest perplexity are boilerplate and machine-written prose. Qwen3.8-27B, scoring documents under FineWeb-Edu's rubric from its next-token probabilities, uses a far stricter scale than Llama-3-70B did (about 1.4% against 9% at 3 or more) yet orders documents alike. A linear head on a frozen embedder learns its labels about as well as the released classifier does. Both stay below the F1 of about 0.67 at which Qwen reproduces its own labels when asked a second way. Since $\mathrm{F1} = 2\pi\,\mathrm{TPR}/(\pi + \rho)$, a threshold is a choice of retained fraction, here about 3% of the documents. An audit that resamples whole sites finds that the classifier removes Australian domains and shops more often, and near its threshold it mostly removes pages that a general corpus would keep.

20.2.7 Exercises

1. **Two F1 scores on one card.** The released classifier's card reports an F1 of 82% "when converted to a binary classifier using a score threshold of 3", and a classification report in which score 5 has an F1 of 0.02.
    1. Explain why both can be true, and what each says about using the classifier as a filter at 3.
    2. The card's confusion matrix over its 46,867 hold-out rows has these rows, true scores 0 to 5, and columns, predicted scores 0 to 5: (2791, 2858, 45, 0, 0, 0), (919, 22343, 3180, 69, 1, 0), (3, 3225, 6330, 757, 7, 0), (1, 66, 1473, 1694, 173, 0), (0, 4, 98, 420, 283, 2), (0, 0, 18, 85, 21, 1). Compute the F1 of the positive class "score at least 3". Which average over the two classes gives 82%?
    3. code Our test rows are drawn from this hold-out. Compute the released classifier's F1 against Llama's labels at its rounded score 3, and compare it with the table's 0.54 at t^*. Why do the two differ?
2. **Thresholds on a regression.**
    1. Why is the F1 at the threshold that maximizes F1 on the test rows an optimistic estimate of the F1 at deployment? Name two ways to avoid the bias.
    2. Among the documents that a head cannot tell apart, a share q is labelled 3 and the rest 1. Show that the prediction minimizing the expected squared error on them is $1 + 2q$, and find the q at which it reaches 2.5. Use this to explain why our regression head keeps nothing at a cut of 2.5.
    3. Would the logistic head's probability have the same problem with a cut at 0.5? Compare its t^* with 0.5 and explain.
3. **The cost of a false removal.** A crawl holds T tokens in documents of equal length, of which a share π are labelled educational.
    1. Using Equation 20.2, write the educational tokens that a filter with retained fraction ρ and score F1 removes, in terms of T, π, ρ and F1.
    2. Put in this section's numbers ($\pi \approx 0.014$, $\rho \approx 0.029$, F1 ≈ 0.44) for $T = 10^{12}$. How many educational tokens does t^* remove?
    3. A classifier at the noise ceiling of Equation 20.3 keeps the same ρ. Bound the educational tokens it removes, and say when your bound is vacuous. Which part of the loss could a better classifier recover, and which part is in the labels?
4. **Asymmetric noise.** ● The labeller misses a true positive with probability η_1 and invents a positive from a true negative with probability η_0.
    1. Derive the precision, recall and F1 against the labels of a perfect classifier of the true label.
    2. With $\pi^* = 0.0926$ and $\eta_1 = 0.02$, find the η_0 at which this ceiling equals the symmetric ceiling at $\eta = 0.05$.
    3. Our two protocols disagree on 19 test rows, 17 of them in one direction. Can η_0 and η_1 of each protocol be estimated from two annotations alone? What would a third annotation add?
5. code **Two labellers, two filters.** Train a second regression head on Llama's scores, choose its threshold on the validation rows against Llama's labels, and apply both heads to the stream. Report the share each keeps, their Cohen's kappa with an interval, and the host classes and country codes where their decisions differ most. Then

predict which of the two filtered corpora would train the better model, and say how the proxy runs of Section 20.4 could test your prediction.

6. code **How far behind is the bag?** Before measuring, state the largest F1 gap between the hashed bag and the regression head that you would accept for a filter that runs on a CPU. Measure the gap with a paired bootstrap over the test rows. Then try to close it without a GPU: more epochs, character n-grams, or training the bag on the score rather than the binary label. Which change helps, and is the improvement larger than its interval?

7. code **A human review.** Read the 200 reviewed documents yourself and label each one under the two-line rubric of the review cell, without looking at the judge's labels. Compute the removal precision of each arm with its Wilson interval and Cohen's kappa between your labels and the judge's. Do your labels change the conclusion about the two arms? Where you and the judge disagree, which of you followed the rubric?

8. [extended] **Quality or script?** Choose one of the six FineWeb-2 languages that you read. Draw 50 of its documents that the English rules remove, label each as worth keeping or not, and record which rule fired first. Are the removals quality or script artifacts? Rewrite the rules that fire most so that they suit the language (a word tokenizer for the script, stop words of the language), and report the removal rate and your labels' precision again.

20.3 Deduplication and Decontamination

The filters of Section 20.2 judge one page at a time. They can tell a manual from an advertisement for love spells, but they cannot notice that they have just kept the same manual for the third time. The web is full of such repeats. Mirror sites copy whole pages, blogs republish a post with a paragraph added, and shop software prints the same notice about card payments under thousands of products. A model trained on a corpus with repeats reads those texts again and again, and what a model reads often it learns to reproduce word for word. The repeats also use compute that new text would have used better.

Exact copies are easy to find: hash every document and look for equal hashes. The repeats that matter are rarely exact. The cell below prints two posts from one music blog in FineWeb's output, the second of which is the first with one paragraph added, and their SHA-256 hashes have nothing in common. To catch such a pair we need a measure of similarity, and comparing every pair of documents is out of reach: the cell times about eight microseconds per pair, which is half an hour for the 20,000 documents of our stream and about 10^5 years for a billion.

The way out goes back to Andrei Broder, who in 1997 needed to find near-duplicate pages in the index of the AltaVista search engine. Give every document a short *signature* such that two signatures agree in any one position with probability equal to the similarity of the documents. Cut the signatures into pieces and use the pieces as keys of a hash table, and similar documents meet in a bucket without being compared with the rest. How the pieces are cut sets a threshold, which we can tune on labelled pairs like that of any classifier. This section builds the signature, checks it against its derivation and tunes it, then adds two methods that see what document signatures cannot: long spans shared by otherwise different documents, and documents that say the same thing in other words. It closes on the duplicates that matter most, test items that leaked into training data, and on the last three stages of the manifest that Section 20.1 began.

Everything in this notebook runs on the CPU, with four worker processes, in a few minutes and about 7 GiB of memory. Two inputs were made once on a GPU and are read from registered files: the paraphrased test items, written by Qwen3.5-4B, and the embeddings of the test items and of windows of FineWeb documents, made by Qwen3-Embedding-0.6B. The labelled pairs, the decisions for our crawl, the manifest and the section's numbers are registered as well, so that a reader's run can be compared with ours. Setting `D2L_RERUN` to names from `ARTIFACTS` regenerates those files under new names. `dedup-plants` and `dedup-emb` need a GPU, and `dedup-plants` runs alone, or with `dedup-pairs`, because the detectors read the plants before the cell that makes them. The last cell compares whatever this run computed with the registered results.

None of the registered files holds text of our crawl. The labelled pairs are stored as document ids and edit parameters, and the cell that reads them rebuilds both texts of every pair from FineWeb's stream. The planted test set holds benchmark items under their licences, FineWeb ids and character offsets, and for every paraphrase the hash of its prompt and the model's revision. The embeddings are of FineWeb text and of benchmark items only. The decisions for our crawl and the manifest are ids, reason codes, counts and hashes.

The opening cell reads the 20,000 documents of the audit stream of Section 20.2 and 6,000 more, four pages from each of 1,500 hosts, so that pages of one site can be compared with each other. It finds the most similar pair of same-host pages that are not identical, prints the lines in which they differ, and then times the exact comparison of all pairs among 1,000 documents.

The two pages are 193 and 268 words long, and the only difference is a paragraph that the longer one adds about two EPs on Bandcamp. Their hashes differ, so an exact method treats them as two documents. The resemblance J of Section 20.3.2.1 puts them at 0.70, below the threshold of 0.8 that we will use, while the share of the shorter page found in the longer one is 1.00. Which of these numbers describes "a duplicate" is the first decision of the section. The timing is the second fact. A quadratic method that costs half an hour on the 20,000 documents of the stream would take about 10^5 years on 10^9 documents, and no amount of hardware closes a gap of that size. The method has to avoid comparing pairs, not compare them faster.

20.3.1 Exact Duplicates

A document hash finds copies. We hash the NFC text of every document with SHA-256 and keep the first document of each hash. NFC matters here as it did in Section 20.1: the same "é" written as one code point or as two gives different bytes, and different bytes give different hashes. A collision of two different texts under SHA-256 is not a practical concern, so equal hashes mean equal texts.

The same idea applied to lines finds shared parts. Hash every line of at least five words and count the documents that contain it. A line that occurs in many documents is almost always boilerplate: a cookie notice, a navigation bar, the text that blog or shop software prints under every post. Such a line is a span problem, not a document problem. The documents that carry it differ, and removing them would throw away their content to get rid of one sentence. C4 handled this at the span level, discarding all but one of every three-sentence span that occurred more than once in the corpus (Raffel et al. 2020).

One pitfall belongs here because it is easy to commit and hard to notice. Deduplication must come before the split into training and validation data. After the split, copies of one page

land on both sides, and the validation loss partly measures how well the model remembers its training set.

FineWeb's output has no exact copies at all: 26,000 documents, 26,000 distinct hashes. Yet 1,482 lines occur in more than one of its documents, and 1,742 documents, about one in fifteen, contain at least one of them. The most frequent is a notice about secure card payments in 36 documents, followed by the notices that shop software prints under products and WordPress's "Your email address will not be published". Our own crawl after the rules, c1, has 12 exact copies among its 1,032 documents. Nothing has deduplicated it yet, while FineWeb removed copies within its dump before we drew the stream.

20.3.2 MinHash and Banding

An exact hash answers one question, equal or not. It cannot be a little bit equal: change one character and the two digests share nothing. Near-duplicates need a similarity and a way to find similar pairs without the comparison of all pairs that the opening cell timed. The three subsections below build this. We define similarity as the overlap of two sets of word sequences, show that a signature of 128 numbers per document estimates it, and cut the signature into bands that act as hash keys, so that similar documents meet in a bucket and dissimilar ones almost never do.

20.3.2.1 Similarity as Set Overlap

A document becomes a set by *shingling*: its *shingles* are its runs of n consecutive words. FineWeb uses $n = 5$ (Penedo et al. 2024), and so do we. For two documents with shingle sets A and B, Broder defined two measures of overlap,

$$J(A,B) = \frac{|A \cap B|}{|A \cup B|}, \qquad C(A,B) = \frac{|A \cap B|}{|A|}.$$

The *resemblance* or Jaccard similarity J is symmetric and equals 1 only for equal sets. The *containment* C of A in B asks how much of A is found in B. The opening pair is the case in which the two disagree. When A lies inside B, the containment is 1 and the resemblance is $|A|/|B|$, so a page cut to half its length is a perfect match by C and a poor one by J. FineWeb and this section use J. A truncated copy therefore counts as a duplicate only if most of the page survives, which is a choice and should be recognised as one. Readers who met the intersection over union of boxes in Section 32.4 know J already, with areas of pixels in place of counts of shingles.

The code follows a fixed specification, so that two implementations can be compared bit for bit. Text is normalized to NFC and lowercased, and a word is a match of the regular expression `\w+`. A document with fewer than five words has no shingles, and later no signature, so it never matches anything. Shingles are hashed with blake2b, never with Python's built-in `hash`, which is salted afresh in every process: signatures built on it would change from run to run, and so would every manifest hash computed from them.

How similar are web pages to each other? The cell shingles all 26,000 documents and computes the exact J of 5,000 random pairs and of 5,000 pairs of pages from one host.

A document has a median of 360 shingles, and all the shingle sets together take 1.76 GiB as Python sets; signatures of 128 numbers take 25 MiB, about seventy times less. Two random pages share no five-word sequence at all, up to the 99th percentile. Pages of one site share

more, through their templates, and the figure shows their tail on the log scale, but even their 99th percentile is 0.32, and no pair in either sample reaches 0.8. This is the shape the method has to exploit. Almost every pair is far below the threshold, and the work worth saving is the work of looking at those pairs at all.

20.3.2.2 MinHash

Let us start with a thought experiment that is too expensive to run. Put all possible shingles in a random order π, and let $h_\pi(A)$ be the shingle of A that comes first in this order, the *minimum* of A under π. Two documents agree in this one value with a probability that we can compute.

Proposition. *For a uniformly random order π and non-empty sets A and B,* $\Pr[h_\pi(A) = h_\pi(B)] = J(A, B)$.

Proof. Let x^* be the element of $A \cup B$ that comes first under π. The order is uniform, so every element of the union is equally likely to be x^*, and the probability that x^* falls in a subset is the size of the subset over the size of the union, as for any uniform choice in Section 1.6. If x^* lies in $A \cap B$, it is the minimum of both sets and the two values agree. If x^* lies in A but not in B, it is the minimum of A, while the minimum of B comes later, so the values differ, and the same holds with the roles exchanged. The values therefore agree exactly when $x^* \in A \cap B$, which has probability $|A \cap B|/|A \cup B|$. ■

One order gives one coin flip with success probability J. A *MinHash signature* repeats the experiment with k independent orders and stores the k minima. The share of positions in which two signatures agree estimates J, and since the number of agreeing positions is a binomial count of k trials (Section 1.6), the estimate is unbiased with a variance we can write down:

$$\hat{J} = \frac{1}{k}\sum_{i=1}^{k} \mathbf{1}\big[h_{\pi_i}(A) = h_{\pi_i}(B)\big], \qquad \mathbb{E}[\hat{J}] = J, \qquad \mathrm{Var}[\hat{J}] = \frac{J(1-J)}{k}. \tag{20.4}$$

The remarkable part is what the signature does not depend on. It has k numbers whether the document has 50 shingles or 50,000, and two signatures estimate the similarity without the documents. The estimate is noisy: at $J = 0.8$ and $k = 128$ the standard deviation is $\sqrt{0.16/128} \approx 0.035$, so pairs at 0.75 and at 0.85 are not reliably told apart.

A random order of all possible shingles cannot be stored, so implementations use hash functions instead. Each shingle is hashed to a number x below the prime $p = 2^{61} - 1$, and position i of the signature is the minimum of $(a_i x + c_i) \bmod p$ over the document's shingles. For $a_i \neq 0$ this map is a bijection of $\{0, \dots, p-1\}$, so it does order the shingles, but it is one of about p^2 such maps rather than a uniform choice among all orders, and the proposition holds only approximately. Whether that matters is a question for measurement. The specification fixes every remaining choice:

1. NFC, lower case, `\w+` words, shingles of five words joined by one space;
2. each shingle hashed by blake2b with an 8-byte digest, read as a little-endian integer and reduced modulo p;
3. (a_i, c_i) for $i = 1, \dots, 128$ drawn from `numpy.random.default_rng(0xD2)` as integers in $[1, p)$;
4. the product $a_i x$ computed exactly.

The last point hides a trap. Both factors are below 2^{61}, so their product needs up to 122 bits, and NumPy's `uint64` arithmetic silently discards everything above 64. The library splits the multiplication into 32-bit halves.

We check the estimator on sets whose similarity we choose: for each J from 0.1 to 0.9, 200 pairs with unions of 200 random words. If the hash family behaves like random orders, the mean of $\hat{J}$ lies within three standard errors of J and the variance across pairs is close to $J(1-J)/k$. The same pairs go through datasketch's `MinHash`, an independent implementation. Finally, the signatures of five fixed strings, whose hash the library pins, are compared position by position with a version of the specification in Python integers, which never overflow.

In every bin the bias is within two standard errors (the largest $|z|$ is 1.85), and the variance is between 0.88 and 1.16 times its formula. Datasketch behaves the same way. The fixture signatures are equal to the integer reference in all five strings, and their hash equals the pinned one, so any implementation of the specification can test itself against these five. For sets of this size, then, the $(ax+c) \bmod p$ family is as good as a random order, and the 95% half-width at $J = 0.8$ is $1.96\sqrt{0.8 \cdot 0.2/128} = 0.069$, as the formula says.

20.3.2.3 Banding and the S-Curve

An estimate of J for one pair still leaves us comparing pairs. *Banding* turns the signature into a search. Cut the $k = br$ positions of every signature into b bands of r positions, and use each band, hashed, as the key of a bucket. Two documents become a *candidate pair* if they share a bucket in at least one band. For a pair of similarity s, one position agrees with probability s, and the positions come from different hash functions, so a whole band agrees with probability s^r. All b bands disagree with probability $(1-s^r)^b$, and the pair becomes a candidate with probability

$$P(s) = 1 - (1 - s^r)^b. \tag{20.5}$$

For small s the curve is close to bs^r, tiny, and for s near 1 it is close to 1; in between it rises steeply, which gives it its name, the *S-curve*. Its derivative $P'(s) = brs^{r-1}(1-s^r)^{b-1}$ is largest where $(r-1)(1-s^r) = (b-1)rs^r$, that is at $s^* = ((r-1)/(br-1))^{1/r}$, close to $(1/b)^{1/r}$. More rows per band move the step to the right, more bands move it to the left. The smallest case needs four numbers. With $b = r = 2$, $P(s) = 1-(1-s^2)^2$, which is 0.4375 at $s = 0.5$ and 0.964 at $s = 0.9$, so a signature of four values already separates these two similarities most of the time.

The budget k is fixed by memory and by the cost of hashing, so the design question is how to split it. A natural answer compares the S-curve with the ideal step at the threshold τ. The area under the curve left of τ counts pairs below the threshold that become candidates, the area above the curve right of τ counts duplicates that are missed, and two weights say what each error costs:

$$E(b,r) = w_{\text{fp}} \int_0^{\tau} P(s)\,ds + w_{\text{fn}} \int_{\tau}^{1} (1 - P(s))\,ds. \tag{20.6}$$

`best_br` minimizes E over r with $b = \lfloor k/r \rfloor$, as datasketch's `MinHashLSH` does internally. The integral weighs every similarity in $[0,1]$ equally, an assumption that will matter.

FineWeb's setting, 112 positions as 14 bands of 8 rows, gives candidate probabilities of 0.56, 0.77, 0.92 and 0.988 at similarities 0.7, 0.75, 0.8 and 0.85, the four values its paper reports. Its steepest point is at 0.71, because FineWeb aimed at pages about 75% similar. The steepest points agree with the formula to four decimals. Under equal weights the best split of 128 positions for $\tau = 0.8$ is $(9, 13)$, found alike by `best_br`, by a brute-force search over all $br \leq 128$ and by datasketch. A pair at the threshold becomes a candidate with probability 0.40 there, and the steepest point lies at 0.84, so this optimum misses more borderline duplicates than it admits borderline non-duplicates. Weighting misses five times as heavily moves the choice to $(12, 10)$.

To tune (b, r) on data we need pairs with known similarity. The stream cannot provide near-duplicates, because FineWeb deduplicated its dump with MinHash before we drew from it, so the pairs are made by editing stream documents. From 2,000 documents of at least 50 words, the generator makes three copies each, every copy by one random edit: words substituted or deleted at a rate between 1% and 30%, a block of 20 to 200 words of boilerplate inserted, the paragraphs shuffled, or the text truncated to 30% to 90% of its words. Then come 3,000 pairs of different pages from one host, which share templates, and 3,000 random pairs. The label is the exact $J \geq 0.8$ of the final texts. This makes the task a test of the sketch: estimate a known J well enough to threshold it. Whether $J \geq 0.8$ is the right definition of a duplicate is a separate question, which no labelled pair can settle. The pairs are split into training and test halves by the SHA-256 of the base document, so that the copies of one document stay together.

The rebuilt texts reproduce every stored J exactly. The table shows how unevenly the edits move a page across the threshold. Shuffled paragraphs stay duplicates most often, because only the shingles that cross a paragraph boundary change. Substitutions do surprising damage. Each changed word removes up to five shingles, so a substitution rate q leaves a share of about $x = (1 - q)^5$ of each document's shingles intact, and then $J = x/(2 - x)$. One word in fifty gives $J \approx 0.82$, a duplicate; one word in twenty gives 0.63, not one. Truncation is the case of containment: a copy cut to a share f of its words has $J \approx f$, so only copies that keep at least 80% of the page are labelled duplicates.

The derivation predicts that a pair of exact similarity J_i becomes a candidate with probability $P(J_i)$, and the pairs let us test this. We test 13 settings, the 12 splits of 128 positions with r from 4 to 16 and FineWeb's $(14, 8)$ on the first 112 positions, with three hash seeds each. In every bin of J of width 0.05, the number of candidates is a sum of independent trials with different probabilities, a *Poisson-binomial* count, whose exact distribution gives a 95% interval around the expected count $\sum_i P(J_i)$. The curve at the bin's centre would not do: at $(9, 13)$ it rises from 0.40 to 0.69 between 0.80 and 0.85. A hash that behaves as derived leaves about 5% of the (setting, bin, seed) cells outside their intervals, or fewer; a flawed one leaves many more.

Of the 780 cells with at least 30 pairs, 19 fall outside their interval, 2.4%, against an upper bound of 59 at the 0.999 level. Every setting keeps at least 93% of its cells inside. In the table for $(9, 13)$ the bin from 0.80 to 0.85 holds 813 pairs and expects 445 candidates, with an interval from 418 to 473, and the three seeds give 431, 438 and 429; below 0.5 no pair becomes a candidate at all. The figure shows the same agreement against five theoretical curves, among them RefinedWeb's 450 bands of 20 rows (Penedo et al. 2023), and the bucket pipeline makes the same decisions as the pair-by-pair test. The intervals treat the pairs of a bin as independent, although the three copies of one document share shingles, but the margin to the bound is wide. The sketch does what the derivation says.

Now we choose (b, r) like a hyperparameter. On the training pairs we count false positives and false negatives of each setting, averaged over the three seeds, and take the setting with the fewest errors when a miss weighs $w_{\text{fn}} = 1$ and when it weighs 5. On the test pairs we report precision, recall and F1, and we compare the chosen setting with its neighbours on the grid and with the optimum of Equation 20.6 by a bootstrap that resamples base documents, since a document and its copies move together.

With $w_{\text{fn}} = 1$ the training pairs choose $(11, 11)$, and with $w_{\text{fn}} = 5$ they choose $(14, 9)$: a heavier weight on misses moves the choice to fewer rows per band, as the derivation suggests. On the test pairs $(11, 11)$ reaches precision 0.86, recall 0.89 and F1 0.87, ahead of the equal-weight optimum $(9, 13)$ by $+0.04$ $[+0.03, +0.05]$ in F1. Its lead over its neighbours on the grid is small: against $(12, 10)$ the F1 difference is not resolved, although the error count it was chosen for is lower by a small resolved margin. FineWeb's $(14, 8)$ has recall 0.99 at precision 0.72 on our labels, since a curve built for 0.75 counts many pairs between 0.7 and 0.8 as duplicates.

Why do the pairs disagree with Equation 20.6? The hashes are not to blame; the measurement above showed that. The integral weighs every similarity between 0 and 1 equally, and the pairs do not: most negatives sit at $J = 0$, where every setting is right, and the copies crowd around the threshold. Replace the uniform weight by the pairs' own similarities, so that the expected weighted error is $\sum_i [P(J_i)(1 - y_i) + w_{\text{fn}}(1 - P(J_i))\, y_i]$, and its minimum lies at $(11, 11)$ and at $(14, 9)$, the two settings that the hashed decisions chose; the cell asserts it. The derivation is right about the curve and wrong about the data. A deployment should tune (b, r) on the similarities of the pairs it will actually decide, and labelled pairs, even synthetic ones, are the cheapest way to see them.

A threshold that looks right on labelled pairs can still fail at scale. By linearity of expectation, the expected number of candidates among N documents is $\sum_{i<j} P(s_{ij})$, the number of pairs times the mean of P over their similarities. Nearly all pairs are dissimilar, so the total is decided far below the threshold, by $P(0.3)$ and $P(0.5)$, and every candidate from that bulk costs a lookup and a union like a true one. The count can also explode through templates. Templated pages share whole bands, so a single bucket can collect thousands of documents, and a bucket of m documents yields $m(m-1)/2$ pairs. `lsh_candidates` therefore cuts any bucket above `max_bucket` members to a seeded sample and reports every cut.

At $(11, 11)$ a pair of similarity 0.3 becomes a candidate with probability 2×10^{-5}, at FineWeb's $(14, 8)$ with about 10^{-3}, fifty times more. For a million documents with 0.1% of their pairs at similarity 0.5, the two settings expect about 3×10^6 and 3×10^7 candidates. On our slice neither setting produces a single candidate, and even the loose $(32, 4)$ finds only 104 pairs, about four per thousand documents, with no bucket above six members. This is a measurement of an already deduplicated corpus, not an estimate for a raw crawl, which is where the giant buckets live.

20.3.3 From Pairs to a Deduplicated Corpus

Candidate pairs are not yet a corpus. Treat them as edges of a graph; the *clusters* are its connected components, which `union_find_clusters` computes in almost linear time. Clusters are transitive: if A resembles B and B resembles C, all three land in one cluster even when A and C are below the threshold, as with a chain of revisions of one page. Each cluster keeps one document, and which one is a choice. We keep the one with the lowest index, so that the result depends neither on the order of the pairs nor on a random draw. Keeping the document with the highest quality score or the longest one is also reasonable, and whichever

rule is used belongs in the manifest. The function `near_dedup` wraps shingling, signatures, banding and clusters in one call, and Section 24.3 uses it on instruction data.

Deduplication also needs a scope. FineWeb deduplicates each Common Crawl dump on its own (Penedo et al. 2024). Its authors tried deduplicating all dumps together and found that it did not improve the models trained on the result: in the older dumps, the documents that survived global deduplication made worse training data than those it removed. Global deduplication sounds stricter and therefore better, and on their evidence it is not. Our corpus is one archive range of one dump, so the question returns only in the last exercise.

The slice keeps all 26,000 documents, as expected after FineWeb's own deduplication with a looser setting. Our crawl is different. At $(11, 11)$, the setting chosen on the training pairs and the one the manifest uses, c1 keeps 1,014 of its 1,032 documents. Its 13 clusters hold 31 documents; the largest is four copies of one page on three hosts, and the next ones are copies within one site. The default of `near_dedup` is the equal-weight optimum $(9, 13)$, because a library cannot know the reader's pairs, and it keeps one document more.

20.3.3.1 Substring Duplicates

MinHash compares whole documents, and some duplication lives in parts of them. A footer of 60 words shared by two otherwise different pages of a few hundred words each adds about 56 shared shingles and leaves J near 0.1. No setting of (b, r) will flag such pairs, and none should, because the pages are different, yet a model reads a footer on thousands of pages thousands of times. Lee and colleagues (2022) found in C4, for example, one sentence of 61 words that occurred more than 60,000 times. Their *exact-substring* deduplication finds every span of at least 50 tokens that occurs more than once and removes all copies but one.

The tool is a *suffix array*: the starting positions of all suffixes of the token sequence, sorted lexicographically. Two occurrences of a span start two suffixes that begin with it, so they sort next to each other, and the repeats appear as long common prefixes of neighbouring suffixes. The array `lcp` stores the length of the prefix that each suffix in sorted order shares with the previous one, and every entry of at least 50 marks a span of 50 tokens that occurs twice. *Prefix doubling* sorts by the first token, then by the first two as a pair of ranks, then by the first four, each round one sort of integer pairs, so $\log n$ rounds of $O(n \log n)$ finish the job. Kasai's algorithm computes `lcp` in $O(n)$, because the common prefix shrinks by at most one from the suffix at i to the one at $i+1$. The production tool of Lee and colleagues is written in Rust and builds the array over the whole corpus, with memory that grows with it. Ours runs in NumPy on 2 MiB of the slice, tokenized with the reference tokenizer of Section 20.6, with a unique separator after every document so that no repeat crosses a document boundary.

The sample has 627 documents and about 450,000 tokens, and the arrays take a second or two. It contains three maximal repeats of at least 50 tokens, covering 0.08% of its tokens: a blog's footer inviting readers to newer posts, a function signature from a software manual, and the Fourth Amendment to the Constitution of the United States. None of the four documents involved is in a MinHash cluster. A sample this small cannot contain the 60,000-fold sentences, but it shows the kind, and it shows a trap. Exact-substring deduplication would delete the amendment from one of the two pages that quote it, whatever that page was about. The same trap returns in decontamination.

20.3.3.2 Semantic Duplicates

The third relative works in a different space. *SemDeDup* (Abbas and colleagues, 2023) embeds every document, clusters the vectors with k-means, and within each cluster removes a document whose cosine similarity to another member exceeds $1-\varepsilon$. The clusters do the job that bands do for MinHash: they confine comparisons to documents that are already close, so a pass costs $O(n^2/k)$ instead of $O(n^2)$ for k clusters. The one difference from MinHash is the similarity. Two texts close in embedding space can share few words, and this is the point of the method. We use the Qwen3-Embedding vectors that Section 20.2 registered for the whole stream (Section 19.3 describes what such vectors encode), the k-means of Section 19.4 with 64 clusters, and remove a document when an earlier member of its cluster is closer than the threshold.

The median cosine of a document to its most similar earlier neighbour is 0.46, the 99th percentile 0.70 and the largest 0.94. These numbers belong to this embedder, and so must ε: a threshold that removes nothing here could remove a great deal under a model whose cosines between unrelated texts sit at 0.8, and SemDeDup's values do not transfer to ours. At $\varepsilon = 0.1$ the method removes one document, a genuine near-duplicate that MinHash missed: two pages from one template about signing files, at cosine 0.94 and $J = 0.17$, whose wording was varied phrase by phrase. From $\varepsilon = 0.15$ on it removes something else, different pages on one topic: online gambling, essay-writing services, plumbers' advice on frozen pipes, surfing in Ericeira, all at J near 0. At $\varepsilon = 0.3$ it removes 181 documents, 0.9% of the stream. Whether a second article about frozen pipes should go is a question about how much of each topic a corpus should hold. D4 (Tirumala and colleagues, 2023) builds on SemDeDup to select documents for diversity, and Section 20.4 takes up the question of proportions with training runs.

20.3.4 Decontamination

The duplicates that matter most are not pages copied from each other but test items copied into training data. Section 18.5.2.3 looked at this from the model's side, comparing accuracy on GSM8K problems with accuracy on variants of them. Here we look from the data's side: *decontamination* removes training text that overlaps evaluation items before any model sees it. The authors of GPT-3 (Brown et al. 2020) looked for overlapping sequences of 13 words, ignoring case and punctuation, between their training data and their test sets and removed overlapping documents from training. A bug in the filter left part of the overlap in place, and their paper measured its effect rather than retrain. We build the same test as an index: every 13-word sequence of every test item, normalized like the shingles and hashed, is stored with the item's id, and a document is looked up by its own 13-word sequences.

The index misses some things by construction. A paraphrase shares no long sequence with its source, a translation shares none at all, a problem with changed numbers breaks every 13-gram that contains a number, and an item shorter than 13 words has no 13-gram to find. To measure what it finds we need leaks whose location we know, so we plant them. We draw 100 test items from each of GSM8K, ARC-Challenge and MMLU and insert each in three forms into 900 different documents of the stream: *verbatim* (the question, its lettered options and an answer line), *reformatted* by rule (lower case, spacing and punctuation changed, options in reverse order with new letters), and *paraphrased* by a language model. A further 1,000 documents stay untouched as controls. The paraphrases themselves are examined after the two detectors.

The index holds 633,848 distinct 13-grams of 16,533 test items, and it has blind spots before

any plant is placed: 102 ARC-Challenge items and 1,589 MMLU items are shorter than 13 words even with their answer, and 304 and 4,080 of their questions are shorter on their own. No leak of these can be found this way. The plants were drawn from items whose question has at least 13 words, so that a missed verbatim plant would be a bug.

All 300 verbatim and all 300 reformatted plants are found. The second result says less than it seems. The index ignores case, spacing and punctuation, and reversing the options keeps each option's words, so the reformatted form is found by construction; its recall of 1 shows that the normalization works. The paraphrases are a different matter, 0, 2 and 6 of 100. A 13-gram detector finds copies and nothing else.

One control is flagged. The page quotes "we hold these truths to be self evident that all men are created", and so does MMLU item 3828. A rule that removes every overlapping document deletes every page that quotes the Declaration of Independence or a famous poem, because benchmarks quote them too. Before removing a document, look at the span.

Why do leaked items and duplicates deserve this effort? Language models reproduce text they have seen often. Carlini and colleagues (Carlini et al. 2021) extracted hundreds of verbatim sequences from GPT-2's training data, among them names, phone numbers and code, and later work by the same group found that the share of training data a model reproduces grows with the model's size, with the number of copies of a sequence and with the length of the prompt. Lee and colleagues found that models trained on their deduplicated corpora emit memorized text about ten times less often. Deduplication is a privacy measure as well as a quality measure, and Section 25.7 measures extraction on a model whose training data is known. An overlap, however, is evidence of leakage and not of memorization: a model can see an item once and not learn it, and what a leak did to a score can only be measured on the model, as in Section 18.5.2.3.

A paraphrase keeps the meaning of an item, and meaning is what embeddings measure. The second detector cuts every document into windows of 128 words starting every 64 words, so that a short item is not lost in a long page, and scores each window by the cosine of its closest test item; a document's score is its best window's. The threshold is the 99th percentile of the 1,000 controls, a false-positive budget of 1%, and since a threshold fits the documents it was set on, the false positives are counted on 1,000 other untouched documents. The fair comparison for the paraphrases is the verbatim form under the same detector, its ceiling, not a recall of 1. The vectors were made once on a GPU; the cell checks 16 of them on the CPU.

The held-out controls confirm the budget: 7 of 1,000 are above the threshold. The detector finds 0.42 of the paraphrases, about two in five, with an interval of $[0.37, 0.48]$, against 0.49 of the verbatim plants and 0.54 of the reformatted ones. Paraphrasing costs it little. What limits it is dilution, as the split by length shows. About 20 plants per form are too long for any window to hold whole, most of them over 100 words; they fill their windows, and 95% to 100% of them are found. The other 280 or so have a median under 50 words, share their window with about 80 words of the host page, and only 38% to 51% are found. Smaller windows would help the short plants and add false positives, since every window is another chance to resemble some test item by accident. We keep this detector out of the pipeline: at its budget it would remove about one innocent document in a hundred to find fewer than half of the plants, which makes it a tool for reviewing a corpus rather than for filtering one.

The planted set is an artifact of its own. Its 300 items were drawn with a fixed seed from items whose question has at least 13 words and whose page form has at most 180, and each form was inserted as a line of its own at a sentence start of a stream document. Qwen3.5-

4B wrote the paraphrases once, with thinking off and greedy decoding, and the prompt's hash and the model's revision are stored in every row. It takes two prompts. A prompt that mentions answer options at all makes this model invent four options for GSM8K problems, which have none, so pages with lettered options and pages without get different instructions. Detection is by n-grams and embeddings, so no model grades its own paraphrases. GSM8K and MMLU are under the MIT licence and ARC-Challenge under CC BY-SA 4.0, whose share-alike term is the reason the planted items live in a file of their own with its licence stated.

The three forms of the ARC item show what the paraphraser does: it keeps the question and the answer and changes almost every phrase, so that "a cat has a kitten with a broken leg" becomes "a feline offspring is born with a fractured limb". The check table, printed and never used to filter, says the same for all 300: the median 5-gram J between a paraphrase and its verbatim page is between 0.01 and 0.06, and no paraphrase is empty, lost its answer line or gained options. Two departures remain. In 26 of the 100 GSM8K paraphrases the set of digits changed, mostly because numbers were written as words ("two dozen"), which leaves the problem the same and hides it from the 13-gram index. One MMLU "paraphrase" repeats its item unchanged. Removing such rows after seeing the detectors' results would tune the test to the detectors, so they stay.

Planted paraphrases are not a hypothetical worry. Yang and colleagues (2023) showed that test items rephrased by a language model pass n-gram decontamination and that a 13B model trained on them reaches scores on the original benchmarks far above its ability. The perturbed variants of GSM-Symbolic (Mirzadeh et al. 2025), used in Section 18.5.2.3, attack the problem from the other end, with problems that a model cannot have seen.

20.3.4.1 The Version-1 Manifest

The teaching pipeline ends with three stages on c1. `exact_dedup` keeps the first document of each hash of the NFC text, in c0 order. `minhash_dedup` clusters the rest at $(11, 11)$, the setting chosen on the training pairs, and keeps the lowest index of each cluster. `decontam` removes documents with a 13-gram of any test item and charges each to the benchmark of its first hit. The result is c2. The manifest `lm-corpus-manifest-v1` records all nine stages from the archive range of Section 20.1 on, with parameters, counts and hashes, and every step is deterministic: no salted hash, fixed hash seeds, lowest index per cluster, documents in their order. The cell builds c2 twice, computing the signatures with one process and with four, and compares the manifest hashes. Token counts are of the reference tokenizer; for the first stages they are of the c0 text, which is the text after personal data was removed. `lm-c2-docs-v1` holds, for every c0 document, whether it is kept, the stage that dropped it, the reason and the document it copied, without text.

The two manifests have the same SHA-256, and so do the registered ones. The funnel shows how small deduplication's part is in one archive range: of 1,032 documents, 12 exact and 6 near-duplicates go, about 0.6% of the tokens, and the decontamination stage removes nothing, since our range holds no 13-gram of these test sets. It may still hold paraphrases, which the 13-gram index cannot see. On a quarter of one archive file a page rarely meets its copy; across a whole dump it meets it often, which is why deduplication removes far more at the scale of FineWeb. Of 9,731 records, 1,014 documents with 918,627 tokens reach the corpus, about one record in ten and a third of the English text that extraction produced.

Deduplication decides that each text is seen once. It does not decide which texts deserve to be seen more than once, or how much of a corpus should be code, mathematics or prose. Those are questions about proportions, and Section 20.4 answers them with training runs.

20.3.5 Summary

Repeated text wastes compute and raises memorization, repeated test items inflate scores, and most repeats on the web are near copies that exact hashes miss. MinHash gives every document a signature of k numbers whose positions agree with probability equal to the Jaccard similarity of the two shingle sets, an unbiased estimate with variance $J(1-J)/k$, and banding turns signatures into hash-table lookups that make a pair a candidate with probability $1-(1-s^r)^b$. On 12,000 labelled pairs the measured candidate rates follow this S-curve for 13 settings and three hash seeds, and the best split of 128 positions, $(11, 11)$ with test F1 0.87, differs from the uniform-weight optimum only because the pairs' similarities are not uniform. Suffix arrays find repeated spans inside different documents, and embeddings find rewordings and, at loose thresholds, pages that merely share a topic. A 13-gram index finds every verbatim and reformatted test item planted in FineWeb pages and almost no paraphrase. An embedding detector finds about half of the copies and two in five paraphrases, limited by the host text around short items. On our crawl the three stages remove 1.7% of the documents and leave a manifest whose hash does not depend on the number of workers.

20.3.6 Exercises

1. **Containment.** A document has 100 five-gram shingles, all of which occur in a document of 1,000 shingles.
    1. Compute J and the containment of the smaller in the larger. Will MinHash at $\tau = 0.8$ make the pair a candidate?
    2. Show that the containment can be computed from J and the sizes $|A|$ and $|B|$. Why is an estimate of C from $\hat{J}$ noisy when J is small, and why would banding not find the pair anyway?
    3. Should a deduplicator remove the shorter document? Give one case in which it should and one in which it should not.
2. code **Short documents and salted hashes.**
    1. Show that `minhash_signature(shingles(t))` is `None` for every text with fewer than five words, and that `lsh_candidates` never pairs such a document. What should a pipeline do with such documents instead?
    2. Replace blake2b by Python's built-in `hash` in a copy of the signature function and compute the fixture's signatures in two separate processes. Name two places in this section's pipeline where the result would break something.
3. **Candidates from the bulk.** A corpus of N documents has a share ϕ of its pairs at similarity s and the rest at similarity 0.
    1. For $s < \tau$, derive the expected number of false-positive candidates under b bands of r rows.
    2. Show that $P(s) \le bs^r$ by the union bound over bands, and that the bound is tight when $bs^r \ll 1$. Use it to evaluate the expected count for $N = 10^8$, $\phi = 10^{-4}$, $s = 0.3$ and $(b, r) = (14, 8)$.
    3. Keeping b fixed, by what factor does lowering r by one multiply this count? Why is that factor large where the count matters most?
4. **Limits of the S-curve.**

   1. Write $P(s)$ for $r = 1$ and for $b = 1$, and explain in words what each extreme does.
   2. Among the splits of 128 positions with b a power of two, which has $(1/b)^{1/r}$ closest to 0.8? Compare its exact steepest point with that of $(9, 13)$ and say which approximation is worse, and why.

5. **Shingle size.**
   1. A copy replaces a share q of the words of a document at random. Derive the approximate J of the pair under n-word shingles, and find the largest q at which the pair is still a duplicate at $\tau = 0.8$ for $n = 3$, 5 and 8.
   2. code Before measuring, predict how the test F1 of the best (b, r) changes with n. Then rebuild the labelled pairs' labels and decisions for n from 3 to 8 and plot F1 against n. Is the change a property of the sketch or of the labels?

6. code **The signature budget.** For $k \in \{64, 128, 256\}$, predict, then measure, the setting chosen on the training pairs, its test F1, and the number of candidate pairs it produces on c1. Report each F1 difference with a bootstrap over base documents. Is doubling k worth its cost in memory and hashing time at $\tau = 0.8$?

7. code **Changed numbers.** Make a fourth form of the 100 planted GSM8K problems that needs no model: replace every number by a different number of the same magnitude, and keep the wording. Before running, predict the recall of the 13-gram index and of the embedding detector on this form. Measure both with intervals, and explain the 13-gram result from the number of words between the numbers of a typical problem.

8. [extended] **Two snapshots.** Extract documents from the same byte range of the archive files of two Common Crawl dumps a year apart, with the pipeline of Section 20.1 and Section 20.2. Deduplicate each dump on its own and both together, and compare the retained tokens, the near-duplicate rate within and across dumps, and the edu scores of the documents that global deduplication removes from the older dump. Does your result agree with FineWeb's argument for per-dump deduplication?

20.4 Data Mixtures

The previous three sections decided which documents to keep. A model is not trained on a set of documents, though, but on a stream of them, and someone has to decide how often each kind of text appears in that stream. Suppose we want the model of the next chapter to write prose, Python and the occasional proof. How much of its training budget should go to web pages, how much to code and how much to mathematics? Released models state their answers to the percent. By its dataset card, the pretraining mixture of Olmo 3 is 76% web text, 14% scientific PDFs, 7% code and 2.6% mathematical web pages (Team OLMo 2025). Nobody derives such numbers. They are hyperparameters, like a learning rate, with one difference that makes them expensive: every candidate needs a pretraining run of its own.

The way out is the one Section 11.6 took for model size and data: study small models and hope that they predict large ones. RegMix (Liu and colleagues, 2024) and the data mixing laws of Ye and colleagues (2024) make the hope into a method. Train many small *proxy* models on randomly chosen mixtures, fit a function from the mixture weights to the loss on each domain, and minimize that function. Two worries come with the method. A mixture that looks best after a short run might be overtaken later, its loss curve crossing that of another; and a mixture that suits a model of five million parameters might not suit one a

hundred times larger. This section builds the method for three domains, web text, Python and mathematics. It measures the noise that any fitted function has to beat and compares the mixture it selects with uniform weights and with the weights of DoReMi, a method that optimizes a different objective. The first worry is put to the training runs, the second to a model four times larger. Temperature sampling across languages, the value of repeated data and annealing at the end of training come along the way, because each changes how a mixture should be read.

Everything here is computed for three domains, `web`, `code` and `math`, and judged against two target distributions over them that are fixed in `MIX_TARGETS` before any run. `t_avg` weighs the domains equally. `t_dep`, $(0.7, 0.15, 0.15)$, stands for a deployment that reads mostly web text with some code and mathematics. It is an illustration, fixed in advance because a target chosen after the results can make almost any mixture look best. One launcher, `tools/run_mix_campaign.py`, makes all training runs of the section and stores them in a registered run set. A normal build reads that file and needs a GPU only for a short live check. Setting `D2L_RERUN=mix-t1` retrains all 65 runs on the GPUs named in `CUDA_VISIBLE_DEVICES`, which takes about twenty minutes on four RTX 4090s, and writes the result under a new name.

20.4.1 Mixture Weights as Hyperparameters

A *mixture* over m domains is a vector of weights $\mathbf{w}$ on the simplex, $w_i \geq 0$ and $\sum_i w_i = 1$. Each training sequence is drawn from domain i with probability w_i; our sampler allocates the sequences so that every domain stays within one sequence of its share at every step, which removes the sampling noise of the shares themselves. Write $b_i(\mathbf{w})$ for the loss on held-out text of domain i of a model trained on mixture $\mathbf{w}$. We will judge mixtures by two objectives: the average $\frac{1}{m}\sum_i b_i(\mathbf{w})$, which is the target-weighted loss $\sum_i t_i b_i(\mathbf{w})$ with $\mathbf{t}$ set to `t_avg`, and the same sum with $\mathbf{t}$ set to `t_dep`.

The losses must be comparable across domains, and losses per token are not. A token of web prose stands for about 4.5 bytes of text under our tokenizer and a token of Python for about 2.4, so a model can have a lower loss per token on code and still predict code worse. We therefore report *bits per byte*, as in Section 18.4.3: the summed negative log-likelihood in nats, divided by $\ln 2$ times the number of UTF-8 bytes the scored tokens stand for (`bpb_from_nll`). Bits per byte do not depend on the tokenizer, so a gain measured in them is a gain in prediction and not in segmentation. To credit a difference in loss to the mixture, everything else must be held fixed: the tokenizer, the model, the number of training tokens, the learning-rate schedule and its peak, the evaluation sets and the seed that orders the data.

The study comes in two tiers of the same code, fixed in `MIX_CONFIGS` before any run. T1 trains proxies of 4.6 million parameters for 2^{24} tokens per run and fits on one consumer GPU. T2 trains proxies of 20.3 million parameters for 2^{27} tokens per run, eight times the tokens on a model four times larger, and is packaged as a campaign for a larger machine. Every number quoted in the text comes from the T1 runs, and each such sentence says so. A test of the T2 design at half its tokens, run on four RTX 4090s, appears only in Section 20.4.5, as a first look at a larger proxy. The full T2 campaign has not been run.

The web domain is FineWeb-Edu as released, the corpus whose recipe Section 20.2 rebuilt. Its filter is the released classifier, trained on the labels of Llama-3-70B and cut at a rounded score of 3, which keeps about twice as much text as the cut on Qwen3.8-27B's stricter scale in that section. The chapter splits it into 256 buckets by a hash of each document's id, so the bucket of a document depends on nothing but its id, and every section that uses the corpus agrees on which document lies where.

The three pools follow. Web text comes from buckets 1 to 7, with bucket 8 as its validation set. Code is Python from CodeParrot's cleaned GitHub files, kept only where a file's own licence is permissive (MIT, Apache 2.0, BSD or ISC). These files carry individual licences, so the book hosts only their metadata and per-file attribution, and `tools/build_mix_pools.py` builds the pool on the reader's machine. Mathematics is FineMath at its highest quality level (4 and above), web pages about mathematics selected by a classifier much like that of Section 20.2. Every pool is tokenized with the reference tokenizer that Section 20.6 trains, and every pool holds at least one run's full budget of tokens, so even a run on a single domain reads each token once. Code is split into pool and validation by repository and path, FineWeb-Edu by document id, so forks and near-duplicates can land on both sides of the split; CodeParrot is deduplicated exactly but not fuzzily. At the model sizes of this section and a single epoch the effect is too small to matter, but a production pipeline would split after the near-duplicate stage of Section 20.3.

Bytes per token differ by almost a factor of two between web text and code, which is why the losses below are always per byte. The pools also differ in documents: 20 million tokens are about 19,000 web pages, 12,000 mathematics pages or 4,800 Python files, so the same weight yields very different numbers of distinct documents in each domain.

20.4.1.1 Temperature Sampling and Repetition

Before training anything, it is worth asking what a mixture costs in data. When the sources differ greatly in size, as languages do, sampling in proportion to size starves the small ones, and sampling uniformly reads the small ones over and over. *Temperature sampling* interpolates between the two. Source i with n_i documents (or tokens) is sampled with probability

$$p_i = \frac{n_i^{\alpha}}{\sum_j n_j^{\alpha}}, \qquad e_i = \frac{p_i D}{n_i} = \frac{D\, n_i^{\alpha-1}}{\sum_j n_j^{\alpha}}, \tag{20.7}$$

where D is the number drawn in all and e_i the number of epochs of source i. At $\alpha = 1$ the sampling is proportional and every source is read equally often, $e_i = D/\sum_j n_j$. At $\alpha = 0$ it is uniform. For any $\alpha < 1$ the factor $n_i^{\alpha-1}$ decreases with n_i, so the smallest sources are repeated most. Multilingual BERT sampled languages with $\alpha = 0.7$, and XLM-R and mT5 with $\alpha = 0.3$.

Repeated tokens are worth less than fresh ones. Muennighoff and colleagues trained models on data repeated for many epochs and found that up to about four epochs of repetition change the loss little compared with fresh data, while beyond that the value of each further pass decays (Muennighoff, Rush, et al. 2023). They summarized the effect in an *effective* number of tokens. For U unique tokens read for E epochs, with $R = E - 1$ repetitions,

$$D' = U + U R^{*}\bigl(1 - e^{-R/R^{*}}\bigr), \tag{20.8}$$

with a fitted constant $R^{*} \approx 15.4$. For small R the exponential is close to $1 - R/R^{*}$ and $D' \approx U(1 + R) = UE$: repeats count as fresh tokens. For $R \gg R^{*}$ the value saturates at $U(1 + R^{*})$, and further epochs add nothing. The form is the integral of $dD'/dR = Ue^{-R/R^{*}}$, an assumption that each repeat is worth a little less than the previous one; the paper fits it, it does not derive it. Three short functions implement these formulas and the sampler of random mixtures that the proxy runs will need.

The first check uses three toy sources of 1,000, 100 and 10 documents, where Equation 20.7 can be compared with a simulated sampler. Then we apply the formula to ten real languages: the nine FineWeb-2 languages that Section 20.6 uses, with document counts read from the dataset on 2026-10-28, and English from FineWeb, the English corpus that FineWeb-2 extends, read on 2026-11-16. The budget is 10^{10} documents, about a third of all ten together.

The formula and the simulation agree, and the smallest toy source is read about 1,400 times. The real languages show the same effect at scale. In proportion to size, English takes 92% of the samples and every language is read a third of a time. At $\alpha = 0.3$ English falls to about a third, Swahili, with 1.2 million documents, rises from 0.004% to 1.7% of the samples, and is read 143 times. Five of the ten languages pass four epochs at $\alpha = 0.3$; at $\alpha = 0.7$ only Swahili does. Temperature sampling does not create data. It decides how often the small languages are repeated, and the next cell says what such repetition is worth.

For the effective-data law we take $U = 10^9$ unique tokens and evaluate four epochs, the saturation, and the point at which counting repeats as fresh tokens overstates their value by 10%.

Four epochs keep about 93% of their nominal value, and the simple product UE is off by 10% only at about 4.8 epochs, which is why "up to four epochs is almost free" is a fair summary of the law. The saturation is severe, though. Swahili read 143 times is worth $U(1 + 15.4)$, about 11% of what 143 fresh copies would be, so temperature sampling at $\alpha = 0.3$ spends most of Swahili's share on tokens that teach almost nothing. UniMax (Chung and colleagues, 2023) draws the consequence and caps the epochs of each language instead of choosing a temperature. In our three domains no pool is ever read more than once, by construction, so repetition plays no part in the experiments below; it returns in Section 20.5, where rephrasing a small source is a way to make unique tokens out of repeated ones.

20.4.2 Proxy Runs and Regression

RegMix turns the choice of weights into a regression problem in five steps. Draw many mixtures at random from the simplex. Train a small proxy model on each, with everything else held fixed. Measure the loss of each proxy on each domain. Fit a function from the weights to these losses. Minimize the fitted target loss and train the minimizing mixture. RegMix fitted gradient-boosted trees to 512 proxies of one million parameters, then trained a model of one billion parameters, a thousand times larger, on the chosen mixture. Our version is much smaller, and checks each step against the noise of the proxies themselves.

20.4.2.1 The Proxy Model

A proxy is the book's `d2l.GPT` with the reference tokenizer's vocabulary of 32,768, trained by AdamW with a warmup and a decaying learning rate as in Section 9.7. `train_proxy_lm` takes the pools, the weights and a token budget, and its data stream depends only on the triple (seed, weights, tokens). The pools are cut into windows of `seq_len + 1` tokens, each domain's windows are read in a fresh random order per epoch, and the allocation of sequences to domains follows the weights as above. A list of `stages` switches to other weights at given fractions of the run, which is how the annealed arm below is trained. Losses come back as summed negative log-likelihoods and byte counts per domain, so they convert to bits per byte with `bpb_from_nll`, and the function refuses a budget that would read any pool more than `max_epochs` times instead of silently repeating tokens.

Before any GPU run, four properties are checked on the CPU in 32-bit floating point with a two-block model of width 32. The stream must be a function of (seed, weights, tokens). The allocation must keep every domain within one sequence of its share. A model that gives every token probability $1/32{,}768$ scores exactly 15 bits per token, so its bits per byte must be 15 divided by the bytes per token. And the parameter counts of both tiers must match the arithmetic of Section 11.6, $Vd + 12Ld^2$ for vocabulary V, width d and L blocks.

All four hold. The parameter counts say something about the proxies themselves: nine tenths of the T1 proxy, 4.2 of its 4.6 million parameters, is the embedding table, and its two transformer blocks hold about 400,000. The T2 proxy is half embedding. A T1 proxy is close to a model of which token follows which, with a little context on top, and what it prefers is evidence about mixtures only for models that learn the same things first. We will return to this when we ask what transfers.

20.4.2.2 The Run Design

The design draws the training mixtures from two Dirichlet distributions: six with concentration 1, uniform on the simplex, and six with concentration 0.3, which puts most of its mass near the edges where one weight is small. Three fixed mixtures near the corners, $(0.8, 0.1, 0.1)$ and its permutations, are added. Without them no training mixture would put more than about two thirds on web text, and `t_dep`'s region would be reached only by extrapolation; a design sampled only from the interior of the simplex cannot say much about its edges. Four held-out mixtures are drawn from Dirichlet(1) with another seed and never used for fitting. The rest of the runs measure the noise, the arms and two checks. There are three seeds of each pure-domain run, four more seeds of the uniform mixture on the schedule of the training runs, and three seeds each for the arms of Section 20.4.3 and the annealing arms of Section 20.4.4. The checks train three mixtures at half the chosen learning rate and the uniform mixture on two schedules at four times the tokens. No weight exceeds 0.9.

The two held-out draws `held 0` and `held 1` came out almost equal by chance, both with about 5% code, so the four held-out mixtures cover three distinct points; any rank statistic over them is a description, not a test.

One regeneration writes the whole run set. The launcher first chooses the peak learning rate on the uniform mixture from four values at half the run's tokens. It then trains the runs in dependency order on all visible GPUs, fits the regression and chooses the selected mixture by code, trains DoReMi's weights, and finally the arms that need them. The registered run set is the second version of the design. It keeps the 38 runs of the first version that the second still contains, unchanged, and adds the 27 runs of the extra seeds, the annealing arms and the checks, trained afterwards with the same code on the same cards; a launcher pointed at a directory of finished runs trains only the missing ones. A normal build reads the registered result, and the cell asserts that it is the design above, trained on these pools with this tokenizer.

At T1 scale the learning-rate choice is clear and interior: a peak of 2×10^{-3} beats its neighbours 10^{-3} and 4×10^{-3} by 0.2 and 0.09 bits per byte on the uniform mixture. It is chosen once and used for every run. Tuning it per mixture would be tempting, since each mixture has its own best rate, but then a difference in loss would credit the mixture with what the rate did.

The registered file could, in principle, be anything. The next cell retrains the first sixteen steps of the pure-web run on this machine and compares its losses with the logged ones.

The same regeneration also ran a short smoke test of the T2 configuration on one RTX 4090: 100 steps with and without `torch.compile`, a checkpoint, a killed process and a resume. It measures what the T2 campaign will cost. *Model FLOP utilization* (MFU) is the share of the card's peak arithmetic rate that the training step achieves, counting $6ND$ FLOP for N parameters and D tokens as in Section 11.6.

The T2 proxy reaches about 30% MFU when compiled, peaks at 8.4 GiB, and resumes from a checkpoint without any difference in loss. Two fresh runs of the same 100 steps differ by up to 0.03 nats, because the fastest bf16 kernels on this card do not add in a fixed order; regenerated runs are therefore close to the registered ones, not identical. The whole T2 design, 49 runs and about 10^{18} FLOP, comes to about 3 A100-hours at the measured utilization, or a little over five hours on one RTX 4090.

Now the first worry of the opening. If the ranking of mixtures changed during training, a short run could not be trusted to choose. For each of the 105 pairs of training mixtures we compare their `t_dep` bits per byte at a quarter of the run and at its end. A pair counts as crossing only if both gaps exceed the noise of a difference between two runs, $2\sqrt{2}$ seed standard deviations. The training runs share one data-order seed, so this bound is conservative. The cell plots the pair with the largest crossing, or, if none qualifies, the pair with the largest early gap. It then prints the bits per byte of the three pure-domain proxies on every domain, and the losses of the uniform mixture per token and per byte.

At T1 scale the worry does not materialize: about one pair in ten swaps places between a quarter of the run and its end, and none by more than the noise. The plotted pair is 0.15 bits per byte apart at both points. Early rankings predict late ones here, which is what makes proxy runs usable at all; it does not yet say that small models predict large ones.

The pure-domain matrix shows why mixing is a real choice. At T1 scale each proxy is best on its own domain, and the costs off the diagonal are large and asymmetric. The web proxy scores 5.2 bits per byte on Python and the code proxy 2.6 on web text, while the mathematics proxy reaches 2.15 on web text, much nearer the web proxy's 2.05. FineMath is a collection of web pages written in English prose about mathematics, so much of what it teaches carries over to web text. The last table makes the earlier warning concrete. Per token, code looks like the easiest domain, 5.1 bits against 8.7 for web text; per byte it is the harder one, 2.1 against 1.9, because a token of Python stands for less text.

20.4.2.3 Regression and Its Noise Floor

Three regressions map the weights to the per-domain bits per byte. *Ridge* regression is linear in the weights. Since the three weights sum to one, the three of them and an intercept are collinear, so ridge uses two free weights and an intercept. *Gradient boosting*, an ensemble of shallow trees, is RegMix's learner. The third is the *exponential mixing law* of Ye and colleagues, one curve per domain i:

$$b_i(\mathbf{w}) = c_i + k_i \exp\Big(\sum_j t_{ij} w_j\Big), \tag{20.9}$$

with five parameters per domain, fitted by least squares from several random starts. A negative t_{ii} lets the loss on domain i fall as its own weight rises and level off at c_i; the cross terms t_{ij} say how much the other domains help or hurt. `choose_mixture` minimizes a fitted target loss over 5,000 random mixtures, polishes the best one by Nelder-Mead with the weights written as a softmax, and stays inside the convex hull of the training mixtures, where the

regression was fitted. The mixing law was fixed as the selecting regression before any run, for a reason that has nothing to do with accuracy. A model linear in $\mathbf{w}$, like ridge, predicts a target loss that is linear in $\mathbf{w}$, and a linear function on a polytope has its minimum at a vertex. Ridge can only ever choose a corner of the region it is given. The law's exponentials can place the optimum inside.

How well can any regression do? Each measured loss carries noise of standard deviation σ from the data order, and the held-out loss we compare a prediction with is just as noisy. No predictor, however good, can therefore reach a root-mean-square error below σ against a held-out run. A fitted predictor also carries the noise of the runs it was fitted to. Take a model linear in p parameters, fitted by least squares to n runs with design matrix $\mathbf{X}$. Its prediction at a new point $\mathbf{x}$ is $\hat{y} = \mathbf{x}^\top \hat{\beta}$ with $\hat{\beta} - \beta = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \epsilon$, and the new observation is $y = \mathbf{x}^\top \beta + \epsilon'$ with independent noise. The two error terms are independent, so

$$\mathbb{E}\big[(\hat{y} - y)^2\big] = \sigma^2 \big(1 + \mathbf{x}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}\big), \qquad \frac{1}{n} \sum_{k=1}^{n} \mathbf{x}_k^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_k = \frac{p}{n}. \tag{20.10}$$

The second identity is the trace of the hat matrix $\mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top$, which is p. A correctly specified least-squares model with p parameters therefore reaches a root-mean-square error of $\sigma \sqrt{1 + p/n}$ on average over the design points. We call this level, with the $p = 3$ of a model linear in two free weights and an intercept, the *noise floor*. It is a yardstick, not a bound. The bound is σ, and a correct model with fewer fitted parameters comes closer to it; the mixing law has five parameters per domain and gradient boosting many more. A regression far above the floor is wrong about the shape of the function. The cell checks Equation 20.10 by simulation, estimates σ from the four extra seeds of the uniform mixture on the training runs' schedule, fits the three regressions on the training runs and judges them only on the held-out ones.

Two design facts qualify the comparison. Every training and held-out run uses the same data-order seed, so part of the noise is shared and the floor estimated from independent seeds is an upper bound on the noise the held-out errors face. And the same validation sets choose the learning rate, fit the regression and score the held-out mixtures: "held out" means held-out mixtures, not held-out text. Those choices have few degrees of freedom, a learning rate and two free weights, so the bias they introduce is small, but it is not zero. Panel (a) of the figure plots predicted against measured bits per byte for each domain with the identity line and a band of two floors; panel (b) places every run on the simplex, coloured by its `t_dep` loss, with the selected mixture as a star.

The simulation matches the formula to within a few tenths of a percent. On the real runs, at T1 scale, the floor is about 0.01 bits per byte. Its σ rests on four runs, so it is known only roughly: the 95% interval, which counts the seeds and not the three correlated domains of each run as the independent measurements, runs from about 0.006 to 0.04. Over the three domains no regression reaches the floor, and on code none comes near it; only on web text, where every loss is close to every other, do the mixing law and gradient boosting fall below it. Gradient boosting comes closest with a held-out error of about 0.03, ridge has about 0.06, and the mixing law about 0.07. The law's error is almost all in one domain: on web text it predicts to a few thousandths, on code it misses by about 0.12. Code's loss falls steeply as its weight rises from zero, the web proxy scores 5.2 bits per byte on Python, and two of the held-out mixtures sit at 5% code, the region where a single exponential has the hardest time following it. The method's limit at this scale is therefore the shape of the law, not the

number of runs, since more runs lower the floor but not the bias. A good fit to the training mixtures would have said nothing about this: the law has five parameters per domain for fifteen training runs, and gradient boosting can match its training points almost exactly.

20.4.3 Choosing a Mixture

With a fitted function in hand, the choice is an optimization. The cell minimizes each regression's prediction of the `t_dep` loss, and the mixing law's also for `t_avg` and without the bound to the training hull. It then refits the law on 200 bootstrap resamples of the training runs to see how firmly the data determine the chosen weights.

The selected mixture at T1 scale is the result of this section that a reader would least expect. For a target that puts 70% of its weight on web text, the mixing law chooses about a third of each domain, $(0.34, 0.31, 0.35)$. In the fitted law the web loss barely moves with the web weight, while the losses on code and mathematics fall steeply with their own weights, so the optimizer moves tokens from web text to code and mathematics; the next cell looks at the runs behind that flat curve. The choice is a statement about these proxies, not advice for a web-heavy deployment, and Section 20.4.5 finds that a larger proxy moves it toward web text. Without the hull bound the law picks the same point, so it is not pressed against the edge of its data. Ridge, as promised, picks a corner, the fixed mixture $(0.1, 0.8, 0.1)$; gradient boosting picks $(0.24, 0.55, 0.22)$. For `t_avg` the law shifts weight from web text to mathematics, $(0.20, 0.36, 0.43)$. The bootstrap is sobering: across resamples each weight moves over a range of about 0.15, web from 0.25 to 0.38, code from 0.24 to 0.43. The runs determine a neighbourhood, not a point.

The flat web curve deserves a look of its own, because the pure-web run scored worse on web text than several mixtures with less of it, which more web tokens should not do. The cell prints the web loss of every run on the training schedule against its web weight, the seed spread of the pure-domain runs, and three mixtures at the chosen peak rate and at half of it.

Among the mixtures, the web loss at T1 scale is nearly flat: from 20% to 85% web text it moves from about 2.00 to about 1.98 bits per byte, while a run with less than 20% web text can lose half a bit. The pure-web runs do not continue the curve. Their mean, about 2.03, is worse than that of the mixtures with 60% to 85% web text, and their three seeds spread from 2.00 to 2.05, a seed standard deviation of about 0.025 against 0.004 for the uniform mixture on the same text; the pure code and mathematics runs are just as unsteady on their own domains. At half the peak rate the pure-web runs are steadier and within about one of their seed deviations of the 80%-web mixture (2.04 against 2.03), while the uniform mixture falls behind them (2.07). The rate that the design chose on the uniform mixture is thus too high for a proxy that reads a single domain, and the drop at pure web text comes from it, not from the other domains teaching web text better than web text does. The selection does not rest on these runs: the regression is fitted on the fifteen training mixtures, none of which is a single domain.

Had we picked the regression after seeing the held-out errors, we would have picked gradient boosting and a code-heavy mixture. The rule that the selecting regression and the target are fixed in advance is what keeps two regressions, two targets and a hull bound from becoming a menu.

20.4.3.1 DoReMi

DoReMi (Xie and colleagues, 2023) chooses the weights without a regression, and with one difference in what it optimizes. It trains a reference model on a default mixture. It then trains a proxy whose loss weights α over domains are adjusted during training to maximize the proxy's *excess* loss over the reference, so that the proxy works hardest on the domains where it lags the reference most. This is a minimax game, $\min_\theta \max_{\alpha \in \Delta} \sum_i \alpha_i (\ell_i(\theta) - \ell_{\text{ref},i})$, and the step on the weights has a closed form. With $g_{t,i}$ the excess loss of domain i at step t,

$$\alpha_{t+1} = \operatorname*{argmax}_{\alpha \in \Delta} \langle \alpha, \mathbf{g}_t \rangle - \frac{1}{\eta} \mathrm{KL}(\alpha \,\|\, \alpha_t) \quad \Longrightarrow \quad \alpha_{t+1,i} = \frac{\alpha_{t,i}\, e^{\eta g_{t,i}}}{\sum_j \alpha_{t,j}\, e^{\eta g_{t,j}}}, \tag{20.11}$$

which follows from setting the derivative of the Lagrangian to zero: the stationarity condition gives $\log(\alpha_i / \alpha_{t,i}) = \eta g_i$ plus a constant, and normalization fixes the constant. The weights are then mixed with a little of the uniform distribution and averaged over all steps, and the average is the mixture that a larger model is trained on. The excess loss is clipped at zero per token, against the reference model's loss on the same tokens of the same batch, before it is averaged over a domain. The paper used a proxy of 280 million parameters to set the weights of a model of 8 billion on the Pile. Our miniature follows it with the T1 proxy, taking the final checkpoint of the first uniform-mixture arm as the reference.

The cell checks the closed-form step against a numerical maximization and runs the game on a toy with three quadratic losses whose saddle point is known. It builds a batch on which clipping the mean excess loss of a domain would give no signal at all while clipping per token does. It then prints the weights of the registered run.

The step and the toy agree with their derivations. The clipping check shows why the order matters: on the random batch the domain's mean excess loss is zero, so clipping it gives nothing, while the per-token clip keeps the 0.05 nats by which the proxy is worse on some tokens. At T1 scale DoReMi raises code and lowers web text, $(0.17, 0.47, 0.36)$. The trajectory behind that average swings: code holds three quarters of the weight a quarter of the way in and a quarter of it halfway. With 256 steps the average of so restless a sequence is a noisy estimate; the paper's runs are many thousands of steps long. Note also what DoReMi is built for. Its game, Equation 20.11, weighs the domains on which the proxy lags the reference most; it targets neither `t_dep` nor the average loss, so there is no reason to expect its mixture to win on either target.

20.4.3.2 Four Arms Compared

Three mixtures are now trained with three data-order seeds each: uniform, the regression's choice for `t_dep` and DoReMi's weights. All three use the stable-then-decay schedule with the same peak, so that only the data differ, and each arm's seed s is compared with the uniform arm's seed s, which saw its data in the same order. With three seeds no bootstrap interval means much, so the rule is blunt: an arm differs from uniform only if all three paired differences share a sign and their mean exceeds two seed standard deviations of the uniform arm. The arms use a different schedule from the training runs, so their losses are compared with each other, never with the regression's predictions.

At T1 scale the regression's arm is ahead of uniform in all three seeds, by about 0.007 bits per byte on `t_dep`, which is within the noise; that is no surprise, since the selected mixture

is nearly uniform. DoReMi's arm is behind on `t_dep` by about 0.01 to 0.02. The rule calls that real, but with little margin, and regenerating the run set moves single runs by up to about 0.02 bits per byte, so we read it as "worse on `t_dep` by about 0.01, at the edge of the noise". The per-domain table explains the sign. DoReMi's extra code weight lowered the code loss by about 0.1 bits per byte and raised the web loss by about 0.05, and `t_dep` weighs web text by 0.7. On the average target the same arm is better than uniform by about 0.025. One method, two targets, two verdicts: a mixture is good only for a stated objective, and DoReMi's objective is neither of ours.

20.4.4 Annealing and Curricula

A different question is whether it matters when in training a mixture is read. Under the stable-then-decay schedule of Section 9.7 the learning rate stays at its peak for most of training and then falls to a small value over the last fifth of the steps. A model fits most closely what it reads while its learning rate falls, which suggests saving the best data for the end. This is *annealing*, and it is now standard. SmolLM2's last stage, the final 10% of its 11 trillion tokens, raises mathematics to 14% and code to 24% of the mixture, using FineMath and educational code that were held back until then to make them count most. Our miniature is the *anneal* arm: the uniform mixture for 80% of the tokens, then the decay on the mathematics corner $(0.1, 0.1, 0.8)$. A *recency* arm does the same but returns to the uniform mixture for the last tenth of the steps, which asks whether the gain lasts once training continues on general data. Both are paired seed by seed with the uniform arm. The cell plots the per-domain curves with the stage boundaries marked and prints the change of each domain's loss during the decay, arm minus uniform. It also compares the two schedules on the uniform mixture at the run length of T1 and at four times the steps.

At T1 scale the decay does what the recipe expects, in all three seeds. Reading mathematics while the learning rate falls lowers the mathematics loss by about 0.04 bits per byte against the uniform arm and raises the web and code losses by about 0.02 and 0.07: the model fits most closely what it reads last. The recency arm keeps about two thirds of the mathematics gain after a tenth of the steps on uniform data and gives back about half of the cost on web text and code. Part of an annealing gain, at this scale about a third, is thus recency in the plainest sense, and it fades as soon as the data change. The schedule itself matters too. At the same peak rate, the uniform mixture under stable-then-decay ends about 0.1 bits per byte below cosine on `t_dep` after 256 steps and about 0.05 below after four times the steps; the gap shrinks with the length of the run, which is why the arms, all on one schedule, are compared only with each other.

20.4.4.1 Annealing Gains and Recency

The harder question is what an annealing gain means. If the decay is run on mathematics and question-answer pairs, scores on mathematics and question-answering benchmarks rise, and they rise fast. Some of that rise can be *recency*: the model has adapted to the format and vocabulary of what it read last, not acquired a skill it lacked, and a gain of that kind fades when training continues on other data. Two checks separate the cases. One measures the loss on held-out data of the annealed domain that does not resemble any benchmark; the other continues training on the general mixture after the anneal and asks whether the gain survives; the recency arm above is the second check in miniature, and at T1 scale a third of its mathematics gain did not survive. Blakeney and colleagues (2024) proposed upsampling domains at the end of training as a cheap way to test which data help, and the method is valuable because it is fast. It should not be read as a measure of what a model can do after the

anneal is over. Decontamination, as in Section 20.3, matters doubly here, since annealing data are often written to look like test items.

20.4.4.2 Curricula of Two Released Models

Olmo 3 documents its data in unusual detail, and it reads best as a case study of everything above rather than as a recipe to copy (Team OLMo 2025). Its pool, Dolma 3, holds 9.3 trillion tokens, almost all of it Common Crawl (8.1 trillion), with 970 billion tokens of scientific PDFs converted to text, 137 billion of educational code, 34 billion of FineMath, 21 billion of arXiv and 4 billion of Wikipedia. The pretraining mixture takes 5.9 trillion tokens from it. By the two dataset cards' counts, Common Crawl is subsampled to a little over half of its pool, while code is read about three times, arXiv about two and a half times and FineMath about four and a half times. The small, valuable sources are thus upsampled into the range where Equation 20.8 starts to discount repetition, and the report states that it avoids repeating any domain more than a few times. The weights come from our method at a larger scale. A swarm of proxies of 30 million parameters, five times as many as there are domains, is trained for 3 billion tokens each, a hundred tokens per parameter, on mixtures drawn from a Dirichlet distribution centred on the natural proportions. A separate regression per evaluation task predicts its bits per byte, and the mixture minimizes the average prediction under the repetition constraint. After pretraining comes a mid-training stage of 100 billion tokens, the Dolmino mixture. It combines the highest-quality pretraining data with mathematics, code, question answering, instruction following and reasoning traces, the annealing of the previous paragraphs at scale. Candidate data for it are tested by short anneals of 10 billion tokens, half candidate, half web. Section 21.4 takes up that stage.

SmolLM2 shows the other common pattern, a curriculum of four stages with fixed weights inside each. The first 6 trillion tokens are web text and at most 10% code, with no mathematics at all because the mathematics corpora were too small to last; later stages add mathematics and educational code; and the decay stage holds the highest-quality sets. Neither report claims that its proportions are optimal for the final model: Olmo 3's are what its proxies preferred under a repetition constraint, and SmolLM2's were revised between stages from evaluations of the large run itself.

20.4.5 Transfer Across Scale

Everything so far was decided by models of 4.6 million parameters. Three things limit how far such a decision carries. The first is the number of tokens per parameter. The T1 proxies see about 4 tokens per parameter and the T2 proxies about 7, against the roughly 20 of compute-optimal training (Hoffmann et al. 2022) and 100 for the Olmo 3 swarm. An undertrained model has learned the easy statistics of every domain and few of the hard ones. The second is the model itself: a proxy whose parameters are mostly an embedding table learns which tokens follow which, and a model that learns long-range structure may value code and mathematics quite differently. The third is the tokenizer: the weights are shares of sequences of tokens, and since bytes per token differ by domain, the same weights under another tokenizer put a different share of text from each domain into the run. RegMix chose for a model a thousand times larger than its proxies and checked the choice against 64 other mixtures trained at the large size; DoReMi transferred over a factor of 30. Without such a check a proxy's ranking is a hypothesis about the large model, not a measurement of it.

The T2 configuration is the next step of that check, packaged in `tools/lm_campaigns.yaml`: the same design with 16 Dirichlet training mixtures and 8 held-out ones, at 20.3 million

parameters and 2^{27} tokens per run. The launcher runs it on as many GPUs as it is given, checkpoints every run, stops itself after a time limit and resumes where it stopped.

A first reading of transfer is already possible. The T2 design was run at half its tokens, 2^{26} per run, on four RTX 4090s, which took 46 minutes; it is a test of the T2 code path and a first look at a larger proxy, not the T2 result. The 22 mixtures that both scales trained, the pure-domain runs and the shared design draws, can be ranked at both sizes, and the regression, the choice and the arms can be repeated at the larger one.

The rankings agree only in part. Over the 22 shared mixtures the rank correlation of the `t_dep` losses between T1 and the half-length T2 test is 0.70, and only one of the three best mixtures at T1 scale is among the three best in the test. The learning-rate choice moves from 2×10^{-3} to 10^{-3}, as expected for a wider model. The mixing law's held-out error is still about 0.07 on code and 0.05 on mathematics, against a floor of about 0.02. Its choice for `t_dep` moves toward web text, to $(0.44, 0.27, 0.30)$. That is a shift of about 0.1 in the web weight, about the width of the T1 bootstrap range, and here the regression's arm beats uniform beyond the noise, by about 0.01 bits per byte in all three seeds. DoReMi's weights move most, to $(0.29, 0.30, 0.41)$, and its arm, like the test's staged arm (which decays on the selected mixture), is within the noise of uniform. So the small proxies located the neighbourhood of a good mixture and did not fix the point: a model four times larger prefers more web text, and at that size its own choice beats uniform. Whether the trend continues to a model a hundred times larger, the size at which mixtures are actually chosen, only a run at that size can answer.

20.4.6 Summary

A data mixture is a hyperparameter whose every trial costs a pretraining run, so it is chosen with small proxy models: train proxies on random mixtures, fit a function from weights to per-domain bits per byte, and minimize a target loss fixed in advance. Bits per byte, not bits per token, make the domains comparable. No fitted function predicts a new run better than that run's noise σ, and a correct least-squares fit reaches $\sigma\sqrt{1 + p/n}$. At T1 scale, early rankings of mixtures predicted late ones, and no regression reached the floor of about 0.01 bits per byte; the exponential mixing law failed on code. Its choice for a web-heavy target was close to uniform, because among the mixtures the web loss barely moved with the web weight; the pure-web proxy fell off that curve only because the shared learning rate was too high for a single domain. DoReMi's objective moved weight to code and lost slightly on that target. In a test of a model four times larger, at half its planned tokens, the ranking of mixtures agreed only in part (rank correlation 0.7), and the chosen weights moved toward web text and beat uniform. Annealing on mathematics lowered the mathematics loss, and a third of that gain faded when training returned to general data. Proxies locate a region of good mixtures rather than a point. Temperature sampling changes the mixture over sources and is limited by the value of repeated data, which saturates after a few epochs. Annealing changes it over time, and its gains may be capability or recency.

20.4.7 Exercises

1. **Repetition in a budget.** A run of 100 billion tokens gives weight 0.2 to a source of 2 billion unique tokens.

    1. How many epochs of the source does the run read? Using Equation 20.8, how many effective tokens does the source contribute, and what share of its 20 billion

nominal tokens is that? Confirm with `d2l.effective_tokens`.
2. Find the weight above which the source's nominal tokens overstate its effective tokens by more than 10%. How does the answer change with the size of the run?
3. The law has a single fitted constant. Name one property of a source, for example of a code corpus against a web crawl, that you would expect to change R^*, and say in which direction.

2. **The temperature for a target share.** Three languages have $n_1 = 1000$, $n_2 = 100$ and $n_3 = 10$ documents.
   1. For two languages, derive in closed form the α that gives the smaller one a share s of the samples. When does no $\alpha \in [0, 1]$ work?
   2. For the three languages, find numerically the α that gives the smallest a share of 10%, and the number of epochs it is then read at $D = 10^5$. Show that the share of the smallest language is monotone in α, so the answer is unique.

3. **What DoReMi's step does.** Use the update Equation 20.11 before smoothing.
   1. Show that $\alpha_{t+1,i} \geq \alpha_{t,i}$ exactly when $g_{t,i} \geq \frac{1}{\eta} \log \sum_j \alpha_{t,j} e^{\eta g_{t,j}}$, and that this threshold lies above the weighted mean $\sum_j \alpha_{t,j} g_{t,j}$ by Jensen's inequality. Conclude that a domain whose excess loss is at or below the weighted mean never gains weight.
   2. Which weights are fixed points of the update? Why is the average of the iterates, rather than the last iterate, the natural output of the game?
   3. Because the excess loss is clipped at zero per token, a domain on which the proxy is better than the reference on average can still have $g_{t,i} > 0$. Construct a batch with this property and say whether the behaviour is desirable.

4. **Why ridge picks corners.**
   1. Show that a predicted target loss that is linear in $\mathbf{w}$ has its minimum over a polytope at a vertex. Which vertex of the hull of the training mixtures does ridge choose for `t_dep`, and why that one?
   2. code Count, over the 200 bootstrap resamples, how often ridge, gradient boosting and the mixing law choose a point within 0.05 of the hull boundary. What does the count say about using each of them to select?

5. code **A law for code.** Plot the measured code loss of the training runs against the code weight. Propose a law that follows the steep drop near zero weight, for example $c + k(w_{\text{code}} + \epsilon)^{-\beta}$ for the code domain with the other domains' weights as a linear correction, and fit it on the same training runs. Compare its held-out error per domain with the mixing law's and with the floor. Does its choice for `t_dep` move?

6. code **Annealing on code.** Train the anneal and recency arms with the decay on the code corner $(0.1, 0.8, 0.1)$ instead of the mathematics one, three seeds, paired with the uniform arm.
   1. Before running, predict the change of the code and web losses during the decay, using the mathematics result of the annealing section (Section 20.4.4).
   2. Measure both, and the share of the code gain that the recency arm keeps. Then continue each annealed model and its uniform partner for another 20% of the tokens on the uniform mixture at a low constant learning rate. How much of the gain survives now? What does the answer say about recency?

7. code **Does the ranking transfer?** Train the T1 design with the T2 proxy shape at T1's 2^{24} tokens per run on one GPU (about 40 minutes on an RTX 4090). Before running, predict whether the rank correlation of the `t_dep` losses with T1 will be closer to 1 or to the 0.70 of the half-length T2 test, which changes model size and tokens at once. Measure it, compare the selected weights at the two sizes, and say which of the two changes moves the selection more.

20.5 Synthetic and Rephrased Data

The previous sections took text as the web offers it and decided what to keep, how to remove its copies and how often to read each kind. At the end of Section 20.4 the supply ran short: a small source read many times is worth far less than as many fresh sources of the same size. A language model offers a way out that would have sounded odd a few years ago. It can write more text.

Here is the smallest version of the idea, which we run later in this section. A model of two billion parameters reads a paragraph from an educational web page about a mouthwash for oral pain and rewrites it in the style of an encyclopedia. The rewrite is cleaner than its source, it keeps every fact, and it costs the model a few seconds. If one paragraph can be rewritten, so can a million, and a pretraining run could read each source once as written and once rephrased instead of twice as written. Maini and colleagues (2024) did this with the C4 web crawl and report that their models reached the same perplexity about three times faster. Whole crawls have since been rewritten the same way.

Generated text has costs, and they are hard to see in any single example. A rewrite can change a number or add a claim and still read perfectly well. Samples from one prompt resemble each other far more than documents written by different people. And a model that learns from a model's text learns the generator's habits along with its content. This section measures these costs. It builds a rephrasing pipeline and checks what comes out, then trains small models on an equal budget of real text, rewritten text and mixtures of the two, and evaluates each on both kinds of text. Two questions close it: what happens when models learn from models generation after generation, and who may train on generated text at all.

The rewrites shown in the text, about 150 of them, are generated live by Qwen3.5-2B in bf16 on a GPU in a few minutes. Everything larger was computed once and registered: a corpus of 4.7 million tokens of source chunks with their rewrites, the verdicts of a judge model on sixty of them, and the fifteen training runs of the comparison. A normal build reads these files and repeats the start of one training run as a check; setting `D2L_RERUN` to a name in `ARTIFACTS` regenerates that file instead. The runs use the wider proxies of Section 20.4 at that section's smaller scale, T1, so every result of the comparison is stated at T1 scale (8.1M-parameter proxies, 2^{24} tokens).

Two files are registered. The corpus is FineWeb-Edu text (ODC-By) rewritten by an Apache-2.0 model, so it ships as text with the attribution that ODC-By asks for, and every printed example carries it. The results file holds the judge's verdicts, the logs of the fifteen runs and three Cosmopedia rows.

20.5.1 Kinds of Synthetic Data

Text written by a model enters training in four ways. A model can write new documents from a seed, such as a topic, an outline or a web page: a textbook chapter, a story, an exercise with its solution. It can rewrite existing documents, as in that example. It can write demonstrations for post-training, the requests and answers that teach a pretrained model to follow instructions. And it can label data: the educational scores of Section 20.2 were assigned by Qwen3.8-27B, so the classifier of that section learned from synthetic labels. This section treats the first two kinds as pretraining data.

The two differ in what they can add. A rewrite that does its job changes the form of a text but not its content, since the facts are those of the source. A generation from a seed can add content, which is both its promise and its risk, because the content comes from the generator's memory, errors included.

Fluency proves nothing here; a fluent paragraph can carry a wrong number. Generated data must be judged by its effect: how much a model trained with it improves on held-out data, compared with a model trained without it at the same cost. The best-known demonstration that generated text can help is phi-1 (Gunasekar and colleagues, 2023), a code model of 1.3 billion parameters trained on about 6 billion tokens of filtered web code and about 1 billion tokens of textbooks and exercises written by GPT-3.5. It reached 50.6% pass@1 on HumanEval, a strong score for its size. The result is real and also narrow. It concerns short Python functions of the kind HumanEval tests, the paper itself examines whether its generated exercises resemble the benchmark, and it does not show that generated textbooks teach a general language model more per token than good real text does. That question needs a controlled comparison at equal cost, which we run below on a small scale.

20.5.2 Rephrasing the Web

Maini and colleagues (2024) call their recipe WRAP, for web rephrase augmented pretraining. An off-the-shelf instruction-tuned model rewrites chunks of web text in a few styles, among them "like Wikipedia" and as questions and answers, and the language model trains on real and rephrased text in equal parts. On C4, a crawl with plenty of noise left in it, they report pretraining about three times faster, and at equal compute a perplexity more than 10% lower on average over subsets of the Pile. They explain the gain in two parts: the rewrites are cleaner than the web, and their styles are closer to the text that evaluations use. The second part makes a prediction that we can test, and we return to it when we evaluate.

Rephrasing has since reached the scale of whole crawls. Nemotron-CC (Su and colleagues, 2024) sorts Common Crawl with quality classifiers, rewrites low-quality documents into cleaner text and turns high-quality ones into question-answer pairs and other forms. Its current release, Nemotron-CC-v2, adds crawls from 2024 and 2025, and by its dataset card about 2.5 trillion of its tokens were written by Mistral-NeMo-12B-Instruct and Qwen3-30B-A3B; the card also lists DeepSeek and other Qwen models among its generators. It is released under the NVIDIA Data Agreement for Model Training, so this book cites it and ships none of it. FinePhrase (Niklaus and colleagues, 2026) rewrites FineWeb-Edu, the source we use, into 486 billion tokens of FAQs, tutorials, tables and mathematical word problems, generated by SmolLM2-1.7B-Instruct and released under ODC-By. Its authors compare prompts, generators and sources over more than a trillion generated tokens. They find that generators larger than about a billion parameters add nothing and report generation costs up to thirty times lower than earlier synthetic datasets. That finding is why a rephraser of two billion parameters is a reasonable choice here and not only a cheap one.

Our pipeline is the same in miniature. Rephrasing has four steps: cut a document into chunks, wrap each chunk in a prompt, generate, and filter the replies. The two prompts follow two of the styles of Maini and colleagues, an encyclopedia passage and a conversation of questions and answers. Both end with the same instruction, to preserve every fact, name and number and to add nothing. Both also forbid Markdown. Small instruction-tuned models like to answer with bold headings and bullet lists, and an encyclopedia article has neither.

Chunks hold at most 400 tokens and end where a sentence ends, so the model rewrites a passage it can keep in view and never half a sentence. `rephrase_docs` sends batches of prompts of similar length through Transformers' `generate` and records for each reply whether the model ended its turn or ran out of tokens. A reply that ran out stops mid-sentence and is dropped. One more detail matters for a Qwen model. Its chat template, not its weights, decides whether the model first reasons in a `<think>` block (Section 18.1). Reasoning text has no place in a pretraining corpus, so the template is called with `enable_thinking=False`, and the function asserts that no reply contains a thinking tag.

How can we tell a good rewrite from a bad one without reading it? Three numbers are cheap. The *copy rate* is the Jaccard similarity of the two texts' sets of character 5-grams: 1 for a copy, near 0 for a text that shares no phrasing with its source. A copy adds nothing, so a high copy rate is a warning. *Number fidelity* is the share of the source's digit strings that reappear in the rewrite, a crude test of whether the facts survived. The *length ratio* divides the length of the rewrite by that of the source, in characters, and catches replies that were cut short or padded. For the diversity of a set of texts we count the share of distinct word 4-grams among all their 4-grams: 1 when no four-word phrase repeats, small when the texts say the same thing in the same words.

Now the example of the opening. The source is the first chunk of the training split S1 with at least three numbers and at most 200 tokens. The splits are cut from the FineWeb-Edu web pool of Section 20.4: S1 and S2 hold 2^{21} tokens of chunks each for training, and a third split holds 2^{19} tokens of chunks from the pool's separate validation documents. After one rewrite we sample the same prompt nine more times at temperature 0.7, the setting of every rewrite in this section.

The rewrite is what one hopes for. It keeps the fourfold effectiveness, the 48 of 50 patients and the sixteen complaints about the taste, and it reads more like an encyclopedia than its source does. Yet its number fidelity is 0.67, because the model wrote "approximately 30 minutes" as "approximately thirty minutes" and a check on digit strings counts that as a lost number. The cheap check is wrong here, in the harmless direction. We will meet rewrites where it is wrong in the other one.

The nine samples show the second cost. They differ in a word here and there, but the three printed open with the same ten words, and fewer than half of the nine samples' 4-grams are distinct. Temperature 0.7 gives the model enough freedom to vary a word and not enough to vary a text. An instruction-tuned model has one preferred answer to a prompt, and sampling explores the neighbourhood of that answer.

Before generating at scale, we check the chunker on twenty documents of the pool.

Every document is recovered exactly from its chunks, so chunking loses nothing, and the median chunk holds 382 of the 400 tokens allowed.

Now sixty chunks of S1 are rewritten in each style, in batches of 32 with up to 512 new tokens. Two rules decide which replies are kept: a reply that ran out of tokens is dropped, and so is

one whose length ratio lies outside $[0.5, 1.5]$, which catches refusals, replies cut short and padded ones. Copy rate and number fidelity only flag a reply. They are reported and not used to select, because we have just seen number fidelity misjudge a good rewrite, and a corpus selected by a misjudging metric inherits its errors. Every threshold is a parameter of the pipeline, recorded in its manifest, not a claim about what makes a good rewrite.

The two styles behave differently. The encyclopedia style is well behaved: all but about one of the 60 replies are kept, and the rewrites are about as long as their sources. The conversations are longer than their sources. About a quarter of them ran out of the 512 new tokens before they ended, and with those that fell outside the length range, only a little over half survive. These counts come from one sampled run, and on other hardware they move by a few. A style that expands its source needs a larger budget than one that restates it, and no prompt can change that.

The histograms show what the flags see. Copy rates spread from about 0.2 to 1. The near-copies above 0.8 include chunks with little to rewrite, such as the one-sentence medical disclaimer printed above. Number fidelity is 1 for about three in five of the encyclopedia rewrites and for about half of the conversations. The rewrite with the lowest copy rate turns a blog post about ghee into an encyclopedia entry and drops its notice about affiliate links, which is what we want from a rewrite. It also scores 0 on number fidelity, and only reading it can tell whether a fact was lost. Cheap checks are alarms, not verdicts.

20.5.2.1 Generating from Seeds

Rewriting is bound to its source. Generation from a seed is its freer relative: the source only supplies a topic, and the model writes a new text about it. Cosmopedia, over 25 billion tokens written by Mixtral-8x7B-Instruct and released under Apache-2.0, is the best-documented example. Its prompts turn three knobs: a seed text (a web page, a course outline, a textbook passage), a format (a textbook, a blog post, a story) and an audience (young children, college students, researchers). Its dataset card states the reason: varying the audience and the style of the prompt raises the diversity of the output. We print three of its rows and then test the claim on a small scale. From the opening's chunk as seed we generate nine texts with one plain prompt and nine with three formats times three audiences, and compare both with the nine rephrasings of the opening. Each output is cut to the length of the shortest, because the share of distinct n-grams falls as texts grow longer. Diversity is measured twice, by distinct 4-grams and by the mean Jaccard similarity of the word 5-gram sets of all pairs, which is the measure of near-duplication of Section 20.3.

The prompt knobs work. Cut to 70 words each, the nine conditioned texts share almost no 4-gram (0.995 distinct, against about 0.76 for the plain prompt), and the mean Jaccard similarity of their pairs is zero to three decimals. All three settings sample at the same temperature, so the gain comes from the prompt alone. The plain prompt already varies more than the rephrasings (about 0.44), because a request to write about a topic leaves the model room that a request to rewrite does not. That room is the point of generation and also its risk. The first conditioned output is a textbook section for young children about "the magic of mouthwash for stomach pain"; the mouthwash of the source treated pain in the mouth. Diversity from the prompt is diversity of form. Whether the content stays true is a separate question, and the generator answers it from its own memory.

20.5.2.2 Checking Generated Text

Sixty live rewrites are too few to train on. The registered corpus holds the encyclopedia-style rewrites of every chunk of S1, S2 and the validation split, generated once with the same prompt, model and sampling settings (the next cell shows how). We load it, verify that its files are what this notebook would write, and ask it the questions that matter at scale. How many rewrites were dropped, and why? How often are numbers kept? Do the rewrites repeat each other more than their sources do? Generators are known to fall back on the same phrasings, and the MinHash of Section 20.3 finds pairs of chunks whose shingle sets have Jaccard similarity above 0.8; we use the bands and rows that suit that threshold for 128 hash values, $(b, r) = (9, 13)$. And did the generator reproduce benchmark items it saw in its own training? A rewrite could bring in contamination that its source never had, so we search sources and rewrites alike for 13-gram hits in the index of GSM8K, ARC-Challenge and MMLU built in the same section.

Of the 14,305 chunks, 13,809 rewrites are kept: 77 ran out of tokens and 419 fell outside the length range. In characters the median rewrite is as long as its source, yet the rewrites take about 9% fewer tokens. A token of a rewrite covers about 4.8 bytes against 4.5 for the source, a sign of plainer, more common words, which the tokenizer encodes in larger pieces. About 70% of the kept rewrites keep every number, in all three splits alike, and about a quarter have a copy rate above 0.8.

The generator does not repeat itself across chunks. Two pairs of sources are near-duplicates and no pair of rewrites is: at temperature 0.7 with a different source each time, the rewrites stay as distinct as their sources. The repetition of the opening came from nine samples of one prompt, not from one sample each of many prompts. One source chunk hits a benchmark 13-gram and no rewrite does, so the generator added no contamination to this corpus. That has to be checked for every corpus, not assumed.

The corpus was generated by setting `D2L_RERUN` to `reph-s1`, `reph-s2` and `reph-val`, at batch 96 on one RTX 4090: about twenty minutes for each training split and six for validation. S1 holds the chunks of the first documents of the pool up to 2^{21} tokens, S2 the next 2^{21}, and the validation chunks come from the pool's validation documents. Each part writes its own rows, and the last one assembles token files, rows and dataset card into one archive.

Number fidelity catches lost numbers and nothing else. A rewrite can keep every digit and still change a name or add a claim that its source never made, and no string check sees that. A second model can, at a price. Our judge is Qwen3.8-27B, the model that labelled documents in Section 20.2, in a 4-bit build served by vLLM, one server per GPU. It is a much larger model than the rephraser and a different one, so it does not grade its own writing; it is of the same family, though, which is worth keeping in mind. For sixty pairs of S1 it reads source and rewrite and answers one question: does the rewrite state a claim that the source does not support? The answer is a line of JSON that also quotes the first such claim, so that a reader can check every verdict.

The judge reasons before it answers, and we let it. Its replies are greedy, limited to 12,000 new tokens within a context of 16,384, with no separate budget for the reasoning. The verdicts are registered; setting `D2L_RERUN` to `reph-judge` regenerates them, with one judge server per GPU.

The judge needs that room. Its median reply is about 2,800 tokens, most of them reasoning, so a budget of a thousand reasoning tokens would have stopped most of them part way through the argument. Even at 12,000 tokens, 4 of the 60 replies ended without a verdict.

They are left out, and the rate is computed on the other 56.

By the judge, the rewrite adds a claim in 39 of 56 pairs: 70%, with a 95% interval from 57% to 80%. Many of the added claims are small. One rewrite calls the CMS Web Guide "an article", another says that something "had been known for years". Others are not small, such as a sentence about the United States supporting a revolt in Syria and another in Bahrain. The judge reads strictly, and no person has checked its verdicts, so 70% is the rate that one strict reader with one prompt reports, not a measured error rate. By that reading, a rephraser of two billion parameters, told to add nothing, adds something most of the time.

The judge and the number check agree on only half of the pairs. In 25 pairs every number was kept and the judge still found an added claim; in 3, a number was lost and the judge found nothing to object to. These are not contradictions. The number check asks what was lost, the judge what was added, and the lost numbers include harmless rewritings such as "thirty". Neither check is the truth. A pipeline at scale would run the cheap one on every row and the expensive one on a sample, and publish both rates with the data.

20.5.3 Equal Budgets and Fair Accounting

Now the question of the opening: what does rephrased text do to a model trained on it? To answer it we fix the budget and vary only the data. Every run trains the same proxy model for 2^{24} tokens, and five arms fill those tokens differently:

- **A**, real text repeated: S1 read eight times;
- **B**, S1 and its rewrites, each read about four times, which is the WRAP recipe applied to a fixed source;
- **C**, the rewrites of S1 alone, read for the whole budget (they are shorter than S1, so almost nine times);
- **D**, fresh real text: 2^{24} tokens of the pool read once, the reference for what more real data would give;
- **E**, S1 and the rewrites of the other split S2, each read about four times: new information, but in rephrased form.

Every pool, D's included, consists of chunks with an end-of-text token after each, so all arms see text cut the same way.

Before any run, the law of repeated data of Section 20.4.1.1 limits what B can gain over A. For U unique tokens read for E epochs it counts

$$D'(U, E) = U + UR^*(1 - e^{-(E-1)/R^*}), \qquad R^* \approx 15.4,$$

effective tokens: repeats count almost fully for a few epochs and less and less after that. If the rewrites teach nothing beyond their source, B is worth A's eight epochs of U. If they were as good as fresh text, B would be worth two sources of size U read four times each. So

$$D'(U, 8) \le D'_B \le D'(2U, 4). \tag{20.12}$$

The lower bound assumes that a varied surface never hurts. The upper bound says that a rewrite can be no better than a new document of the same size, since it adds no facts. Both use a constant that Muennighoff and colleagues fitted in another setting (Muennighoff, Rush, et al. 2023), so they are a reference line, not a prediction.

Eight epochs of U are worth $6.62\,U$ and the upper bound is $7.45\,U$, so B can gain at most 12.5% in effective tokens over A; with the measured size of the rewrites, 8% shorter than S1, the margin is 11.9%. How large a difference in loss is that? Arm D will give a scale. It holds about a fifth more effective tokens than A, and B's best case is a little over half of that. Three seeds per arm may well not resolve a gain of this size, and we say so before training rather than after. A design with a smaller source read more often leaves B far more room at the same cost, and exercise 8 works it out.

20.5.3.1 The Five Arms

The arms become inputs of `train_proxy_lm`: a dictionary of pools and their weights. The training stream reads each pool's windows in epochs, one after another, each a fresh permutation (Section 20.4), which is the reading that the law assumes. Rewriting changes length, so arms with equal tokens differ slightly in epochs. The table prints for each pool its unique tokens, its windows per epoch, the epochs read and the effective tokens.

All arms train on 16,777,216 tokens. A reads S1 exactly eight times, C reads the shorter rewrites 8.7 times, and B and E read rewrites 4.4 times beside four passes over S1. Counted by the law, B and E hold about 15.5 million effective tokens against A's 13.9 million. That is the upper bound of Equation 20.12, since the table counts rewrites as if they were fresh text.

Each arm trains with three data-order seeds. The recipe is that of Section 20.4, with its peak learning rate and a cosine schedule, and with two changes. The model is the wider proxy of 8.1 million parameters, 6.3 million of them in its embedding table. And the warmup lasts 10% of the steps instead of 2%, because at the learning rate chosen in that section the wider model trains less steadily with only five warmup steps. The warmup was fixed before any arm was compared, all five arms share it, and exercise 9 measures what it changes. Each run is evaluated in bits per byte on two sets, the held-out real documents of the pool and the rewrites of the same documents, at a quarter, half, three quarters and the end of training. A normal build reads the registered runs and retrains the first million tokens of arm A as a live check; training all fifteen runs (`D2L_RERUN=synth-arms`) takes ten to fifteen minutes on one GPU.

20.5.3.2 Real and Rephrased Validation

The live check matches the registered losses to within 0.001 nats. A difference between two arms counts only if all three seed-paired differences have the same sign and their mean exceeds twice the pooled standard deviation of the seeds, estimated from all fifteen runs with ten degrees of freedom. Otherwise we write "no difference detected at this scale". The plot below shows the three runs of each arm and their mean on both validation sets, with a band of two standard deviations around arm A, and in its third panel the real-validation curves of A, B and D with the boundaries of A's epochs.

The seeds agree closely, to about 0.007 bits per byte on both sets, so differences above 0.014 are resolved. Read the first panel first. At T1 scale (8.1M-parameter proxies, 2^{24} tokens), fresh text is best, as it must be: arm D is lower than A by about 0.03. Arm B is not lower than A at all. The mean difference is 0.002, and the seeds disagree on its sign: no difference detected at this scale. The rewrites of the same chunks added nothing measurable. A null result was what the bound made likely, but even its best case, a little over half of D's gain, would have been near the edge of what three seeds resolve, and we did not see it.

The rewrites alone are a different matter. At T1 scale (8.1M-parameter proxies, 2^{24} tokens), arm C loses to A on real validation by about 0.07 bits per byte, and on rephrased validation it wins by about 0.06. The second panel shows the reversal: on rewrites every arm beats A, those that read rewrites (B, C and E) by more than fresh text does, and C most of all. Recall from Section 3.6 that a model trained on samples of one distribution and tested on another is subject to distribution shift. Training on a generator's output moves the training distribution toward the generator's: a model that has read the rephraser's style finds that style easy, and a model that has read nothing else is worse at the web. Had we evaluated only on rewrites, C would be the best arm in the table. This is the second half of WRAP's explanation at work: style that matches the evaluation helps the evaluation, whatever it does for other text.

Mixing repairs most of the damage. At T1 scale (8.1M-parameter proxies, 2^{24} tokens), B beats C on real validation by about 0.06, in every seed. Arm E, new information in rephrased form, ends below B in the table but by less than the threshold: no difference detected at this scale.

Did rephrasing behave as WRAP reports? On the kind of text where WRAP measured, it did. Arm B gains on rephrased validation, text in a style other than the source's, where it beats A by about 0.05 bits per byte, more than fresh text does. WRAP's perplexity result is likewise reported on text other than its C4 source, subsets of the Pile, and its own explanation, that the rewrites' styles are closer to the evaluation text, predicts this pattern. On held-out text of the source distribution, where WRAP made no claim, the rewrites of the same chunks added nothing measurable. There was also little to gain at our scale: the bound allows 12% more effective tokens, and the curves of A and B in the third panel lie on top of each other from the first evaluation to the last, while D pulls away. Whether rewrites help more on a noisier source than FineWeb-Edu, the first half of WRAP's explanation, this comparison does not test. What carries over to any scale is the protocol: equal tokens, both validation sets, a noise threshold fixed in advance and a bound computed before the runs. A claim that synthetic data helps should come with all four.

20.5.4 Recursive Training and Collapse

So far a generator trained on human text wrote data for a model that also read human text. As generated text spreads over the web, future crawls will contain the output of earlier models, and future models will learn from it. Shumailov and colleagues (2023) asked what happens when this repeats, each model trained on the output of its predecessor, and called the result the curse of recursion. The rare events of the original distribution vanish first, and the models converge to something narrower than the data they started from.

The smallest model of the process is a Gaussian. Generation 0 is the true distribution $\mathcal{N}(\mu, \sigma^2)$. Fit t draws n points from fit $t-1$ and estimates their mean $\hat{\mu}_t$ and variance $\hat{\sigma}_t^2$ by maximum likelihood. In *replace* mode it uses only those n points; in *accumulate* mode it uses all points drawn so far. With $q = (n-1)/n$, the two modes give

$$\begin{aligned} \text{replace:} \quad & \mathbb{E}[\hat{\sigma}_T^2] = q^T \sigma^2, \qquad \operatorname{Var}(\hat{\mu}_T) = \sigma^2 (1 - q^T), \\ \text{accumulate:} \quad & \operatorname{Var}(\hat{\mu}_T) \approx \frac{\sigma^2}{n} \sum_{t=1}^{T} \frac{1}{t^2} < \frac{\pi^2}{6} \frac{\sigma^2}{n}. \end{aligned} \tag{20.13}$$

The derivation takes three steps. First, the maximum-likelihood variance of n points is

biased low by the factor q, $\mathbb{E}[\hat{\sigma}_t^2 \mid \hat{\sigma}_{t-1}^2] = q\,\hat{\sigma}_{t-1}^2$, and the factors multiply over the generations. Second, the mean takes a random step at each generation, $\hat{\mu}_t = \hat{\mu}_{t-1} + \hat{\sigma}_{t-1} z_t/\sqrt{n}$ with z_t standard normal and independent of the past, so its variance is the sum of the step variances, $\sum_{t=1}^{T} q^{t-1}\sigma^2/n = \sigma^2(1-q^T)$. Third, under accumulation the n new points are only a share $1/t$ of the nt points behind fit t, so the step shrinks to $\hat{\sigma}_{t-1} z_t/(t\sqrt{n})$; with $\hat{\sigma}_{t-1} \approx \sigma$ the step variances $\sigma^2/(nt^2)$ have a finite sum.

The formulas describe two different fates. Under replacement the fitted spread shrinks by 1% per generation for $n = 100$ while the mean wanders, so after many generations the model is a narrow distribution around a point drawn at random from the original one. Under accumulation the mean stays within the error of the first fit, and the spread stays near the truth. The simulator below fits by maximum likelihood exactly as described.

We check the closed forms at $n = 100$ over 20 generations and 1,000 repetitions, and then move to text. The discrete toy takes 200,000 words of the web pool and fits a bigram model over the 20,000 most frequent words plus a token for all others. Each generation samples a corpus of the same size from the fitted model and refits, on that corpus alone (replace) or on all corpora so far (accumulate). We track the word types that the fitted model can still emit, and what happens to the rarest tenth of the original types: how many survive and how much probability they hold.

The closed forms hold. After 20 generations of replacement the mean fitted variance is 0.80 against $q^{20} = 0.82$, and the variance of the mean is 0.17 against 0.18, both within two Monte-Carlo standard errors. Under accumulation the variance of the mean is 0.0157, below the bound $\pi^2/(6n) \approx 0.0164$, and the fitted variance stays at 0.99.

The bigram model loses words. Under replacement it can emit 16,001 of its 20,000 types after one generation, 10,238 after five and 7,655 after ten; under accumulation all 20,000 remain. The rarest tenth are 2,000 words that occur exactly once, 1% of the 200,000. A word seen once appears in a resampled corpus of the same size about once on average, and with probability about e^{-1} not at all. A type that is not drawn gets count zero, and the refitted model can never emit it again. The survival after one generation, 62%, is close to $1 - e^{-1} \approx 0.63$, and after ten generations 17% of these words remain. Curiously, their total probability does not shrink: it stays near 1%, because the survivors inherit the counts of the lost. The tail is lost type by type, not as a falling share.

The toy shows a mechanism under a stated protocol, in which every generation learns only from the previous model's output, with no fresh data and no filter. Real pipelines keep real data, as accumulation does, and they filter what they generate. Gerstgrasser and colleagues (2024) prove for linear models that accumulating data keeps the test error bounded however many generations pass, and find the same in experiments with language models. The collapse is therefore not a forecast for the field. It is a forecast for one practice, replacing real data with generated data again and again, which nobody should follow.

20.5.5 Licences and Disclosure

Who may train on generated text? The question has two halves. A rewrite does not shed the licence of its source. Our rewrites of FineWeb-Edu remain FineWeb-Edu text under ODC-By and, as the FineWeb-Edu card says, also subject to Common Crawl's terms of use. And the generator has terms of its own. Qwen3.5-2B is released under Apache-2.0, which places no condition on its outputs, so our corpus carries the source's attribution and the generator's name. Other licences do set conditions. The Llama 3 licence, for example, asks that a model

trained with the help of Llama outputs carry "Llama" at the start of its name, and the card of Nemotron-CC-v2 warns that models trained on it may be subject to the terms of the Qwen and DeepSeek models that wrote parts of it. Hosted models add a second document. As Section 18.7 found, the licence of the weights can permit training on outputs while the terms of the service that ran them forbid it, so both are read before an API model writes a single training example. These statements describe licences and are not legal advice; the legal status of model outputs is unsettled in several jurisdictions.

The practical rule is to record everything needed to answer the question later. The manifest stage `rephrase` holds the generator and its revision, the hash of the prompt, the sampling settings and seed, the documents and chunks of each split, the flags and the drops with their reasons, and hashes of the input and output texts. The dataset card states the synthetic share in one line.

Of the archive's tokens, 48% were written by the model, the rewrites of the three splits beside their sources. The card carries that number so that anyone who trains on the data knows it. The same checks return in Section 24.3, where a model writes the instructions and answers for post-training and generated text becomes the main ingredient rather than a supplement. For pretraining one question stays open at our scale: whether a stronger rephraser, or a style that adds structure rather than polish, turns the null result of arm B on real text into a gain.

20.5.6 Summary

Language models can rewrite existing documents or write new ones from a seed, and both kinds of text now enter pretraining at the scale of whole crawls. Rewrites have to be checked. Cheap string measures catch lost numbers and near-copies. A strict judge model finds the added claims they miss, and by its reading about 70% of the rewrites of a two-billion-parameter model add one. The two checks see different failures, losses and additions. At one temperature, conditioning the prompt on format and audience raised distinct 4-grams from about 0.76 to 0.995. At T1 scale (8.1M-parameter proxies, 2^{24} tokens), rewrites mixed with their own source changed nothing measurable on real text, within the 12% that the law of repeated data allowed, and helped on rewritten text. Rewrites alone made the model better on rewrites and worse on real text, so a claim about synthetic data needs both validation sets. Training each generation only on the previous model's output loses variance and rare words, and accumulating real data prevents it. The rights to generated text follow both its source and its generator.

20.5.7 Exercises

1. **Two flagged rewrites.** One rewrite has copy rate 0.95 and number fidelity 1.0; another has copy rate 0.05 and number fidelity 0.5.
    1. Is either of them good training data? What would you check before deciding?
    2. Write a rewrite of the opening's chunk that scores copy rate below 0.3 and number fidelity 1.0 and is still wrong. Which of this section's checks would catch it?
2. code **The corpus keeps its promises.** Using only the registered archive, check that no rewrite contains a thinking tag, that every row whose `finish` is `length` or whose length ratio lies outside $[0.5, 1.5]$ is marked as dropped and is absent from the token files, and that the token files decode to the kept texts. Which of these properties would a change of chat template break first?

3. **The rephrasing budget.** A generator of N_g parameters rewrites a chunk of L tokens into about L tokens, and a student of N_s parameters trains on the rewrite.
    1. Count the forward FLOPs of the generation (the prefill of the prompt and the decoding of the reply, at about $2N_g$ per token each) and the training FLOPs of one pass over the rewrite (about $6N_s$ per token). At which ratio N_g/N_s do the two costs match?
    2. Evaluate the ratio for this section (Qwen3.5-2B, about 1.9 billion parameters in its language model, and the 8.1-million-parameter proxy) and for a 1.7-billion-parameter generator writing data for a student of 8 billion parameters trained for several epochs.
    3. Decoding is limited by memory bandwidth, not arithmetic (Section 11.3). Does that make FLOPs an underestimate or an overestimate of the generation's cost in GPU time?
4. **How fast replacement collapses.** In replace mode with n points per generation:
    1. Show that $\log \hat{\sigma}_t^2$ is a random walk whose steps have negative mean, and conclude that $P(\hat{\sigma}_T^2 < \epsilon\sigma^2) \to 1$ as $T \to \infty$ for every $\epsilon > 0$.
    2. Find the number of generations after which $\mathbb{E}[\hat{\sigma}_T^2] = \sigma^2/2$ for $n = 100$, and compare it with the median of $\hat{\sigma}_T^2$ in a simulation (extend `collapse_sim` to return it). Why do the two differ?
    3. Show that $\mathrm{Var}(\hat{\mu}_T) \to \sigma^2$. What is the limiting model, and how much does it know about the original distribution?
5. code **Temperature and diversity.** Rewrite the 60 live chunks in the encyclopedia style at temperatures 0.3, 0.7 and 1.0. Before running, predict how distinct 4-grams across the rewrites, the near-duplicate rate among them and number fidelity will move. Measure all three. Is there a temperature that raises diversity without lowering fidelity, and how does the gain compare with the prompt conditioning of Section 20.5.2.1?
6. code **Omissions.** The judge asks only whether a rewrite adds a claim. Write a second prompt that asks whether the rewrite leaves out a fact of the source, run it on the same 60 pairs, and tabulate it against the number check and against the first verdict. Do omissions or additions explain more of the lost numbers?
7. code **A stronger rephraser.** Rewrite S1 with `Qwen/Qwen3.5-4B` instead of Qwen3.5-2B, keeping prompt, sampling and filters. Before running, predict whether the copy rate, the number fidelity and the difference between arms B and A will change. Then measure the fidelity statistics and train arm B on the new rewrites with the three seeds. Compare with the original B by the section's rule and say what a null result would mean here.
8. code **Room to gain.** Arm B of this section could gain at most 11.9% in effective tokens over A. Keep the budget of 2^{24} tokens, but let A read a source of $U = 2^{19}$ tokens 32 times and B read that source and its rewrites 16 times each.
    1. Compute both sides of Equation 20.12 for this design. How much more room does B have?
    2. Run A, B and D at this size with three seeds each, and apply the section's rule on both validation sets. Before running, predict which of the differences it will resolve.
    3. A smaller source read more often also costs A more. Which of the two designs answers the question of the opening better, and why?

9. code **Warmup and seed spread.** The arms warm up over 10% of their steps; the proxies of Section 20.4 warm up over 2%. Train arm A with both warmups at the same peak learning rate, three seeds each, and compare the standard deviation of the final real-validation bits per byte. Plot the training losses of the first 40 steps. Where does the difference come from, and how small a difference between two arms could the section's rule resolve under each warmup?

10. code **Fresh data against collapse.** Extend `collapse_sim` so that a fraction ϕ of the n points of each generation is drawn from the true distribution and the rest from the previous fit, in replace mode. Find the smallest ϕ for which $\mathbb{E}[\hat{\sigma}_T^2]$ stays above $0.9\,\sigma^2$ for all T, first by simulation and then from the recursion for the expected variance. Do the same for the bigram toy, and find the fraction at which the rarest tenth of the types stops disappearing. Are the two fractions alike, and should they be?

20.6 Tokenizers at Scale

Every model in this part reads text through a tokenizer, and so far we have taken the tokenizer as given. Section 8.2 built one, a byte-level BPE, and noticed in passing that it treats languages unequally: GPT-2's tokenizer spent about seven tokens on a Greek word where an English word needed one. That looked like a curiosity of an old tokenizer. It is more than that, because a language model counts everything in tokens. A language that needs three times the tokens for the same text costs three times the compute to train on and to serve, and fits a third as much into the context window. Below, the same passages in ten languages go through four released tokenizers, and under all but the newest of them the Hindi version of a passage needs several times the tokens of the English one.

Recall how that tokenizer works. Byte-level BPE starts from the 256 byte values, so that any string can be encoded, and repeatedly merges the most frequent adjacent pair of symbols into a new symbol until the vocabulary is full (Sennrich et al. 2016; Radford et al. 2019). A regular expression first cuts the text into words, numbers and punctuation, so that no merge crosses those boundaries, and a few special tokens such as `<|endoftext|>` are reserved outside the merges. Section 8.2.5.3 measured what this does to different scripts and to numbers.

This section asks four questions that the builders of a model must answer before its first training step. Is merging the only way to build a vocabulary? It is not: the unigram model gives every piece a probability and segments text by maximizing it. What does the text a tokenizer is trained on do to each language? How large should the vocabulary be? The answer is a question of compute, with a short derivation. And can a trained model's vocabulary be changed afterwards? At the end we freeze the tokenizer that the rest of this part uses and write the token files that the next chapter trains on. A tokenizer is the one component of a language model that cannot be changed cheaply once a model has been trained on it, so these choices deserve more thought than they usually get.

Most of this section runs on a CPU. Two experiments need a GPU: six small language models that compare tokenizers, and eight runs that extend the vocabulary of a released model. A normal build reads their registered results, checks that they match this build's tokenizers, text and configuration, and repeats part of each. Both are small, at what this chapter calls T1 scale, and the cell below prints what that means.

The parallel passages are those of the Belebele reading-comprehension benchmark (CC BY-SA 4.0), downloaded from a pinned commit and never re-hosted. The ten-language slice is

FineWeb-2 text for nine languages and FineWeb-Edu text for English (Penedo et al. 2024), both ODC-By: about 4.5 MB of training text per language with a tenth held out, plus 30,500 Hindi documents for the extension experiment. The reference tokenizer and its shards were built once by `tools/build_r2_shards.py`; this notebook reads and checks them. The results of both GPU experiments sit in one registered file, `lm-data-tok-results-v1`.

Section 8.2.5.3 measured a tokenizer's *fertility* as tokens per word. Words are a poor unit across languages: Thai and Chinese put no spaces between them, and a German compound is a single word. Parallel text lets us do without them. Petrov and colleagues (2023) define the *tokenization premium* of a language as the number of tokens its version of a set of passages needs, divided by the number the English version needs. The passages say the same thing, so a premium of 2 means twice the compute and twice the context for the same content. `fertility_table` also reports bytes per token and the share of tokens that are single bytes of a multi-byte character. Such a token means that the tokenizer had no piece for the character at all and spelled it out.

We compare four released tokenizers: GPT-2's (2019) and `o200k_base` (OpenAI's tokenizer of 2024), both through `tiktoken`, and those of Qwen3 and Qwen3.5, the model family this part of the book uses, loaded from pinned revisions. The text is Belebele's 488 distinct passages in each of the ten languages. (Belebele calls simplified Chinese `zho_Hans`; FineWeb-2 calls it `cmn_Hani`.)

GPT-2's tokenizer needs more than seven times English's tokens for Hindi and nine times for Thai, and almost half of its Hindi tokens are lone bytes. Qwen3's tokenizer, three times larger, brings Thai down to 2.6 but leaves Hindi at 4.5, and a quarter of its Hindi tokens are still pieces of a character. Qwen3.5's tokenizer halves the Hindi premium again, to 2.0. Notice that Qwen3.5 reads *more* bytes per Hindi token (6.1) than per English token (4.8) and still needs twice as many tokens. The reason is the encoding: a Devanagari character takes three bytes in UTF-8 and a Latin letter one, so the Hindi version of the passages is about 2.6 times as long in bytes as the English. Part of every premium belongs to UTF-8, and no tokenizer removes it without pieces of many bytes.

20.6.1 The Unigram Model

BPE builds its vocabulary by a sequence of decisions: merge the most frequent pair, then the next most frequent, and so on. Encoding replays these decisions in the order they were made, so the segmentation of a word is whatever the merge order produces. Nothing ever compares two segmentations of the same word and asks which one is better. The *unigram model* of Kudo (2018) asks exactly that. It gives each piece x of the vocabulary a probability $p(x)$, treats the pieces of a segmentation as independent draws, and prefers the most probable segmentation. Training chooses the vocabulary and the probabilities to make the corpus likely.

Let us make this precise. A segmentation $\mathbf{s} = (x_1, \dots, x_k)$ of a word w has probability $P(\mathbf{s}) = \prod_{m=1}^{k} p(x_m)$, and the word has probability $P(w) = \sum_{\mathbf{s}} P(\mathbf{s})$, summed over all its segmentations. There can be exponentially many, but they have a simple structure. Write the word's characters at positions 0 to n and draw an edge from i to j whenever the substring $w_{i:j}$ is a piece. This is the word's *lattice*. Every path from 0 to n is a segmentation, and its probability is the product of the edge probabilities along it. For the word *sports* (written `▁sports`, with SentencePiece's mark of a word start) the lattice of a trained vocabulary contains the paths `▁s|port|s` and `▁sp|ort|s`, among others.

Sums over all paths of a lattice are computed by dynamic programming. The forward sum f_j collects the probability of every path from 0 to j, and the backward sum g_i that of every path from i to n:

$$f_0 = 1, \quad f_j = \sum_{i<j} f_i \, p(w_{i:j}), \qquad g_n = 1, \quad g_i = \sum_{j>i} p(w_{i:j}) \, g_j,$$

where a term is zero when $w_{i:j}$ is not a piece. Then $P(w) = f_n$, and the probability that a segmentation of w uses the edge from i to j is the share of all paths through it, $f_i \, p(w_{i:j}) \, g_j / P(w)$.

Training maximizes the log-likelihood of a corpus in which word w occurs c_w times, $\sum_w c_w \log P(w)$. The segmentations are hidden, so we use expectation-maximization. The E-step computes the expected number of times N_x that piece x is used, summing the edge probabilities over every edge labelled x in every word. The M-step chooses new probabilities that maximize $\sum_x N_x \log p(x)$ subject to $\sum_x p(x) = 1$. With a Lagrange multiplier λ, setting the derivative of $\sum_x N_x \log p(x) - \lambda(\sum_x p(x) - 1)$ to zero gives $N_x / p(x) = \lambda$, so the probabilities are the expected counts, normalized:

$$N_x = \sum_w c_w \sum_{(i,j):\, w_{i:j} = x} \frac{f_i \, p(w_{i:j}) \, g_j}{P(w)}, \qquad p_{\text{new}}(x) = \frac{N_x}{\sum_y N_y}. \tag{20.14}$$

In words, each piece gets the probability of being used, averaged over all the ways the corpus could have been cut. Each round of EM never lowers the likelihood; the exercises ask you to show it.

Three more operations complete the model. *Viterbi segmentation* replaces the sum in the forward recursion by a maximum and remembers which edge won, which gives the most probable path in time proportional to the word's length times the longest piece; this is `d2l.viterbi_segment`. *Pruning* shrinks the vocabulary, which EM alone never does. Training starts from every character and the 100,000 most frequent substrings, runs two rounds of EM, and then removes the pieces whose removal costs the least likelihood: a piece's loss is how often the Viterbi segmentations use it times how much less probable its best segmentation without it is. Keeping 80% per round until the target size is reached, with every single character kept so that each word stays segmentable, is the procedure of `d2l.UnigramTokenizer`. Finally, because the model is probabilistic, it can *sample* segmentations, drawing $\mathbf{s}$ with probability proportional to $P(\mathbf{s})^\beta$ by running the forward recursion on $p(x)^\beta$ and then drawing edges backwards from n. At $\beta = 0$ all segmentations are equally likely, and as $\beta \to \infty$ the sample becomes the Viterbi path. Kudo trained translation models on a fresh sample each time a sentence was read, so that the model sees many segmentations of each word and cannot rely on any one of them. He called this *subword regularization*. (The code calls β `alpha`, Kudo's name for it.)

Every step of this derivation can be checked by brute force on short strings over the alphabet $\{a, b, c\}$, where all segmentations can be listed. The cell compares the forward sum and the expected counts with their values over the enumerated segmentations, Viterbi with the best enumerated segmentation, each round of EM with the previous one, and the frequencies of sampled segmentations with their probabilities.

Forward-backward agrees with enumeration to rounding error, the log-likelihood rises at every round of EM, and 10,000 samples of the seven segmentations of `abcabc` land within

2.4 standard errors of their probabilities. Four of the 200 random strings have two best segmentations of equal probability; Viterbi then takes the one with fewer pieces.

Now a real vocabulary. We train `UnigramTokenizer` to 4,096 pieces on 1 MB of English from the slice, and the unigram trainer of SentencePiece, the production implementation (Kudo and Richardson, 2018), on the same text. Then we load SentencePiece's pieces and scores into our `viterbi_segment` and ask whether it reproduces SentencePiece's segmentation of 1,000 held-out lines. SentencePiece marks a word start with ▁ (U+2581) attached to the following piece and spells a character that has no piece by its UTF-8 bytes (`byte_fallback`); `sp_viterbi` imitates both. The cell also lists words whose two best segmentations are close and samples five segmentations of one sentence at $\beta = 0.2$.

Our pure-Python trainer needs about a minute where SentencePiece's C++ needs a second or two, but the model is the same: Viterbi on SentencePiece's pieces and scores reproduces every one of its 1,000 segmentations. The two trainers agree on three quarters of their pieces (3,067 of 4,096). They seed and prune differently, and the pieces they disagree on are rare ones whose fate was close. The word list shows what a probabilistic lexicon has that a merge table lacks. For *sports* the two best paths are `▁s|port|s` and `▁sp|ort|s`, with log-probabilities -18.5 and -19.3 nats, so the first is $e^{0.8} \approx 2.2$ times as probable as the second. At $\beta = 0.2$ the ratio shrinks to $e^{0.16} \approx 1.17$, nearly a coin toss. That is why the sampled segmentations of the sentence, a held-out FineWeb-Edu line (ODC-By), look so ragged: *three* stays whole in three samples and falls apart in the other two, and even *Since* is spelled out once. A model trained on such samples has to recognize a word however it is cut.

Two defaults of SentencePiece change the text a model sees, and neither says so. Its default normalization, `nmt_nfkc`, applies Unicode's compatibility folding: ligatures become letters, superscripts become digits, full-width forms become ASCII. That is convenient for machine translation and wrong for a pretraining corpus, in which x^2 and x2 are different things. The notebook normalizes every text to NFC itself, which only composes accents with their letters, and tells SentencePiece to leave the text alone. The second default, `character_coverage` of 0.9995, leaves out of the vocabulary the rarest characters that together make up 0.05% of the training text; byte fallback then spells them in bytes.

Four of the five probe strings change under `nmt_nfkc`; only *café*, already composed, survives. On Japanese, full coverage keeps 2,707 single characters as pieces and the default 2,523. The default spells more of the Belebele text in bytes (1.35% of tokens against 0.96%) and yet needs 0.8% fewer tokens in all, because the 184 slots freed from rare characters go to longer pieces of common text. That is what coverage below 1 is for, and it is a choice to make on purpose.

The unigram model and BPE produce the same kind of object, a list of pieces, and both encode a word as a sequence of pieces. They differ in the rule that chooses the sequence. BPE replays its merges in the order it learned them. The unigram model picks the most probable segmentation and can sample others. In the rest of this section the more consequential differences are not between these two algorithms but between what any tokenizer does to different languages.

20.6.2 The Tokenization Premium

A tokenizer is a compressor fitted to its training text. Frequent strings become single pieces, and rare strings are spelled from smaller ones. A language that is rare in that text therefore gets few pieces and many tokens. Released tokenizers are usually trained on a sample of

the model's pretraining data, in which English dominates, so the premium of the opening is partly a choice of training text. We can test this directly with the temperature weighting of Section 20.4.1.1, which samples a source with n_i documents in proportion to n_i^α: at $\alpha = 1$ in proportion to size, at $\alpha = 0$ uniformly. We train three byte-level BPEs of 16,384 pieces on the ten-language slice, with the languages weighted at $\alpha = 1$, 0.3 and 0 according to FineWeb-2's document counts. FineWeb-2 has no English, so English is given German's count, so that at $\alpha = 1$ it weighs as one large European language among others. (Section 20.4 uses FineWeb's English count instead, about fifty times German's, which at $\alpha = 1$ would hand English about nine tenths of the tokenizer's text.) The most heavily weighted language contributes all of its 4.5 MB of training text and the others proportionally less.

These three tokenizers, and the reference tokenizer later in the section, are built with the Hugging Face `tokenizers` library, which assembles a tokenizer from four parts: a normalizer (here NFC), a pre-tokenizer (the split rule, then a map from bytes to printable symbols), a model (BPE) and a decoder that undoes the byte map. The split rule, `R2_SPLIT_REGEX`, is Qwen3's. It matches contractions, runs of letters with at most one leading non-letter, single digits, runs of punctuation, newlines and whitespace. `train_hf_bpe` builds this pipeline for any vocabulary size and list of special tokens, which take the first ids.

Lowering α moves pieces to the small languages. At $\alpha = 1$ Hindi gets 0.8% of the weight and the tokenizer has 93 pieces in Devanagari script; at $\alpha = 0$ Hindi gets a tenth of the text, the tokenizer has 574 Devanagari pieces, and Hindi's premium falls from 2.42 to 1.77. Swahili, the smallest of the ten corpora, falls from 1.88 to 1.04, almost English's cost. The pieces come from somewhere. The vocabulary has a fixed size, so Russian rises from 1.30 to 1.42 as its Cyrillic pieces drop from 2,597 to 1,269, and Chinese from 0.95 to 0.99. Weighting divides a fixed vocabulary among languages, and every division favours someone.

Even at $\alpha = 0$ Hindi keeps a premium of 1.77, and part of the reason lies before BPE. In the split rule, `\p{L}+` matches letters, but Unicode classes the vowel signs and the virama of Devanagari as combining marks, not letters. The rule therefore cuts हिन्दी (*Hindi*) into ह before BPE sees it, and no merge can cross those cuts. The reference tokenizer shares this rule, which is harmless for the English model of the next chapter and would not be for a Hindi one. Our implementation of the English quality rules in Section 20.2 had the same flaw: its word pattern, Python's `\w`, also skips the vowel signs, so it cut every Hindi word into fragments and removed every Hindi document. A word pattern that keeps the marks with their letters, `[\p{L}\p{M}]+`, avoids both cuts.

20.6.2.1 Bits per Byte and the Choice of Algorithm

Fewer tokens answer only half of the question. A tokenizer that packs more text into each token makes each prediction harder, and a model could lose per token what it saves in tokens. To compare tokenizers, we need a measure of how well a model predicts the text that does not depend on how the text was cut. Perplexity per token is not such a measure, because longer tokens carry more surprise each. Section 18.4.3 and the mixtures of Section 20.4 used *bits per byte* instead: the total surprisal of a text in bits divided by its length in UTF-8 bytes. If L is the mean loss per token in nats and $\bar{b}$ the mean number of bytes per token, then

$$\text{bpb} = \frac{L}{\bar{b} \ln 2}, \tag{20.15}$$

so a tokenizer with twice the bytes per token is allowed twice the loss per token. This is the bits per character of the coding appendix (Section 37.2.4.1) with bytes in place of characters. Two cautions come with it. Bytes must be counted on the same normalized text for every tokenizer, because a text before and after NFC can differ in length. And bits per byte compares models on one language: a byte is a whole English letter but a third of a Devanagari character, whose first two bytes are almost always the same.

The experiment holds everything fixed except the tokenizer. Three tokenizers of 16,384 pieces are trained on the same 45 MB of ten-language text: SentencePiece's unigram model, SentencePiece's BPE, and the byte-level BPE trained at $\alpha = 0$ above. One small `d21.GPT` per tokenizer and seed then trains for one epoch over that text and is scored per language. The models are small and the text is short, so everything here holds at T1 scale and no further.

First the three tokenizers. The cell trains the two SentencePiece models, encodes the 45.7 MB of training text and the evaluation texts with all three, and records fingerprints of the tokenizers, with which a normal build checks that its tokenizers are those the registered runs used.

The three tokenizers cut the same bytes into nearly the same number of tokens, within about 1% of each other. Each tokenizer gets one small model per seed, for two seeds, trained for one epoch over its own tokens of the same text, so the six models read the same bytes but not the same number of steps (368 to 373 steps of 32,768 tokens). The recipe and the learning rate are those of the T1 runs of Section 20.4. Each model is scored on the held-out tenth of every language and on the Belebele passages. A normal build reads the registered runs, checks that they used this build's tokenizers, text and configuration, and retrains the first 2^{19} tokens of one run to compare its losses with the registered log.

The retrained start of the run matches the registered log well within the tolerance of 0.02 nats.

Before comparing languages, a check of the measure itself. On 100 held-out documents the cell computes bits per byte in three ways: from the mean loss per token and the bytes per token, as in Equation 20.15; as the summed loss over the summed bytes; and as the byte-weighted average of per-document values.

The three agree exactly, as they must. The table also shows the pitfall. Perplexity puts the three tokenizers at 214, 218 and 243, a spread of more than 10%, while bits per byte puts them at 1.94, 1.94 and 1.98, and the first two even trade places between the two measures. Per-token perplexity compares models that share a tokenizer and nothing else.

Now the languages. The plot places each language at its premium under each tokenizer and at the bits per byte of the small models on its Belebele passages, with a gray line joining the three tokenizers of one language. The tables add the range over the two seeds, which is the noise against which differences are read: a difference smaller than the larger of two seed ranges is not interpreted. The average over languages is compared between tokenizers with the paired bootstrap of Section 18.5, which resamples the 488 passages.

At T1 scale the algorithm matters little. Unigram against BPE at the same vocabulary size changes a language's bits per byte by at most 3.6% (Thai), and their averages over languages differ by 0.002 bits per byte, with an interval that barely excludes zero. Both SentencePiece models are better than the byte-level BPE by about 0.02 bits per byte. In the plot the lines are short. The premium, by contrast, varies a lot between languages under every tokenizer: the most expensive language needs 1.5 to 1.8 times the tokens of the cheapest. Seven of the ten languages show a unigram-BPE difference larger than their seed range, but these

differences are small, they go both ways, and two seeds cannot rank tokenizers language by language. Bostrom and Durrett (2020) found the unigram model better than BPE for pre-training BERT-sized models in English and Japanese; our small models can neither confirm nor refute that at their scale.

One large tokenizer effect stands out: the byte-level BPE gives Hindi a premium of 1.77, against 1.32 for SentencePiece's BPE, and also the worst Hindi bits per byte of the three (1.30 against 1.21, beyond the seed range). This is the split rule again. SentencePiece does not cut inside a word of one script, while the byte-level BPE inherits the cuts at every vowel sign. So a tokenizer decides how many tokens a language costs far more than how well a model predicts it, at least at this scale, and its pre-tokenization rule can matter more than its algorithm. The vertical order of the languages, finally, says little: Chinese sits near 3 bits per byte and Hindi near 1.2 because their scripts spend their bytes differently, not because one is harder to model.

20.6.3 Vocabulary Size and Pre-Tokenization

Every tokenizer so far had a vocabulary size chosen by habit: 16,384 here, 50,257 for GPT-2, 151,669 for Qwen3. Is there a better reason for a number? The vocabulary enters a model twice. It sets the size of the embedding matrix, V rows of width d, which with tied embeddings is also the output layer that computes a logit for every piece at every position. And through the tokenizer it sets how many tokens a text becomes. A larger V makes every token more expensive and the text shorter. That trade-off can be written down.

Training a transformer with N parameters costs about $6N$ floating-point operations per token, two for each parameter in the forward pass and four in the backward pass. Let A be the parameters outside the vocabulary matrix. With tied embeddings the vocabulary adds Vd parameters, used once per position by the output layer (the input lookup costs nothing). A token covers $\bar{b}(V)$ bytes on average, so the compute per byte of text is

$$C(V) = \frac{6\,(A + Vd)}{\bar{b}(V)}.$$

To find the best V, take logarithms and differentiate with respect to $\log V$:

$$\frac{d\log C}{d\log V} = \frac{Vd}{A + Vd} - \frac{d\log \bar{b}}{d\log V}.$$

The first term is the *softmax share* $s(V)$, the fraction of parameters in the vocabulary matrix. The second is the *elasticity of compression* $\varepsilon(V)$: by how many percent the bytes per token grow when the vocabulary grows by one percent. The derivative is zero where the two are equal, and if ε is roughly constant near that point we can solve for V:

$$\varepsilon(V^*) = s(V^*) = \frac{V^* d}{A + V^* d}, \qquad V^* = \frac{\varepsilon}{1-\varepsilon}\cdot\frac{A}{d}. \tag{20.16}$$

In words, growing the vocabulary is worth it as long as the fraction of tokens it saves exceeds the fraction of compute it adds. Since compression gains shrink as the vocabulary grows, ε falls with V while s rises, and the crossing is a minimum. For a model with 24 blocks of width $d = 1{,}024$, so $A = 12 \cdot 24 \cdot 1024^2 \approx 302$ million, and $\varepsilon = 0.1$, the formula gives

$V^* = 32{,}768$. Two consequences are visible without numbers: a larger model (larger A) deserves a larger vocabulary, and so does text that keeps compressing as pieces are added (larger ε), such as many languages at once.

Tao and colleagues (2024) reach the same direction with a model that also lets the vocabulary change the loss, which ours holds fixed. They estimate, for instance, that Llama 2 70B would have been better served by at least 216,000 pieces than by its 32,000. Our model is the compute half of their argument, and it is enough to see where released vocabularies sit.

To measure $\bar{b}(V)$ we use a property of BPE: merges are learned in order, so the first V ids of a trained vocabulary, with the merges that made them, are exactly the tokenizer that training would have produced had it stopped at V. One BPE of 65,536 pieces therefore gives $\bar{b}$ at every smaller size. We train one on English FineWeb-Edu documents and one on the ten-language slice, measure bytes per token on held-out text at seven sizes, and fit a smooth increasing curve to $\log \bar{b}$ against $\log V$; its slope is the elasticity. A synthetic curve with $\bar{b} = cV^{0.1}$ checks the code against the formula.

For English the elasticity falls from 0.24 at 1,024 pieces to 0.04 at 65,536, while the softmax share at $d = 1{,}024$ rises from 0.3% to 18%. They cross near 27,000 pieces, which is also where the cost curve has its minimum (the two numbers agree because both come from one fitted curve). Ten-language text keeps compressing for longer, with an elasticity of 0.16 at 32,768 pieces against English's 0.07, and its optimum moves to about 51,000 pieces. The synthetic check recovers the formula's 32,768. The right panel of the plot shows how flat the minimum is: a vocabulary half or twice the optimal size costs only a few percent more compute per byte. Any round number near the optimum will do; the cost model does not pin the vocabulary down to better than a factor of two.

Where do released tokenizers sit? For each one we measure bytes per token on the same English held-out text and compute, from the model's own configuration and without loading weights, the share of its parameters in the vocabulary matrix. The reference tokenizer is placed at the width of the next chapter's reference model, $d = 768$.

On English all five tokenizers cover between 4.4 and 4.7 bytes per token, although their vocabularies range from 32,768 to 248,320 pieces. Beyond a few tens of thousands of pieces, English is compressed nearly as far as it goes. The small released models spend a quarter to a third of their parameters on the vocabulary matrix (GPT-2 small 31%, Qwen3-0.6B 26%, Qwen3.5-0.8B 34%), and the reference model 18%. By the cost model these small models have more vocabulary than English needs. Their vocabularies were not chosen for them alone, however: one tokenizer serves a whole family of model sizes up to hundreds of billions of parameters, and many languages, and Equation 20.16 says that both push V up. The reference tokenizer, measured on the training shard later in this section, needs only 1% more tokens than GPT-2's on English prose with a matrix 35% smaller.

A few practical rules come from costs the model leaves out. Round V up to a multiple of 64 or 128 so that the output layer's matrix multiply fits the GPU's tiles; Qwen3's tokenizer has 151,669 ids and its matrix 151,936 rows. Reserve ids for special tokens that a later stage will need, so that adding a chat or tool token does not mean resizing the model. And tie the input and output embeddings in small models, which halves the vocabulary's parameters.

20.6.3.1 Numbers, Whitespace and Code

Before any merge is learned, the pre-tokenization rule has already decided much of how a tokenizer treats numbers and code. Section 8.2.5.3 showed GPT-2 cutting 12345678 wher-

ever BPE had found frequent fragments and `o200k_base` cutting runs of digits into groups of at most three. Qwen3, Qwen3.5 and the reference tokenizer go further and make every digit its own token. For code, what matters is whitespace. An indented line starts with a run of spaces, and a tokenizer with no piece for long runs spends a token on every space or two. We measure both, on a passage full of numbers and on the first 2,000 lines of the book's own library, `d2l/torch.py`.

The three rules cut 12345678 in three ways. Single digits are the only rule under which every number is cut the same way, digit by digit, so that the model sees place value in the same form everywhere. They cost about twice as many tokens on the numeric passage as GPT-2's or `o200k_base`'s groups. On code, `o200k_base` and the Qwen tokenizers have pieces for whitespace runs of up to 128 bytes and need about 11 tokens per line of the library. GPT-2's has none and needs 19. The reference tokenizer, whose longest whitespace piece is two spaces, needs 17.6, about 65% more than Qwen3's. It was trained on educational web prose, where long runs of spaces are rare. A model trained on it will read code expensively, and only a change of vocabulary can fix that, which is the subject of the next part of this section.

20.6.4 Extending a Trained Vocabulary

Suppose a trained model's tokenizer fragments a language you care about. Qwen3-0.6B-Base is an example: its tokenizer needs 4.5 times English's tokens for Hindi, while that of its successor Qwen3.5 needs 2.0. Part of Qwen3.5's improvement is a larger vocabulary, and part is a split rule that keeps combining marks with their letters. Training a new model with a better tokenizer is out of reach for most of us. Can we add pieces to the old one instead?

Adding pieces to a tokenizer is easy. The hard question is what to put in their rows of the embedding matrix, which in Qwen3-0.6B are shared between input and output. Section 19.1 showed that training places the row of a token near the rows of tokens used in similar contexts. An initialization decides where in that space a new row starts. We compare three simple choices. *Random* rows are drawn from the model's own initializer. *Mean* rows are the mean of all old rows plus noise of 1% of their standard deviation, so that no two rows are equal. The *decomposition* uses the old tokenizer: it splits each new piece into old pieces, and the new row is the mean of their rows. WECHSEL (Minixhofer and colleagues, 2022) and FOCUS (Dobler and de Melo, 2023) place a new row more carefully, as a weighted average of the rows of old pieces that are similar to it according to auxiliary word embeddings; we describe them and do not implement them. `extend_vocab` implements the three choices for a Transformers model and tokenizer. It resizes the input matrix and, if the embeddings are untied, the output matrix too, and it updates `config.vocab_size`. Forgetting either of the last two is a common bug that produces no error until the first new id is used.

The new pieces come from a byte-level BPE of 8,192 pieces trained on 30,000 Hindi documents. Its split rule keeps letters and their combining marks together and never puts a space inside a piece. This matters for English. The new pieces are added as *added tokens*, which the tokenizer matches before its own segmentation, so a new piece that contained an ASCII character would change how some English text is cut. We keep the pieces that hold at least two Devanagari characters and no ASCII byte and that are not already in Qwen3's vocabulary, and add the first 4,096 of them in merge order. The cell then checks that 1,000 lines of English get the same ids as before.

Of the Hindi BPE's 7,154 pieces with at least two Devanagari characters, 7,153 are new to Qwen3. The first ones are endings and particles such as के, है and में; the last ones are whole

words such as हिमाचल (Himachal). English is cut exactly as before. The extended tokenizer reads 5.28 bytes of Hindi per token against 2.79 before, close to Qwen3.5's 6.13, so Hindi needs about half the tokens it did. That is the whole benefit the tokenizer can deliver, and it is not yet a benefit to the model. Whether the model can use the new tokens depends on their rows.

20.6.4.1 Initialization at Step Zero

Before any training, three measurements show what an initialization did. The first is the probability the new tokens receive on English text, where none of them should appear. If it is large, the new rows have hijacked the softmax, and the model has become worse at English before training starts. The second is the probability they receive on Hindi text, where about half of the next tokens are new ones. The third is bits per byte on held-out Hindi documents, on Belebele's Hindi passages and on English documents. Bits per byte is the right measure here because the extended and the original tokenizers cut Hindi differently. English ids are unchanged, so only the softmax's normalizer, which now sums over the new rows as well, can move English. The cell also checks an identity of the decomposition. With tied embeddings, the output row of a new token is the mean of its pieces' rows, so its logit is the mean of their logits.

The four arms are the unextended model with its own tokenizer, the *control*, and the three initializations (seed 0). All four read the same 500 Hindi documents, 488 Belebele passages and 200 English validation documents, in bf16.

No initialization disturbs English. English bits per byte is 0.8225 in all four arms, and averaged over any English document the new tokens receive at most 0.07% of the probability. On Hindi the arms differ sharply. The decomposition gives the new tokens 73% of the probability on Hindi text and reaches 1.48 bits per byte. Random rows receive 0.2% and reach 2.39. Mean rows receive almost nothing and reach 2.89, worse than random by 0.52 bits per byte on the Belebele passages (a 95% interval over passages of 0.52 to 0.53). The control, reading Hindi through Qwen3's fragmenting tokenizer, is at 0.62.

Why is the mean worse than random? Every mean row is the same vector up to 1% noise, so every new token receives the same logit at every position, the average of the old logits. The new tokens can win no probability, and as inputs they cannot be told apart. The mean initialization is recommended for a different purpose (Hewitt, 2021, and the default of Transformers' `resize_token_embeddings`): it keeps new rows from hijacking the softmax, and that it does here. It does nothing for the new tokens themselves. The decomposition starts better because a new token's logit is the mean of its pieces' logits (the identity holds to bf16 rounding), which is high exactly where the pieces are likely, that is, on Hindi. Still, 1.48 bits per byte is far from the control's 0.62. The model has never read the new tokens as inputs, and their rows are only a guess.

20.6.4.2 Continued Training

Training on Hindi decides whether the new rows can be learned. Each extended arm and the control train for 150 steps of 8 sequences of 1,024 tokens, in two phases, the usual recipe for vocabulary extension. For the first 50 steps only the new rows train, at a high learning rate of 3×10^{-3}, while the rest of the model, including the old rows of the shared matrix, is frozen; the control has no new rows, so it waits. Then every parameter trains for 100 steps at a low rate of 10^{-5}. Each phase warms up over 10 steps and decays along a cosine, with AdamW.

The low body rate follows from what a released base model is. It ends pretraining with its learning rate decayed to nearly zero, and raising the rate again, on small batches of 8,192 tokens, can move it away from where it ended. A control that got worse in this way would flatter the extended arms, so the body rate is the largest at which the control, which has nothing new to learn, stays where it started on Hindi and on English. The rate of the first phase is the one at which the new rows reached the lowest Hindi loss. Both were chosen on Hindi documents that are neither in the training pool nor in the evaluation set, so no reported number was tuned on them.

All arms read the same documents. An extended arm needs fewer tokens for them, so in 150 steps it reads more Hindi text than the control does. The weights are in fp32 with bf16 arithmetic. Gradient checkpointing and a loss computed in chunks of 1,024 positions keep the $8{,}192 \times 155{,}765$ matrix of logits from ever existing at once, and a run fits in about 14 GB of one GPU.

The eight runs, four arms with two data-order seeds each, are read from the registered results unless regenerated. Hindi bits per byte is measured along training on 100 held-out documents in fp32, so its values at step 0 differ slightly from the table above; English is measured on the 200 English documents before and after training.

The control stays flat, from 0.627 to 0.626 bits per byte, so the recipe does what it was chosen for. The extended arms improve quickly in the first phase, and the gaps between initializations shrink from between 0.5 and 1.4 bits per byte at step 0 to at most 0.2 at step 150. The decomposition stays best throughout and ends at 0.85. The mean overtakes random within 25 steps and ends at 0.92 against 1.03. A plausible reason is that random rows are small vectors in a region the model never visited, while the mean rows, once training pulls them apart, start among the old ones. English barely moves, from 0.822 to at most 0.832.

No extended arm reaches the control, however. After 150 steps, 1.2 million tokens, the best is still about 0.2 bits per byte above it. At this budget the extension halves the number of tokens Hindi needs and loses a fifth of a bit per byte in prediction. Published extensions continue training on far more text, often billions of tokens, and how long the extended model needs to catch up is something 150 steps cannot tell. The number of new tokens is not the benefit. The benefit is fewer tokens per byte, and it reaches the model only after the model has learned to use them.

20.6.4.3 Byte Patches

Every tokenizer in this section makes a compression decision once, before the model sees any data, and the extension experiment showed how hard that decision is to revisit. The Byte Latent Transformer (Pagnoni and colleagues, 2024) moves the decision into the model. A small byte-level model predicts the next byte, and a new *patch* starts wherever its prediction becomes uncertain, so predictable stretches become long patches and surprising ones short. The toy below imitates only the boundary rule, with a character trigram model trained on Hindi text: a patch ends where the entropy of the next character jumps. It compares patch lengths with token lengths, both in UTF-8 bytes because a byte-level token can be part of a character. It says nothing about how well a model would learn from such patches.

On one paragraph of 1,092 bytes, the entropy rule makes 134 patches of 8.15 bytes on average, against 2.94 bytes for Qwen3's tokens and 2.53 for the reference tokenizer's, which was trained on English. That Qwen3.5's tokenizer happens to make exactly 134 tokens of the paragraph is a coincidence. Even a trigram model with a hand-set threshold produces

units as long as Qwen3.5's tokens. Whether a learned version matches tokenized models at equal compute, as BLT's authors report, is a claim we cite here and do not test.

20.6.5 The Reference Tokenizer and Its Shards

Every model trained in the rest of this part reads text through one tokenizer, and the next chapter reads that text from token files written once. Changing either later would mean retraining every model built on them, so we fix both here, in Table 20.3, and test them. The reference tokenizer is a byte-level BPE, so that any string can be encoded without an unknown token. It has 32,768 pieces, a power of two in the flat part of the English cost curve. It normalizes to NFC and nothing more, uses Qwen3's split rule with single digits, and reserves the first 32 ids for special tokens. Only `<|endoftext|>`, id 0, occurs in pretraining, at the end of every document. There is no beginning-of-sequence token: the end of one document is the context in which the next one begins. The tokenizer was trained on the first 80,000 documents of the shuffled training stream, which shares no document with the validation set. The alternative we rejected, GPT-2's tokenizer, would have given the reference model an embedding matrix 53% larger, numbers cut by frequency and no better handling of whitespace.

One rule is easy to get wrong: special-token strings inside a document are text. A web page about tokenizers may contain the characters `<|endoftext|>`. If the tokenizer matched them as the special id, the document would end in the middle, and the model would learn that the string ends documents. Released tokenizers differ here; Qwen3's, for instance, matches added tokens such as `<think>` inside ordinary text.

Table 20.3: The reference tokenizer and its shards (normative; the next chapter reads them).

Field	Value
Tokenizer	byte-level BPE, 32,768 pieces, NFC, single digits, no BOS
Special ids	0 end of text (the EOS after every document), 1 padding, 2 and 3 chat-turn delimiters, 4-31 reserved
`.bin`	little-endian ids, `uint16` for at most 65,536 ids, else `uint32`
`.idx`	`uint32` offsets, one per document plus the token count; document i is ids `offsets[i]` to `offsets[i+1]`, its closing EOS included
`.meta.parquet`	`doc_id`, `n_tokens`, then `url`, `dump`, `bucket`, `edu_score`, `int_score`, `gpt2_tokens`, `src_file`, `src_row`
`manifest.json`	`d2l-corpus/1`: sources, stages, tokenizer hash, format, splits

`r2_tokenizer` downloads the committed `tokenizer.json`, checks its SHA-256 against the value recorded in the library, and wraps it for Transformers with EOS id 0, padding id 1, no BOS, and special strings in text encoded as text. The wrapper is a `PreTrainedTokenizerFast`, which Transformers 5 reports as `TokenizersBackend`. The hash check guards against a quiet failure: a checkpoint paired with a different tokenizer file of the same size runs without any error and produces nonsense.

Can the tokenizer be rebuilt from its recorded inputs? The cell checks the wrapper's contract, decodes the first 80,000 documents of the training shard, trains `train_hf_bpe` on them with the reference special tokens, hashes the result, and round-trips text through the tokenizer.

Retraining on 378 million characters reproduces the committed file byte for byte, so the tokenizer is a function of recorded data and code rather than of one lucky run. The sentence that mentions all four special tokens encodes to 46 ordinary tokens, none below id 32, and decodes back unchanged. On the training documents the reference tokenizer needs 1.010 tokens for every token of GPT-2's.

Token files fix how the tokens are stored. `write_shards` turns each document into its ids followed by one EOS and appends documents to a shard until it holds at least `shard_tokens` tokens. It closes a shard only at a document boundary, so no document spans two shards. Each shard is three files: `.bin` with the raw little-endian ids, as `uint16` when every id fits into 16 bits and as `uint32` otherwise; `.idx` with the offset of every document, so that the range from one offset to the next is the document with its closing EOS; and `.meta.parquet` with one row per document for audits. A `manifest.json` records the sources, the processing stages, the tokenizer's hash and the format. `TokenShards` reads them through memory maps. It finds documents by global index and token ranges by global position, across shard boundaries, and its `verify` recomputes every hash and checks that EOS ends every document and occurs nowhere else.

The checks below write 2,000 validation documents and the special-token sentence into a temporary set of small shards, read everything back and test the invariants. They write the same documents with Qwen3's tokenizer, whose ids need 32 bits, the path the next chapter takes for Qwen3, and they verify the registered shards. The resume cursor matters for training: `locate(i)` gives the shard and offset of document i, and iteration started there continues where an interrupted run stopped.

Every invariant holds. The 2,001 documents become 2,029,682 tokens in 5 shards, and the fixture ends in its text and then EOS 151643 under Qwen3. The registered training shard holds 100,000,084 tokens of 95,793 documents and the validation set 8,390,187 tokens, just over 2^{23}, both as `uint16` and both verified.

One check remains, and it is easy to skip. FineWeb-Edu is deduplicated within each crawl dump but not across dumps, so the same page can sit in validation under one dump and in training under another, and a validation loss would then partly measure memorization. The builder's `val_dedup` stage dropped validation documents that repeat a training document's text or URL. What is left can be measured with the exact n-gram matching on token ids of Section 20.3: hash every window of 50 tokens in validation and in the training shard, and confirm each match of hashes on the ids themselves.

Of 14,277 validation candidates, 658 repeated a training document's text and 164 its URL. After their removal, 211 of the 8,341 validation documents (2.5%) still share a span of 50 tokens with the first training shard, covering about a third of a percent of all validation tokens. The shared spans, printed above as FineWeb-Edu text (ODC-By), are boilerplate: a licence notice that appears in four documents, the interface text of a presentation website, the reuse notice of an article-metrics service. That residue is expected and small. It was measured against one training shard of forty, and the whole training set would find more of the same kind.

The chapter's work ends in a manifest. It records what the next chapter reads, with its hash,

its sources and processing stages, and the sizes of the four artifacts.

The source is FineWeb-Edu's sample of 10 billion tokens at a pinned revision: 5.8 million documents, split by bucket into validation and training and shuffled. The forty training shards of 10^8 tokens each hold 4.0 billion tokens, 8 GB of ids, downloaded shard by shard when they are first read. The last cell compares a normal build with the registered results.

These shards are what Section 21.1 streams into the training of the reference model. The tokenizer they were cut with is now frozen, with its strengths on English prose and its costs on Hindi and on code, and the extension experiment showed how slowly a trained model adapts to a new vocabulary. Whether a model should cut its text into tokens before reading it at all is a question this part leaves open.

20.6.6 Summary

A tokenizer is a compressor fitted to its training text: English-centred tokenizers need several times English's tokens for Hindi and Thai, and giving small languages more weight in that text moves pieces to them. The unigram model replaces BPE's merge order by piece probabilities that EM estimates from forward-backward counts, with pruning; it segments by Viterbi and can sample segmentations for subword regularization. Tokenizers are compared in bits per byte, never in perplexity, and at T1 scale unigram against BPE moved a language's bits per byte by a few percent, far less than token counts vary between languages. Compute per byte is lowest where the elasticity of compression equals the vocabulary's share of parameters, which favours larger vocabularies for larger models and for multilingual text. Pieces can be added to a trained model, and a decomposition initialization starts far ahead of random or mean rows, but at T1 scale no extended model reached the unextended one within 150 steps. The reference tokenizer (byte-level BPE, 32,768 pieces, EOS 0, no BOS) is reproducible from its recorded inputs, and its verified shards are what the next chapter trains on.

20.6.7 Exercises

1. **Same bits per byte, different perplexities.** Two models reach the same bits per byte on a text. Model A reports a perplexity of 20 per token and model B one of 40. Using Equation 20.15, which tokenizer covers more bytes per token, and by what factor? Check the relation against the table of the three small models in the subsection Section 20.6.2.1.

2. **Resuming from a cursor.** Using `d2l.fwedu_shards('val')`, pick 100 random document indices i. For each, check that `locate(i)` returns a cursor from which `iter_docs(start=i)` yields document i first, with the same ids as `doc(i)`. Then check, without calling `verify`, that id 0 occurs in the validation shard exactly at the positions `offsets(k)[1:] - 1`. Which property of `write_shards` would each check catch if it broke?

3. **The vocabulary of a larger model.** A model has $A = 7 \times 10^9$ non-embedding parameters, width $d = 4{,}096$ and tied embeddings, and its tokenizer's elasticity of compression is about 0.08 near the optimum.

    1. Use Equation 20.16 to find V^*. How much compute per byte would a vocabulary of 32,000 cost relative to V^*, if ε stays at 0.08 between the two?
    2. Suppose instead that the cost that matters is memory, the number of parameters, and that the embeddings are untied, so the vocabulary contributes $2Vd$. Redo the derivation. How does V^* change?

4. **EM never lowers the likelihood.** Show that a round of Equation 20.14 never decreases $\sum_w c_w \log P(w)$. Write $\log P(w)$ as $\log \sum_{\mathbf{s}} q(\mathbf{s})P(\mathbf{s})/q(\mathbf{s})$ with q the posterior over segmentations under the old probabilities, apply Jensen's inequality, and show that the M-step maximizes the resulting lower bound, which equals the old log-likelihood at the old probabilities. Where does the argument use the fact that every segmentation is a product of piece probabilities?

5. code **The split rule and Hindi.** Change `R2_SPLIT_REGEX` so that a run of letters keeps its combining marks (`[\p{L}\p{M}]+` in place of `\p{L}+`), retrain the byte-level BPE at $\alpha = 0$, and measure the premium of every language on Belebele. How much of the gap between the byte-level BPE's Hindi premium (1.77) and SentencePiece BPE's (1.32) does the split rule explain? Which other languages move, and why?

6. code **Digits and arithmetic.** Count how the numbers of a passage of your own are cut by GPT-2's tokenizer, `o200k_base` and the reference tokenizer: how many distinct segmentations do numbers of the same length receive? Then score 200 additions of two three-digit numbers with `d21.score_choices` on Qwen3-0.6B-Base, choosing between the true sum and three sums that differ from it in one digit, once with the numbers written normally and once with spaces between their digits. Qwen3 cuts digits singly either way: what changes in its input, and does the accuracy change? What would you predict for a model whose tokenizer cuts 12345678 as `123|45|678`?

7. code **How many new pieces?** Repeat the extension with 1,024, 4,096 and 8,192 new Hindi pieces, all with the decomposition initialization and the two-phase recipe. Before running, predict the Hindi bytes per token, the Hindi bits per byte after 150 steps and the English bits per byte for each. Do more pieces always help within this budget? (A GPU with about 16 GB, roughly 15 minutes.)

8. code **One phase or two.** Replace the two-phase recipe by a single phase in which every parameter trains for 150 steps at 10^{-4}, a rate usual for fine-tuning, with the same warmup and cosine decay. Run the control and the decomposition arm and record Hindi and English bits per byte every 10 steps. Before running, predict what happens to the control, which has nothing new to learn. Then compare the gap between the decomposition arm and the control at step 150 under both recipes. Which recipe makes the extension look better, and which comparison would you trust? (A GPU with about 16 GB, roughly 10 minutes.)

9. **Extension by merges.** The extension of Section 20.6.4 appends whole pieces as added tokens, which the tokenizer matches before its own segmentation. Instead, add the Hindi BPE's merges to Qwen3's merge table, so that the extended tokenizer is a BPE in which every new piece is built by merges. What must be true of the new merges' order and of the split rule for this to work? Compare how the two extended tokenizers cut text that mixes Hindi and English, such as a Hindi sentence with an English product name, and say which behaviour you would want.

Chapter 21

Pretraining

The reader has trained the GPT of Section 11.2 for an afternoon on one GPU and read its loss curve. A real pretraining run lasts days, is interrupted and resumed, spikes at hour six, runs its matrix multiplications in eight bits, is continued on new data after it finishes, and is read almost entirely from its logs. This chapter builds the parts of that run that an afternoon never exercises, and trains the reference model that later chapters shard, fine-tune, quantize and serve.

21.1 The Pretraining Data Path

21.2 The Reference Pretraining Run

21.3 Low-Precision Training

21.4 Continued Pretraining and Mid-Training

21.5 Long-Context Training

21.6 Training Budgets beyond the Compute Optimum

Chapter 22

Hardware for Training and Inference

The reader knows one GPU from Section 13.2 and Section 13.1: a roofline, a memory hierarchy, a prefill that is compute-bound and a decode that is not. A released model is trained on thousands of chips and served from racks, and the chips, the kernels that run on them, the links between them and the power they draw decide what a token costs.

22.1 Accelerator Design

22.2 Kernels, Tiles and Fusion

22.3 Training, Prefill and Decode Workloads

22.4 Memory and Storage Tiers

22.5 Data Paths inside a Server

22.6 Scale-Up Domains and Scale-Out Networks

22.7 Collective Communication at Scale

22.8 Energy, Power and Cost

Chapter 23

Parallelism Beyond One Node

The reader ran DDP on four GPUs in Section 13.6 and FSDP once, on two GPUs, in Section 13.7; an 8B model's 128 GB of training state fits no card, so the state is cut up and the pieces must talk, across machines, for weeks, while the hardware fails under them.

23.1 Multi-Node Jobs and Hang Diagnosis

23.2 Sharded Data Parallelism at Scale

23.3 Tensor and Sequence Parallelism

23.4 Pipeline Parallelism

23.5 Context Parallelism

23.6 Expert Parallelism

23.7 Composed Parallelism and Topology

23.8 Profiling and Performance Debugging of Distributed Runs

23.9 Checkpoints at Scale

23.10 Failures, Elasticity and Goodput

Chapter 24

Fine-Tuning

The reader has a pretrained model that continues text and a task it should do instead: follow an instruction, keep to a format, stop when the answer is complete, classify a message. Changing some weights on a few thousand examples is the oldest route, and the questions that remain are which weights may move, in what precision, on which examples, and what the base model forgets while they move.

24.1 Full Fine-Tuning

24.2 Supervised Instruction Tuning

24.3 Instruction Data

24.4 Low-Rank Adaptation

24.5 Quantized Fine-Tuning

24.6 Fine-Tuning at Scale and Toolchains

24.7 Merging and Retaining Capabilities

Chapter 25

Preference Optimization and Reinforcement Learning

The reader derived GRPO and DPO on a toy verifier task in Advanced and saw the KL-regularized optimum in closed form; on a real language model the reward is a second network that can be wrong, sampling takes most of every step, four copies of the model compete for one GPU, and the policy learns whatever the reward left unsaid. This chapter runs the methods the reader already knows on Qwen3-0.6B and measures the symptoms that decide which variant is usable.

25.1 Reward Models

25.2 RLHF with PPO at Language-Model Scale

25.3 Direct Preference Optimization and Its Variants

25.4 RL with Verifiable Rewards

25.5 RL Training Systems

25.6 Reward Overoptimization

25.7 Safety Evaluation and Red-Teaming

25.8 Further Reading

Chapter 26

Distillation and Reasoning

The reader has a 1.7B model that solves the arithmetic family after the reinforcement learning of Chapter 25, and a 0.6B model that does not. This chapter moves the capability into the smaller model, and then shows how to buy accuracy at the moment of answering with tokens instead of parameters.

26.1 Knowledge Distillation

26.2 On-Policy Distillation

26.3 Training Reasoning Models

26.4 Verifiers and Process Supervision

26.5 Parallel Test-Time Compute

26.6 Sequential and Adaptive Test-Time Compute

Chapter 27

Agents and Tool Use

The reader has prompted a model, fine-tuned it and trained it with a verifier; a model that only emits text can be asked a question, while a model that emits actions can be given a job. This chapter turns the models of Chapters 1 to 9 into agents: systems that call a tool, read what comes back, run code and keep going over many turns.

27.1 Tool Calling

27.2 Structured Outputs and Constrained Decoding

27.3 Agent Loops and Harnesses

27.4 Training Agents with Reinforcement Learning

27.5 Evaluating and Securing Agents

Chapter 28

Model Compression

In Section 24.5 the reader stored a frozen model in four bits so that a fine-tuning run would fit, and the model ran no faster. A served model has to be fast, its activations enter the arithmetic, and it is judged on held-out quality at a stated speed. This chapter builds, one mechanism at a time, the methods that compress a trained model for that purpose, and checks each against brute force, an exact identity, or a paired interval.

28.1 Quantization for Inference

28.2 Activation Outliers and Equivalent Rescaling

28.3 Reconstruction-Based Quantization

28.4 Rotations and Incoherence

28.5 Quantization-Aware Training and Native Low-Bit Formats

28.6 Pruning and Sparsity

28.7 Further Reading

Chapter 29

Efficient Inference

The reader has a compressed model from Chapter 28 and, from Section 11.3 and Section 13.2, a bound on how fast one GPU can decode it; the plain generation loop reaches a small fraction of that bound. This chapter takes one request, or a handful, from the eager loop to the bound and then past its per-token form: the kernels that read the weights and the cache at full bandwidth, the reduction orders that make outputs reproducible, the verification trick that checks several tokens per weight read, and the cache compressions that a trained model tolerates. It ends on a laptop, where the same bound holds with a tenth of the bandwidth.

29.1 A Fast Decoder on One GPU

29.2 Decode Attention Kernels

29.3 Deterministic and Batch-Invariant Inference

29.4 Speculative Decoding

29.5 Drafters and Multi-Token Prediction

29.6 KV-Cache Quantization

29.7 KV-Cache Eviction and Selective Reading

29.8 Inference on CPUs and Devices

Chapter 30

Serving Systems

The reader has Section 29.1's decoder, which answers one request near the bandwidth bound. A service never sees one request: it sees an arrival process, a mix of prompt and output lengths, a latency contract, and a hundred users who are each waiting. This chapter builds the mechanisms inside a serving engine, each with an invariant a test can check and a measurement against a reference server, from the contract a service makes to the layouts that spread one model over a node.

30.1 Workloads and Service Objectives

30.2 Continuous Batching and Chunked Prefill

30.3 Paged KV Memory

30.4 Prefix Caching and Shared-Prefix Workloads

30.5 Scheduling under Overload

30.6 KV-Cache Offload, Stores and Prefix-Aware Routing

30.7 Tensor and Expert Parallelism for Serving

30.8 Prefill and Decode Disaggregation

30.9 Serving Many Adapters

Chapter 31

Advanced Architectures

The reader has the transformer of Advanced (RoPE, GQA, RMSNorm, SwiGLU, a mixture of experts, sliding windows and sinks, DeltaNet and hybrid stacks) and a configuration file from Section 18.1 with fields that match none of it: a latent rank, an indexer that keeps 512 of a million keys, a layer type called `linear_attention`, an `hc_mult` of 4, an embedding table with 384 million rows. This chapter teaches those fields, one design axis per section, and for each change asks what it saves, what it costs, and which training and serving setup makes the trade worthwhile.

31.1 Architecture Configurations

31.2 Mixture-of-Experts Design at Scale

31.3 Latent Attention and Cross-Layer KV Sharing

31.4 Softmax Attention Refinements

31.5 Learned Sparse Attention

31.6 Hybrid Models at Scale

31.7 The Residual Stream across Depth

31.8 Further Reading

Image Models

This part is about seeing: applying convolutional and attention-based architectures to real computer-vision problems. It starts with the techniques that make image models train and generalize in practice — data augmentation and fine-tuning from pretrained backbones — and then works through the major vision tasks beyond classification: object detection and bounding-box regression, anchor boxes and multiscale detectors, semantic segmentation, and neural style transfer.

The emphasis throughout is on the practical pipeline: preparing image datasets, transferring learned features, and assembling the specialized heads each task requires, using the CIFAR-10 and ImageNet-style workflows introduced earlier in the book.

Chapter 32

Computer Vision

Whether it is medical diagnosis, self-driving vehicles, camera monitoring, or smart filters, many applications in the field of computer vision are closely related to our current and future lives. In recent years, deep learning has been a transformative force in advancing the performance of computer vision systems. It can be said that the most advanced computer vision applications are almost inseparable from deep learning. In view of this, this chapter will focus on the field of computer vision, and investigate methods and applications that have recently been influential in academia and industry.

In Chapter 6 and Chapter 7, we studied various convolutional neural networks that are commonly used in computer vision, and applied them to simple image classification tasks. At the beginning of this chapter, we will describe two methods that may improve model generalization, namely *image augmentation* and *fine-tuning*, and apply them to image classification. Since deep neural networks can effectively represent images in multiple levels, such layerwise representations have been successfully used in various computer vision tasks such as *object detection*, *semantic segmentation*, and *style transfer*. Following the key idea of leveraging layerwise representations in computer vision, we will begin with major components and techniques for object detection. Next, we will show how to use *fully convolutional networks* for semantic segmentation of images. Then we will explain how to use style transfer techniques to generate images like the cover of this book. In the end, we conclude this chapter by applying the materials of this chapter and several previous chapters on two popular computer vision benchmark datasets.

32.1 Image Augmentation

In Section 7.1, we mentioned that large datasets are a prerequisite for the success of deep neural networks in various applications. *Image augmentation* generates similar but distinct training examples after a series of random changes to the training images, thereby expanding the size of the training set. Alternatively, image augmentation can be motivated by the fact that random tweaks of training examples allow models to rely less on certain attributes, thereby improving their generalization ability. For example, we can crop an image in different ways to make the object of interest appear in different positions, thereby reducing the dependence of a model on the position of the object. We can also adjust factors such as brightness and color to reduce a model's sensitivity to color. It is probably true that image

augmentation was indispensable for the success of AlexNet at that time. In this section we will discuss this widely used technique in computer vision.

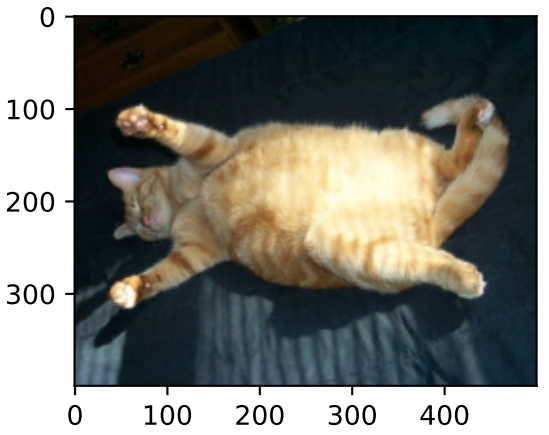
```
# cuDNN's convolution autotuner allocates large transient scratch buffers when
# the input's batch dimension is dynamic -- here the tf.data loader yields a
# variable-size final batch -- spiking the reserved footprint to ~8.6 GiB for
# this ResNet-18 / batch-256 training step. Disabling autotuning falls back to
# cuDNN's default low-memory algorithm (same result), and we cap the workspace
# as a backstop; the true footprint drops to ~4.5 GiB. TensorFlow reads these
# variables when it starts cuDNN, so this cell runs before the imports.
import os
os.environ['TF_CUDNN_USE_AUTOTUNE'] = '0'
os.environ['TF_CUDNN_WORKSPACE_LIMIT_IN_MB'] = '2048'
```

```
import keras
from PIL import Image
```

32.1.1 Common Image Augmentation Methods

In our investigation of common image augmentation methods, we will use the following 400×500 image as an example.

```
d2l.set_figsize()
img = Image.open('../img/cat1.jpg')
d2l.plt.imshow(img);
```



Most image augmentation methods have a certain degree of randomness. To make it easier for us to observe the effect of image augmentation, next we define an auxiliary function `apply`. This function runs the image augmentation method `aug` multiple times on the input image `img` and shows all the results.

```
def apply(img, aug, num_rows=2, num_cols=4, scale=1.5):
    Y = [aug(img) for _ in range(num_rows * num_cols)]
    d2l.show_images(Y, num_rows, num_cols, scale=scale)
```

32.1.1.1 Flipping and Cropping

Flipping the image left and right usually does not change the category of the object. This is one of the earliest and most widely used methods of image augmentation. Next, we define a `RandomHorizontalFlip` function using `tf.image`, which flips an image left and right with a 50% chance. We convert between PIL images and TensorFlow tensors as needed.

```
def RandomHorizontalFlip():
    def aug(img):
        img_tf = tf.constant(np.array(img))
        img_tf = tf.image.random_flip_left_right(img_tf)
        return Image.fromarray(img_tf.numpy())
    return aug

apply(img, RandomHorizontalFlip())
```

Flipping up and down is not as common as flipping left and right. But at least for this example image, flipping up and down does not hinder recognition. Next, we create a `RandomVerticalFlip` function to flip an image up and down with a 50% chance.

```
def RandomVerticalFlip():
    def aug(img):
        img_tf = tf.constant(np.array(img))
        img_tf = tf.image.random_flip_up_down(img_tf)
        return Image.fromarray(img_tf.numpy())
    return aug

apply(img, RandomVerticalFlip())
```

In the example image we used, the cat is in the middle of the image, but this may not be the case in general. In Section 6.5, we explained that the pooling layer can reduce the sensitivity of a convolutional layer to the target position. In addition, we can also randomly crop the image to make objects appear in different positions in the image at different scales, which can also reduce the sensitivity of a model to the target position.

In the code below, we randomly crop an area with an area of $10\% \sim 100\%$ of the original area each time, and the ratio of width to height of this area is randomly selected from $0.5 \sim 2$. Then, the width and height of the region are both scaled to 200 pixels. Unless otherwise specified, the random number between a and b in this section refers to a continuous value obtained by random and uniform sampling from the interval $[a, b]$.

```
def RandomResizedCrop(size, scale=(0.1, 1), ratio=(0.5, 2)):
    target_h, target_w = size
    def aug(img):
        img_tf = tf.constant(np.array(img))
        h, w = tf.shape(img_tf)[0], tf.shape(img_tf)[1]
        area = tf.cast(h * w, tf.float32)
        log_ratio = (tf.math.log(float(ratio[0])), tf.math.log(float(ratio[1])))
        target_area = tf.random.uniform([], scale[0], scale[1]) * area
        aspect = tf.exp(tf.random.uniform([], log_ratio[0], log_ratio[1]))
        crop_h = tf.cast(tf.round(tf.sqrt(target_area / aspect)), tf.int32)
        crop_w = tf.cast(tf.round(tf.sqrt(target_area * aspect)), tf.int32)
        crop_h = tf.minimum(crop_h, h)
        crop_w = tf.minimum(crop_w, w)
        offset_h = tf.random.uniform([], 0, h - crop_h + 1, dtype=tf.int32)
        offset_w = tf.random.uniform([], 0, w - crop_w + 1, dtype=tf.int32)
        img_tf = tf.image.crop_to_bounding_box(img_tf, offset_h, offset_w,
                                               crop_h, crop_w)
        img_tf = tf.cast(img_tf, tf.float32)
        img_tf = tf.image.resize(img_tf, [target_h, target_w])
        img_tf = tf.cast(img_tf, tf.uint8)
        return Image.fromarray(img_tf.numpy())
    return aug

shape_aug = RandomResizedCrop((200, 200), scale=(0.1, 1), ratio=(0.5, 2))
apply(img, shape_aug)
```

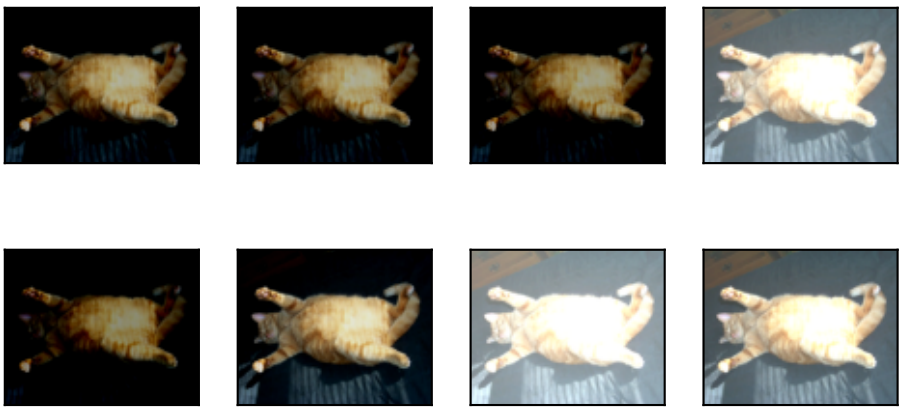
32.1.1.2 Changing Colors

Another augmentation method is changing colors. We can change four aspects of the image color: brightness, contrast, saturation, and hue. In the example below, we randomly change the brightness of the image by up to 0.5.

`tf.image.random_brightness` adds a random offset in $[-0.5, 0.5]$ to pixel values in $[0, 1]$, so the change is additive rather than a scaling.

```
def RandomBrightness(max_delta):
    def aug(img):
        img_tf = tf.cast(tf.constant(np.array(img)), tf.float32) / 255.0
        img_tf = tf.image.random_brightness(img_tf, max_delta)
        img_tf = tf.clip_by_value(img_tf, 0.0, 1.0)
        return Image.fromarray((img_tf.numpy() * 255).astype(np.uint8))
    return aug

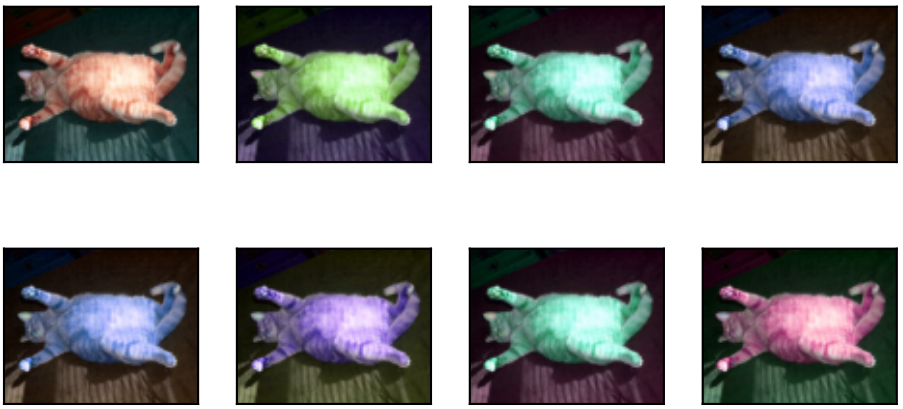
apply(img, RandomBrightness(0.5))
```



Similarly, we can randomly change the hue of the image.

```
def RandomHue(max_delta):
    def aug(img):
        img_tf = tf.cast(tf.constant(np.array(img)), tf.float32) / 255.0
        img_tf = tf.image.random_hue(img_tf, max_delta)
        img_tf = tf.clip_by_value(img_tf, 0.0, 1.0)
        return Image.fromarray((img_tf.numpy() * 255).astype(np.uint8))
    return aug

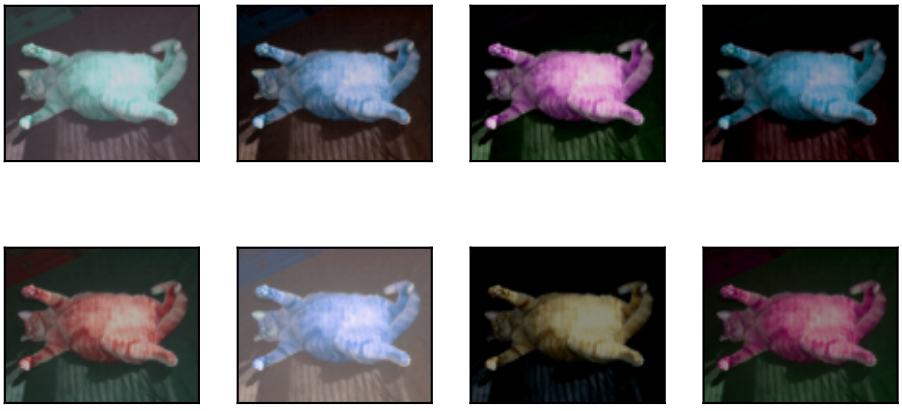
apply(img, RandomHue(0.5))
```



We can also create a color-jitter transform and set how to randomly change the `brightness`, `contrast`, `saturation`, and `hue` of the image at the same time.

```
def RandomColorJitter(brightness=0, contrast=0, saturation=0, hue=0):
    def aug(img):
        img_tf = tf.cast(tf.constant(np.array(img)), tf.float32) / 255.0
        if brightness > 0:
            img_tf = tf.image.random_brightness(img_tf, brightness)
        if contrast > 0:
            img_tf = tf.image.random_contrast(img_tf, 1 - contrast,
                                              1 + contrast)
        if saturation > 0:
            img_tf = tf.image.random_saturation(img_tf, 1 - saturation,
                                                1 + saturation)
        if hue > 0:
            img_tf = tf.image.random_hue(img_tf, hue)
        img_tf = tf.clip_by_value(img_tf, 0.0, 1.0)
        return Image.fromarray((img_tf.numpy() * 255).astype(np.uint8))
    return aug

color_aug = RandomColorJitter(brightness=0.5, contrast=0.5, saturation=0.5,
                              hue=0.5)
apply(img, color_aug)
```

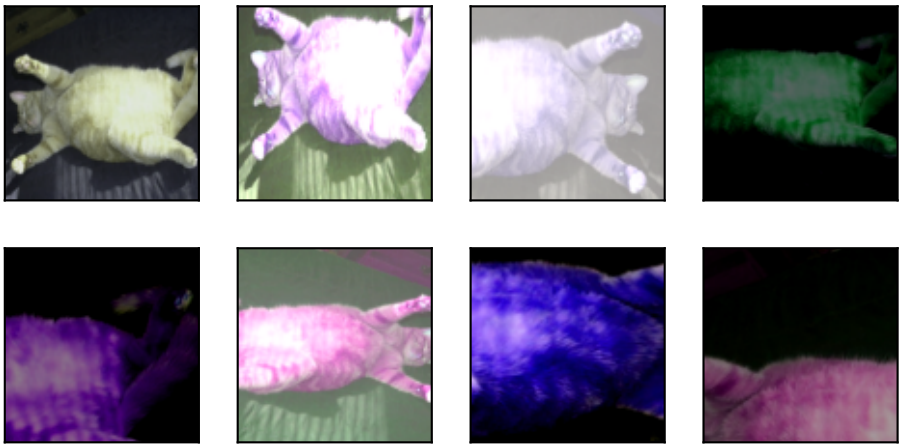


32.1.1.3 Combining Multiple Image Augmentation Methods

In practice, we will combine multiple image augmentation methods. For example, we can combine the different image augmentation methods defined above and apply them to each image via a `Compose` instance.

```
def Compose(transforms):
    def aug(img):
        for t in transforms:
            img = t(img)
        return img
    return aug

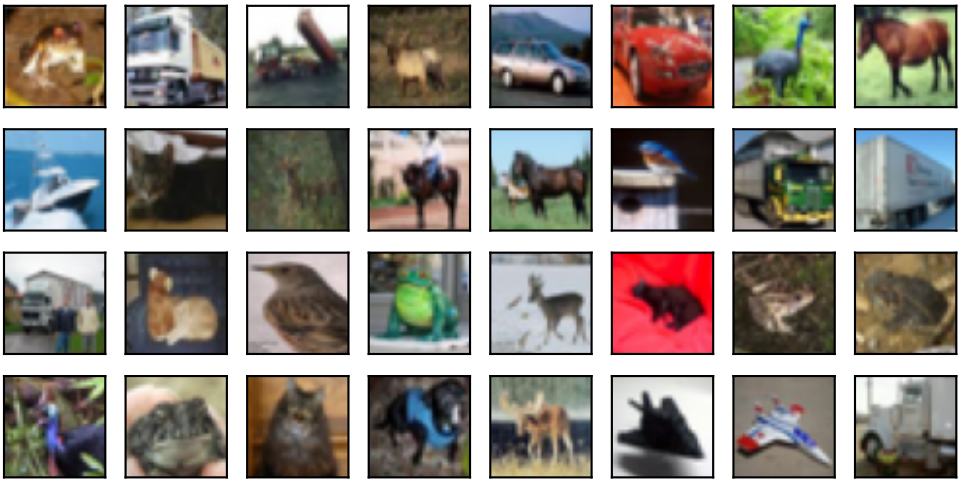
augs = Compose([RandomHorizontalFlip(), color_aug, shape_aug])
apply(img, augs)
```



32.1.2 Training with Image Augmentation

Let's train a model with image augmentation. Here we use the CIFAR-10 dataset instead of the Fashion-MNIST dataset that we used before. This is because the position and size of the objects in the Fashion-MNIST dataset have been normalized, while the color and size of the objects in the CIFAR-10 dataset have more significant differences. The first 32 training images in the CIFAR-10 dataset are shown below.

```
(train_images, train_labels), _ = keras.datasets.cifar10.load_data()
d2l.show_images([Image.fromarray(train_images[i]) for i in range(32)],
                4, 8, scale=0.8);
```



In order to obtain definitive results during prediction, we usually only apply image augmentation to training examples, and do not use image augmentation with random operations during prediction. Here we only use the simplest random left-right flipping method. In addition, we convert a minibatch of images into the format required by the deep learning framework, i.e., 32-bit floating point numbers between 0 and 1.

We cast the images to 32-bit floats and divide by 255; they keep the channels-last shape (batch size, height, width, number of channels).

```
def train_augs(image, label):
    image = tf.cast(image, tf.float32) / 255.0
    image = tf.image.random_flip_left_right(image)
    return image, label

def test_augs(image, label):
    image = tf.cast(image, tf.float32) / 255.0
    return image, label
```

Next, we define an auxiliary function to facilitate reading the image and applying image augmentation. We use `keras.datasets` to load CIFAR-10 and `tf.data.Dataset` for batching and preprocessing. For a detailed introduction to data loading, please refer to Section 3.2.

```
def load_cifar10(is_train, aug_fn, batch_size):
    (train_imgs, train_lbls), (test_imgs, test_lbls) = (
        keras.datasets.cifar10.load_data())
    if is_train:
        images, labels = train_imgs, train_lbls.squeeze()
    else:
        images, labels = test_imgs, test_lbls.squeeze()
    ds = tf.data.Dataset.from_tensor_slices((images, labels))
    if is_train:
        ds = ds.shuffle(10000)
    ds = ds.map(aug_fn, num_parallel_calls=tf.data.AUTOTUNE)
    ds = ds.batch(batch_size).prefetch(tf.data.AUTOTUNE)
    return ds
```

32.1.2.1 Training on the Available Devices

We train the ResNet-18 model from Section 7.4 on the CIFAR-10 dataset. Recall the introduction to multi-GPU training in Section 13.6. In the following, we define a function to train and evaluate the model on the available devices.

Training runs on a single device.

```
def train_batch_ch13(net, X, y, loss, optimizer):
    """Train for a minibatch with Keras (defined in Chapter 13)."""
    with tf.GradientTape() as tape:
        pred = net(X, training=True)
        l = loss(y, pred)
    grads = tape.gradient(l, net.trainable_variables)
    optimizer.apply_gradients(zip(grads, net.trainable_variables))
    train_loss_sum = tf.reduce_sum(l)
    train_acc_sum = tf.reduce_sum(
        tf.cast(tf.argmax(pred, axis=1) == tf.cast(y, tf.int64), tf.float32))
    return train_loss_sum, train_acc_sum
```

```
def train_ch13(net, train_iter, test_iter, loss, optimizer, num_epochs):
    """Train a model with Keras (defined in Chapter 13)."""
    num_batches = sum(1 for _ in train_iter)
    animator = d2l.Animator(xlabel='epoch', xlim=[1, num_epochs], ylim=[0, 1],
                            legend=['train loss', 'train acc', 'test acc'])
    timer = d2l.Timer()
    for epoch in range(num_epochs):
        # Sum of training loss, sum of training accuracy, no. of examples,
        # no. of examples
        metric = d2l.Accumulator(4)
        for i, (features, labels) in enumerate(train_iter):
            timer.start()
            l, acc = train_batch_ch13(net, features, labels, loss, optimizer)
            n = features.shape[0]
            metric.add(float(l), float(acc), n, n)
            timer.stop()
            if (i + 1) % (num_batches // 5) == 0 or i == num_batches - 1:
```

```
                animator.add(epoch + (i + 1) / num_batches,
                             (metric[0] / metric[2], metric[1] / metric[3],
                              None))
        # Evaluate on test set
        correct, total = 0, 0
        for X, y in test_iter:
            logits = net(X, training=False)
            correct += int(tf.reduce_sum(tf.cast(
                tf.argmax(logits, axis=1) == tf.cast(y, tf.int64),
                tf.float32)))
            total += y.shape[0]
        test_acc = correct / total
        animator.add(epoch + 1, (None, None, test_acc))
    print(f'loss {metric[0] / metric[2]:.3f}, train acc '
          f'{metric[1] / metric[3]:.3f}, test acc {test_acc:.3f}')
    print(f'{metric[2] * num_epochs / timer.sum():.1f} examples/sec')
```

Now we can define the `train_with_data_aug` function to train the model with image augmentation. This function uses Adam as the optimization algorithm, applies image augmentation to the training dataset, and finally calls the `train_ch13` function just defined to train and evaluate the model.

```
batch_size = 256

def get_net_tf():
    return d2l.resnet18(10, 3)

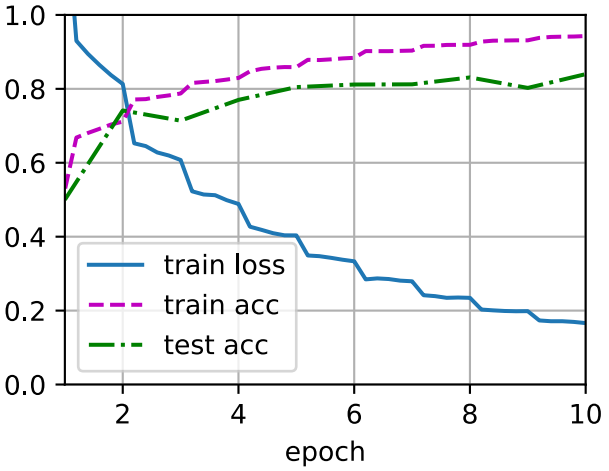
def train_with_data_aug(train_aug_fn, test_aug_fn, net, lr=0.001):
    train_iter = load_cifar10(True, train_aug_fn, batch_size)
    test_iter = load_cifar10(False, test_aug_fn, batch_size)
    loss = keras.losses.SparseCategoricalCrossentropy(
        from_logits=True, reduction='none')
    optimizer = keras.optimizers.Adam(learning_rate=lr)
    train_ch13(net, train_iter, test_iter, loss, optimizer, 10)

net = get_net_tf()
```

Let's train the model using image augmentation based on random left-right flipping.

```
train_with_data_aug(train_augs, test_augs, net)
```

```
loss 0.166, train acc 0.943, test acc 0.840
673.5 examples/sec
```



32.1.3 Summary

- Image augmentation generates random images based on existing training data to improve the generalization ability of models.
- In order to obtain definitive results during prediction, we usually only apply image augmentation to training examples, and do not use image augmentation with random operations during prediction.
- Deep learning frameworks provide many different image augmentation methods, which can be applied simultaneously.

32.1.4 Exercises

1. Train the model without using image augmentation: `train_with_data_aug(test_augs, test_augs, net)`. Compare training and testing accuracy when using and not using image augmentation. Can this comparative experiment support the argument that image augmentation can mitigate overfitting? Why?
2. Combine multiple different image augmentation methods in model training on the CIFAR-10 dataset. Does it improve test accuracy?
3. Refer to the online documentation of the deep learning framework. What other image augmentation methods does it also provide?
4. Augmentation changes the objective that training minimizes. Consider a linear model $f(\mathbf{x}) = \mathbf{w}^\top \mathbf{x} + b$ trained on augmented inputs.
   1. For additive noise $\mathbf{x}' = \mathbf{x} + \epsilon$ with $\epsilon \sim \mathcal{N}(\mathbf{0}, \sigma^2 \mathbf{I})$ and squared loss, show that $\mathbb{E}_\epsilon[(f(\mathbf{x}') - y)^2] = (f(\mathbf{x}) - y)^2 + \sigma^2 \|\mathbf{w}\|^2$. Training with noise is therefore weight decay (Section 2.7) with coefficient σ^2 (Bishop 1995).
   2. Let $\mathbf{P}$ be the permutation matrix that flips an image left to right, and let $L(\mathbf{w})$, the loss averaged over every training image and its mirror image, be convex in $\mathbf{w}$. Show that if $\mathbf{w}^*$ minimizes L, then so do $\mathbf{P}\mathbf{w}^*$ and $(\mathbf{w}^* + \mathbf{P}\mathbf{w}^*)/2$. What does the last minimizer predict for an image and its mirror image?
5. Augmentation teaches a network only the invariances that it is shown. Use the network trained above with random left-right flips and the network trained without augmentation in problem 1.
   1. Evaluate both networks on the CIFAR-10 test set with every image flipped left to

right, with every image flipped upside down, with random brightness changes (`brightness=0.5`), and with random hue changes (`hue=0.5`). Report a table of the five test accuracies of each network, including the unmodified test set. Which accuracy drops does flip augmentation reduce, and which does it leave unchanged?
2. For the network trained with flips, average the softmax outputs on each test image and on its mirror image (*test-time augmentation*) and report the test accuracy. Explain why this classifier is invariant to left-right flips by construction.

32.2 Fine-Tuning

In earlier chapters, we discussed how to train models on the Fashion-MNIST training dataset with only 60000 images. We also described ImageNet, the most widely used large-scale image dataset in academia, which has more than 10 million images and 1000 objects. However, the size of the dataset that we usually encounter is between those of the two datasets.

Suppose that we want to recognize different types of chairs from images, and then recommend purchase links to users. One possible method is to first identify 100 common chairs, take 1000 images of different angles for each chair, and then train a classification model on the collected image dataset. Although this chair dataset may be larger than the Fashion-MNIST dataset, the number of examples is still less than one-tenth of that in ImageNet. This may lead to overfitting of complicated models that are suitable for ImageNet on this chair dataset. Besides, due to the limited amount of training examples, the accuracy of the trained model may not meet practical requirements.

In order to address the above problems, an obvious solution is to collect more data. However, collecting and labeling data can take a lot of time and money. For example, in order to collect the ImageNet dataset, researchers have spent millions of dollars from research funding. Although the current data collection cost has been significantly reduced, this cost still cannot be ignored.

Another solution is to apply *transfer learning* to transfer the knowledge learned from the *source dataset* to the *target dataset*. For example, although most of the images in the ImageNet dataset have nothing to do with chairs, the model trained on this dataset may extract more general image features, which can help identify edges, textures, shapes, and object composition. These similar features may also be effective for recognizing chairs.

32.2.1 Steps

In this section, we will introduce a common technique in transfer learning: *fine-tuning*. As shown in Figure 32.1, fine-tuning consists of the following four steps:

1. Pretrain a neural network model, i.e., the *source model*, on a source dataset (e.g., the ImageNet dataset).
2. Create a new neural network model, i.e., the *target model*. This copies all model designs and their parameters on the source model except the output layer. We assume that these model parameters contain the knowledge learned from the source dataset and this knowledge will also be applicable to the target dataset. We also assume that the output layer of the source model is closely related to the labels of the source dataset; thus it is not used in the target model.

3. Add an output layer to the target model, whose number of outputs is the number of categories in the target dataset. Then randomly initialize the model parameters of this layer.
4. Train the target model on the target dataset, such as a chair dataset. The output layer will be trained from scratch, while the parameters of all the other layers are fine-tuned based on the parameters of the source model.

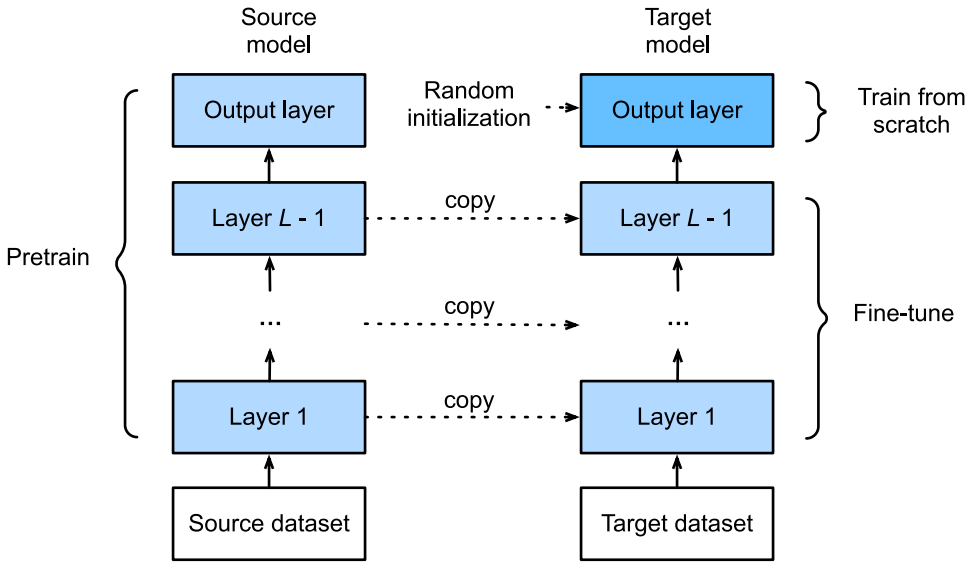


Figure 32.1: Fine tuning.

When target datasets are much smaller than source datasets, fine-tuning helps to improve models' generalization ability.

32.2.2 Hot Dog Recognition

Let's demonstrate fine-tuning via a concrete case: hot dog recognition. We will fine-tune a ResNet model on a small dataset, which was pretrained on the ImageNet dataset. This small dataset consists of thousands of images with and without hot dogs. We will use the fine-tuned model to recognize hot dogs from images.

```
import keras
import os
```

32.2.2.1 Reading the Dataset

The hot dog dataset we use was taken from online images. This dataset consists of 1400 positive-class images containing hot dogs, and as many negative-class images containing other foods. 1000 images of both classes are used for training and the rest are for testing.

After unzipping the downloaded dataset, we obtain two folders `hotdog/train` and `hotdog/test`. Both folders have `hotdog` and `not-hotdog` subfolders, either of which contains images of the corresponding class.

```
d2l.DATA_HUB['hotdog'] = (d2l.DATA_URL + 'hotdog.zip',
                          'fba480ffa8aa7e0febbb511d181409f899b9baa5')

data_dir = d2l.download_extract('hotdog')
```

We create two instances to read all the image files in the training and testing datasets, respectively.

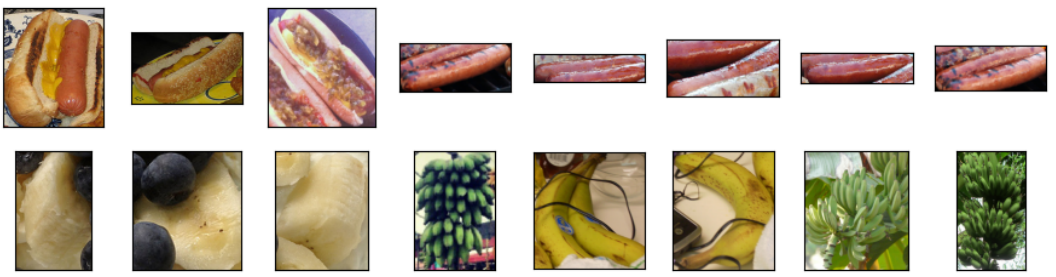
```
from PIL import Image as _PILImage
import pathlib

def _load_image_folder(path):
    """Load images from a directory with class subfolders, returning
    a list of (PIL.Image, class_index) tuples."""
    path = pathlib.Path(path)
    class_names = sorted([p.name for p in path.iterdir() if p.is_dir()])
    class_to_idx = {c: i for i, c in enumerate(class_names)}
    items = []
    for cls in class_names:
        for img_path in sorted((path / cls).iterdir()):
            try:
                img = _PILImage.open(str(img_path)).convert('RGB')
                items.append((img, class_to_idx[cls]))
            except Exception:
                continue
    return items

train_imgs = _load_image_folder(os.path.join(data_dir, 'train'))
test_imgs = _load_image_folder(os.path.join(data_dir, 'test'))
```

The first 8 positive examples and the last 8 negative images are shown below. As you can see, the images vary in size and aspect ratio.

```
hotdogs = [train_imgs[i][0] for i in range(8)]
not_hotdogs = [train_imgs[-i - 1][0] for i in range(8)]
d2l.show_images(hotdogs + not_hotdogs, 2, 8, scale=1.4);
```



During training, we first crop a random area of random size and random aspect ratio from the image, and then scale this area to a 224×224 input image. During testing, we scale both the height and width of an image to 256 pixels, and then crop a central 224×224 area as input. In addition, for the three RGB (red, green, and blue) color channels we *standardize*

their values channel by channel. Concretely, the mean value of a channel is subtracted from each value of that channel and then the result is divided by the standard deviation of that channel.

Images are resized to 256×256 pixels when they are loaded, so the training crop is a random 224×224 window of fixed size and aspect ratio, taken without rescaling. Instead of standardizing, we apply Keras's `resnet50.preprocess_input`, which converts RGB to BGR and subtracts the ImageNet channel means without dividing by the standard deviations, the convention the pretrained Keras weights expect.

```
# Plain tf.image / tf.data preprocessing for Keras ResNet50 (NHWC). Keras
# ResNet50 expects its own `preprocess_input` convention, not an RGB
# mean/std normalization.
IMG_SIZE = 224

def _normalize(x):
    return tf.keras.applications.resnet50.preprocess_input(
        tf.cast(x, tf.float32))

def train_augs(x, training=False):
    # Input is (256, 256, 3) — already resized by image_dataset_from_directory.
    x = tf.image.random_crop(x, (IMG_SIZE, IMG_SIZE, 3))
    x = tf.image.random_flip_left_right(x)
    return _normalize(x)

def test_augs(x, training=False):
    # Input is (256, 256, 3) — already resized by image_dataset_from_directory.
    # Center crop to IMG_SIZE x IMG_SIZE.
    off = (256 - IMG_SIZE) // 2
    x = x[off:off + IMG_SIZE, off:off + IMG_SIZE, :]
    return _normalize(x)
```

32.2.2.2 Defining and Initializing the Model

We use ResNet-50, which was pretrained on the ImageNet dataset, as the source model. (Keras 3's `keras.applications` does not ship a pretrained ResNet-18, so we use ResNet-50 here.) Here, we specify `weights='imagenet'` to automatically download the pretrained model parameters. If this model is used for the first time, Internet connection is required for download.

```
# Load pretrained ResNet50 (full model with top) to inspect the output layer
pretrained_net = keras.applications.ResNet50(weights='imagenet')
```

The pretrained ResNet50 from `keras.applications` contains a number of feature layers and an output layer. We will reuse the pretrained weights for transfer learning. The final layer of the source model is shown below.

```
pretrained_net.layers[-1]
```

```
<Dense name=predictions, built=True>
```

As a fully connected layer, it transforms ResNet's final global average pooling outputs into 1000 class outputs of the ImageNet dataset. We then construct a new neural network as the target model. It is defined in the same way as the pretrained source model except that its number of outputs in the final layer is set to the number of classes in the target dataset (rather than 1000).

In the code below, the model parameters before the output layer of the target model instance `finetune_net` are initialized to model parameters of the corresponding layers from the source model. Since these model parameters were obtained via pretraining on ImageNet, they are effective. Therefore, we can only use a small learning rate to *fine-tune* such pretrained parameters. In contrast, model parameters in the output layer are randomly initialized and generally require a larger learning rate to be learned from scratch. Letting the base learning rate be η, a learning rate of 10η will be used to iterate the model parameters in the output layer.

```
# Pretrained ResNet50 base (no top) + global average pool + fresh 2-class head
finetune_net = keras.Sequential([
    keras.applications.ResNet50(weights='imagenet', include_top=False,
                                pooling='avg',
                                input_shape=(IMG_SIZE, IMG_SIZE, 3)),
    keras.layers.Dense(2, kernel_initializer='glorot_uniform',
                       name='classifier'),
])
```

32.2.2.3 Fine-Tuning the Model

First, we define a training function `train_fine_tuning` that uses fine-tuning so it can be called multiple times.

```
def _make_tf_dataset(img_dir, augs, batch_size, shuffle=False):
    """Create a tf.data.Dataset from an image folder using Keras pipelines."""
    ds = keras.utils.image_dataset_from_directory(
        img_dir, label_mode='int', image_size=(256, 256),
        batch_size=None, shuffle=shuffle)
    ds = ds.map(lambda x, y: (augs(x, training=True), y),
                num_parallel_calls=tf.data.AUTOTUNE)
    ds = ds.batch(batch_size).prefetch(tf.data.AUTOTUNE)
    return ds

def _checkpointed_backbone(base):
    """Run the ResNet50 convolutional backbone with per-residual-block
    activation checkpointing. A plain `tf.GradientTape` over ResNet-50 at batch
    size 128 keeps every layer's activations live for the backward pass (~22 GB
    of GPU memory). Splitting the backbone into its 16 residual blocks and
    wrapping each in `tf.recompute_grad` recomputes a block's activations during
    backprop instead of storing them, dropping the peak to a few GB. The
    gradients are unchanged -- activations are simply traded for a little extra
    compute. Returns a callable `fn(x, training) -> 2048-d pooled features`."""
    boundaries = ['pool1_pool'] + [l.name for l in base.layers
                                   if l.name.endswith('_out')]
    segments = [keras.Model(base.input, base.get_layer(boundaries[0]).output)]
```

```
    for a, b in zip(boundaries[:-1], boundaries[1:]):
        segments.append(keras.Model(base.get_layer(a).output,
                                    base.get_layer(b).output))
    pool = keras.layers.GlobalAveragePooling2D()
    def forward(x, training=False):
        h = x
        for seg in segments:
            h = tf.recompute_grad(
                lambda t, seg=seg: seg(t, training=training))(h)
        return pool(h)
    return forward

# If `param_group=True`, the head (classifier Dense) learns ten times
# faster than the backbone. `momentum` is forwarded to both SGD optimizers; the
# from-scratch baseline uses momentum=0.9 because plain SGD cannot train a
# randomly-initialised ResNet-50 on 2 000 images in five epochs.
def train_fine_tuning(net, learning_rate, batch_size=128, num_epochs=5,
                      param_group=True, momentum=0.0):
    train_ds = _make_tf_dataset(os.path.join(data_dir, 'train'),
                                train_augs, batch_size, shuffle=True)
    test_ds  = _make_tf_dataset(os.path.join(data_dir, 'test'),
                                test_augs, batch_size, shuffle=False)
    # Backbone always trainable; discriminative LR (head at 10x) applied
    # by routing gradients to two separate optimizers below.
    net.layers[0].trainable = True
    # Running averages of the batch statistics decay 0.9 per step (the
    # Keras default is 0.99). tf.recompute_grad runs the forward pass twice
    # per step, so the averages update twice: 0.9 ** 0.5 per update
    for layer in net.layers[0].layers:
        if isinstance(layer, keras.layers.BatchNormalization):
            layer.momentum = 0.9 ** 0.5
    head_layer = net.layers[-1]
    head_vars = head_layer.trainable_variables
    head_var_ids = {id(v) for v in head_vars}
    # Activation-checkpointed backbone (see `_checkpointed_backbone`); the
    # classifier head is applied to its pooled features. Training still runs
    # over `net.trainable_variables`, so the discriminative-LR split is intact.
    backbone = _checkpointed_backbone(net.layers[0])

    opt_head = keras.optimizers.SGD(
        learning_rate=learning_rate * (10 if param_group else 1),
        momentum=momentum, weight_decay=0.001)
    opt_base = keras.optimizers.SGD(
        learning_rate=learning_rate,
        momentum=momentum, weight_decay=0.001)
    loss_fn = keras.losses.SparseCategoricalCrossentropy(from_logits=True)
    acc_metric = keras.metrics.SparseCategoricalAccuracy()
    val_acc_metric = keras.metrics.SparseCategoricalAccuracy()

    @tf.function
    def train_step(x, y):
        with tf.GradientTape() as tape:
            logits = head_layer(backbone(x, training=True))
```

```
            loss = loss_fn(y, logits)
        grads = tape.gradient(loss, net.trainable_variables)
        head_pairs, base_pairs = [], []
        for g, v in zip(grads, net.trainable_variables):
            if g is None:
                continue
            (head_pairs if id(v) in head_var_ids
             else base_pairs).append((g, v))
        if head_pairs:
            opt_head.apply_gradients(head_pairs)
        if base_pairs:
            opt_base.apply_gradients(base_pairs)
        acc_metric.update_state(y, logits)
        return loss

    @tf.function
    def test_step(x, y):
        logits = net(x, training=False)
        val_acc_metric.update_state(y, logits)

    for epoch in range(num_epochs):
        acc_metric.reset_state()
        val_acc_metric.reset_state()
        total_loss, n_train = 0.0, 0
        for x, y in train_ds:  # Weight each minibatch by its size
            total_loss += float(train_step(x, y)) * len(y); n_train += len(y)
        for x, y in test_ds:
            test_step(x, y)
        print(f'epoch {epoch + 1}, loss {total_loss / max(n_train, 1):.3f}, '
              f'train acc {float(acc_metric.result()):.3f}, '
              f'test acc {float(val_acc_metric.result()):.3f}')
```

We set the base learning rate to a small value in order to *fine-tune* the model parameters obtained via pretraining. Based on the previous settings, we will train the output layer parameters of the target model from scratch using a learning rate ten times greater.

```
train_fine_tuning(finetune_net, 5e-5, momentum=0.9)
```

```
Found 2000 files belonging to 2 classes.
Found 800 files belonging to 2 classes.
epoch 1, loss 0.653, train acc 0.651, test acc 0.756
epoch 2, loss 0.400, train acc 0.825, test acc 0.854
epoch 3, loss 0.288, train acc 0.882, test acc 0.877
epoch 4, loss 0.240, train acc 0.909, test acc 0.896
epoch 5, loss 0.216, train acc 0.924, test acc 0.904
```

For comparison, we define an identical model, but initialize all of its model parameters to random values. Since the entire model needs to be trained from scratch, we can use a larger learning rate.

```
# Train from scratch: same architecture but with random (no-pretrain) weights.
scratch_base = keras.applications.ResNet50(
    weights=None, include_top=False, pooling='avg',
    input_shape=(IMG_SIZE, IMG_SIZE, 3))
scratch_net = keras.Sequential([
    scratch_base,
    keras.layers.Dense(2, kernel_initializer='glorot_uniform',
                       name='classifier'),
])
# Plain SGD (momentum=0) cannot train a randomly-initialised ResNet-50 on
# 2 000 images in five epochs, so we use SGD with momentum=0.9 and a single
# uniform learning rate (no head/backbone split) for the from-scratch run.
train_fine_tuning(scratch_net, 1e-3, param_group=False, momentum=0.9)
```

```

As we can see, the fine-tuned model reaches high accuracy in fewer epochs because its initial parameter values already encode useful visual features.

32.2.3 Summary

- Transfer learning transfers knowledge learned from the source dataset to the target dataset. Fine-tuning is a common technique for transfer learning.
- The target model copies all model designs with their parameters from the source model except the output layer, and fine-tunes these parameters based on the target dataset. In contrast, the output layer of the target model needs to be trained from scratch.
- Generally, fine-tuning parameters uses a smaller learning rate, while training the output layer from scratch can use a larger learning rate.

32.2.4 Exercises

1. Keep increasing the learning rate of `finetune_net`. How does the accuracy of the model change?
2. Further adjust hyperparameters of `finetune_net` and `scratch_net` in the comparative experiment. Do they still differ in accuracy?
3. Set the parameters before the output layer of `finetune_net` to those of the source model and do *not* update them during training. How does the accuracy of the model change? You can use the following code.

```
# Freeze the ResNet50 backbone (layer 0 of the Sequential); only head trains.
finetune_net.layers[0].trainable = False
```

4. In fact, there is a "hotdog" class in the `ImageNet` dataset. Its corresponding weight parameter in the output layer can be obtained via the following code. How can we lever-

age this weight parameter?

```
weight = pretrained_net.layers[-1].get_weights()[0]  # Shape: (2048, 1000)
hotdog_w = weight[:, 934]
hotdog_w.shape
```

```
(2048,)
```

5. `train_augs` crops a random 224×224 window from the image resized to 256×256 pixels, while `test_augs` keeps the central 224×224 pixels of the same resized image. A common alternative, `RandomResizedCrop(224)` in torchvision, draws the crop area as a fraction s of the image area uniformly from $[0.08, 1]$ and resizes the crop to 224×224 pixels. Ignore the random aspect ratio of the crop and let the image be a square of side L.
   1. Show that with `RandomResizedCrop(224)` an object of side ℓ in the original image appears with side $224\ell/(\sqrt{s}L)$ during training and with side $256\ell/L$ during testing.
   2. Compute the expected ratio of the training-time to the test-time object size, $\mathbb{E}_s[224/(256\sqrt{s})]$. Do objects look larger or smaller to the network during training, and by what factor?
   3. To what side R would you resize the test images to remove this mismatch on average? Explain why ResNet accepts the larger input without any change to the network.
   4. Does the crop of this section have the same mismatch? What does it give up in exchange?
6. Fine-tuning should help most when the target dataset is small. Train a fresh copy of `finetune_net` and of `scratch_net` on class-balanced random subsets of 100, 250, 500, and 1000 training images per class, with the test set unchanged. For the smaller subsets, increase `num_epochs` so that every run makes about as many minibatch updates as the run on the full training set. Plot the test accuracy of both models against the number of training images on a logarithmic axis. How many images per class does `scratch_net` need to reach the accuracy that `finetune_net` reaches with 100 images per class, if it reaches it at all in this range?

32.3 Object Detection and Bounding Boxes

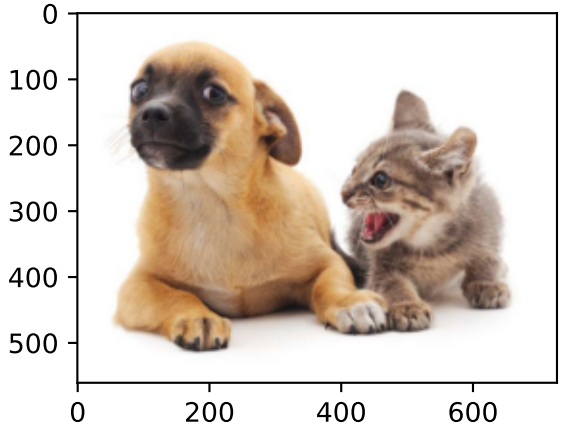
In earlier sections (e.g., Section 7.1 to Section 7.2.3), we introduced various models for image classification. In image classification tasks, we assume that there is only *one* major object in the image and we only focus on how to recognize its category. However, there are often *multiple* objects in the image of interest. We not only want to know their categories, but also their specific positions in the image. In computer vision, we refer to such tasks as *object detection* (or *object recognition*).

Object detection has been widely applied in many fields. For example, self-driving needs to plan traveling routes by detecting the positions of vehicles, pedestrians, roads, and obstacles in the captured video images. Besides, robots may use this technique to detect and localize objects of interest throughout its navigation of an environment. Moreover, security systems may need to detect abnormal objects, such as intruders or bombs.

In the next few sections, we will introduce several deep learning methods for object detection. We will begin with an introduction to *positions* (or *locations*) of objects.

We will load the sample image to be used in this section. We can see that there is a dog on the left side of the image and a cat on the right. They are the two major objects in this image.

```
d2l.set_figsize()
img = d2l.plt.imread('../img/catdog.jpg')
d2l.plt.imshow(img);
```



32.3.1 Bounding Boxes

In object detection, we usually use a *bounding box* to describe the spatial location of an object. The bounding box is rectangular, which is determined by the x and y coordinates of the upper-left corner of the rectangle and the such coordinates of the lower-right corner. Another commonly used bounding box representation is the (x, y)-axis coordinates of the bounding box center, and the width and height of the box.

Here we define functions to convert between these two representations: `box_corner_to_center` converts from the two-corner representation to the center-width-height representation, and `box_center_to_corner` vice versa. The input argument `boxes` should be a two-dimensional tensor of shape $(n, 4)$, where n is the number of bounding boxes.

```
def box_corner_to_center(boxes):
    """Convert from (upper-left, lower-right) to (center, width, height)."""
    x1, y1, x2, y2 = boxes[:, 0], boxes[:, 1], boxes[:, 2], boxes[:, 3]
    cx = (x1 + x2) / 2
    cy = (y1 + y2) / 2
    w = x2 - x1
    h = y2 - y1
    boxes = d2l.stack((cx, cy, w, h), axis=-1)
    return boxes

def box_center_to_corner(boxes):
    """Convert from (center, width, height) to (upper-left, lower-right)."""
    cx, cy, w, h = boxes[:, 0], boxes[:, 1], boxes[:, 2], boxes[:, 3]
```

```
    x1 = cx - 0.5 * w
    y1 = cy - 0.5 * h
    x2 = cx + 0.5 * w
    y2 = cy + 0.5 * h
    boxes = d2l.stack((x1, y1, x2, y2), axis=-1)
    return boxes
```

We will define the bounding boxes of the dog and the cat in the image based on the coordinate information. The origin of the coordinates in the image is the upper-left corner of the image, and to the right and down are the positive directions of the x and y axes, respectively.

```
# Here `bbox` is the abbreviation for bounding box
dog_bbox, cat_bbox = [60.0, 45.0, 378.0, 516.0], [400.0, 112.0, 655.0, 493.0]
```

We can verify the correctness of the two bounding box conversion functions by converting twice.

```
boxes = d2l.tensor((dog_bbox, cat_bbox))
box_center_to_corner(box_corner_to_center(boxes)) == boxes
```

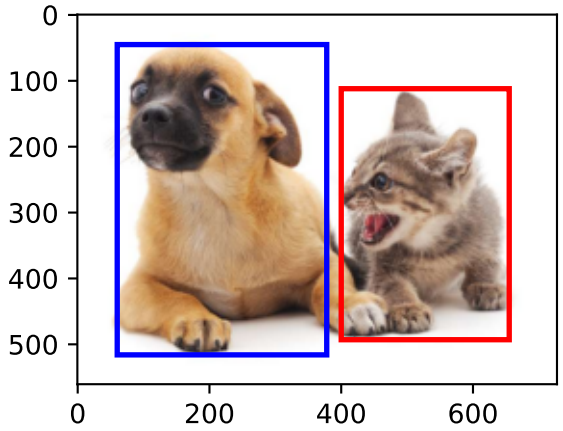
```
<tf.Tensor: shape=(2, 4), dtype=bool, numpy=
array([[ True,  True,  True,  True],
       [ True,  True,  True,  True]])>
```

Let's draw the bounding boxes in the image to check if they are accurate. Before drawing, we will define a helper function `bbox_to_rect`. It represents the bounding box in the bounding box format of the `matplotlib` package.

```
def bbox_to_rect(bbox, color):
    """Convert bounding box to matplotlib format."""
    # Convert the bounding box (upper-left x, upper-left y, lower-right x,
    # lower-right y) format to the matplotlib format: ((upper-left x,
    # upper-left y), width, height)
    return d2l.plt.Rectangle(
        xy=(bbox[0], bbox[1]), width=bbox[2]-bbox[0], height=bbox[3]-bbox[1],
        fill=False, edgecolor=color, linewidth=2)
```

After adding the bounding boxes on the image, we can see that the main outline of the two objects is basically inside the two boxes.

```
fig = d2l.plt.imshow(img)
fig.axes.add_patch(bbox_to_rect(dog_bbox, 'blue'))
fig.axes.add_patch(bbox_to_rect(cat_bbox, 'red'));
```



32.3.2 Summary

- Object detection not only recognizes all the objects of interest in the image, but also their positions. The position is generally represented by a rectangular bounding box.
- We can convert between two commonly used bounding box representations.

32.3.3 Exercises

1. Find another image and try to label a bounding box that contains the object. Compare labeling bounding boxes and categories: which usually takes longer?
2. Why is the innermost dimension of the input argument `boxes` of `box_corner_to_center` and `box_center_to_corner` always 4?
3. Data augmentation for object detection must transform the boxes together with the image. Let the image have width W and height H.
    1. Show that flipping the image left to right maps the box (x_1, y_1, x_2, y_2) to $(W - x_2, y_1, W - x_1, y_2)$, and that rotating it by 90 degrees counterclockwise maps the box to $(y_1, W - x_2, y_2, W - x_1)$ in an image of width H and height W. Why do the corners have to be reordered?
    2. Implement both maps for a tensor `boxes` of shape $(n, 4)$. Apply them to `dog_bbox` and `cat_bbox`, and draw the results with `bbox_to_rect` on the flipped image `img[:, ::-1]` and on the rotated image `img.transpose(1, 0, 2)[::-1]` to check them.
4. Suppose that an annotator places each of the four corner coordinates x_1, y_1, x_2, y_2 with an independent error of standard deviation σ pixels. Write `box_corner_to_center` as a 4×4 matrix acting on $(x_1, y_1, x_2, y_2)^\top$, and use it to show that the center coordinates have standard deviation $\sigma/\sqrt{2}$, the width and height have standard deviation $\sqrt{2}\sigma$, and the center is uncorrelated with the width and height. For the cat box and $\sigma = 5$ pixels, estimate to first order the relative standard deviation of the box area.
5. An axis-aligned box describes a rotated object only loosely. Show that a rectangular object of width a and height b, rotated by an angle $\theta \in [0, \pi/2]$, has a bounding box of width $a\cos\theta + b\sin\theta$ and height $a\sin\theta + b\cos\theta$. Show that the fraction of the box area covered by the object is smallest at $\theta = \pi/4$, where it equals $2ab/(a+b)^2$. Evaluate this for an elongated object such as a pen with $a = 4b$: what fraction of its box is background?

32.4 Anchor Boxes

Object detection algorithms usually sample a large number of regions in the input image, determine whether these regions contain objects of interest, and adjust the boundaries of the regions so as to predict the *ground-truth bounding boxes* of the objects more accurately. Different models may adopt different region sampling schemes. Here we introduce one such method: it generates multiple bounding boxes with varying scales and aspect ratios centered on each pixel. These bounding boxes are called *anchor boxes*. We will design an object detection model based on anchor boxes in Section 32.7.

First, let's modify the printing accuracy just for more concise outputs.

```
np.set_printoptions(2)  # Simplify printing accuracy
```

32.4.1 Generating Multiple Anchor Boxes

Suppose that the input image has a height of h and width of w. We generate anchor boxes with different shapes centered on each pixel of the image. Let the *scale* be $s \in (0, 1]$ and the *aspect ratio* (ratio of width to height) is $r > 0$. Then the width and height of the anchor box are $ws\sqrt{r}$ and $hs/\sqrt{r}$, respectively. Note that when the center position is given, an anchor box with known width and height is determined.

To generate multiple anchor boxes with different shapes, let's set a series of scales $s_1, \ldots, s_n$ and a series of aspect ratios $r_1, \ldots, r_m$. When using all the combinations of these scales and aspect ratios with each pixel as the center, the input image will have a total of $whnm$ anchor boxes. Although these anchor boxes may cover all the ground-truth bounding boxes, the computational complexity is easily too high. In practice, we can only consider those combinations containing s_1 or r_1:

$$(s_1, r_1), (s_1, r_2), \ldots, (s_1, r_m), (s_2, r_1), (s_3, r_1), \ldots, (s_n, r_1). \tag{32.1}$$

That is to say, the number of anchor boxes centered on the same pixel is $n + m - 1$. For the entire input image, we will generate a total of $wh(n + m - 1)$ anchor boxes.

The above method of generating anchor boxes is implemented in the following `multibox_prior` function. We specify the input image, a list of scales, and a list of aspect ratios, then this function will return all the anchor boxes.

```
def multibox_prior(data, sizes, ratios):
    """Generate anchor boxes with different shapes centered on each pixel."""
    in_height, in_width = data.shape[-2:]
    num_sizes, num_ratios = len(sizes), len(ratios)
    boxes_per_pixel = (num_sizes + num_ratios - 1)
    size_tensor = np.array(sizes, dtype=np.float32)
    ratio_tensor = np.array(ratios, dtype=np.float32)
    # Offsets are required to move the anchor to the center of a pixel. Since
    # a pixel has height=1 and width=1, we choose to offset our centers by 0.5
    offset_h, offset_w = 0.5, 0.5
    steps_h = 1.0 / in_height  # Scaled steps in y axis
    steps_w = 1.0 / in_width  # Scaled steps in x axis
```

```
    # Generate all center points for the anchor boxes
    center_h = (np.arange(in_height) + offset_h) * steps_h
    center_w = (np.arange(in_width) + offset_w) * steps_w
    shift_y, shift_x = np.meshgrid(center_h, center_w, indexing='ij')
    shift_y, shift_x = shift_y.reshape(-1), shift_x.reshape(-1)

    # Generate `boxes_per_pixel` number of heights and widths that are later
    # used to create anchor box corner coordinates (xmin, xmax, ymin, ymax)
    w = np.concatenate((size_tensor * np.sqrt(ratio_tensor[0]),
                        sizes[0] * np.sqrt(ratio_tensor[1:]))\
                        * in_height / in_width  # Handle rectangular inputs
    h = np.concatenate((size_tensor / np.sqrt(ratio_tensor[0]),
                        sizes[0] / np.sqrt(ratio_tensor[1:])))
    # Divide by 2 to get half height and half width
    anchor_manipulations = np.tile(np.stack((-w, -h, w, h)).T,
                                   (in_height * in_width, 1)) / 2

    # Each center point will have `boxes_per_pixel` number of anchor boxes, so
    # generate a grid of all anchor box centers with `boxes_per_pixel` repeats
    out_grid = np.repeat(np.stack([shift_x, shift_y, shift_x, shift_y],
                         axis=1), boxes_per_pixel, axis=0)
    output = tf.constant(out_grid + anchor_manipulations, dtype=tf.float32)
    return tf.expand_dims(output, axis=0)
```

We can see that the shape of the returned anchor box variable `Y` is (batch size, number of anchor boxes, 4).

```
img = d2l.plt.imread('../img/catdog.jpg')
h, w = img.shape[:2]

print(h, w)
X = tf.random.uniform(shape=(1, 3, h, w))
Y = multibox_prior(X, sizes=[0.75, 0.5, 0.25], ratios=[1, 2, 0.5])
Y.shape
```

```
561 728
```

```
TensorShape([1, 2042040, 4])
```

After changing the shape of the anchor box variable `Y` to (image height, image width, number of anchor boxes centered on the same pixel, 4), we can obtain all the anchor boxes centered on a specified pixel position. In the following, we access the first anchor box centered on (250, 250). It has four elements: the (x, y)-axis coordinates at the upper-left corner and the (x, y)-axis coordinates at the lower-right corner of the anchor box. The coordinate values of both axes are divided by the width and height of the image, respectively.

```
boxes = tf.reshape(Y, (h, w, 5, 4))
boxes[250, 250, 0, :]
```

```
<tf.Tensor: shape=(4,), dtype=float32, numpy=array([0.06, 0.07, 0.63, 0.82], dtype=float32)>
```

In order to show all the anchor boxes centered on one pixel in the image, we define the following `show_bboxes` function to draw multiple bounding boxes on the image.

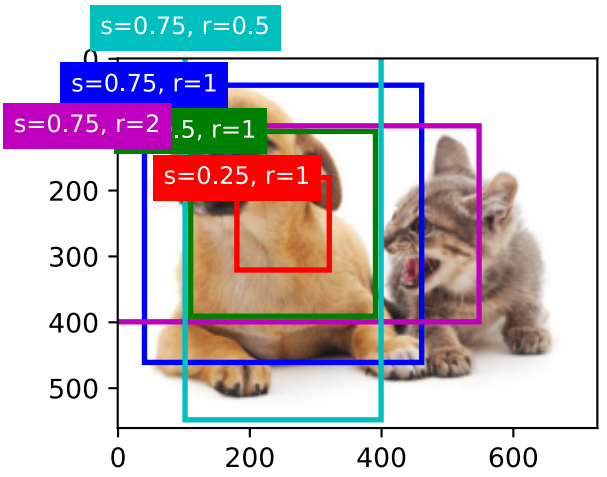
```
def show_bboxes(axes, bboxes, labels=None, colors=None):
    """Show bounding boxes."""

    def make_list(obj, default_values=None):
        if obj is None:
            obj = default_values
        elif not isinstance(obj, (list, tuple)):
            obj = [obj]
        return obj

    labels = make_list(labels)
    colors = make_list(colors, ['b', 'g', 'r', 'm', 'c'])
    for i, bbox in enumerate(bboxes):
        color = colors[i % len(colors)]
        rect = d2l.bbox_to_rect(d2l.numpy(bbox), color)
        axes.add_patch(rect)
        if labels and len(labels) > i:
            text_color = 'k' if color == 'w' else 'w'
            axes.text(rect.xy[0], rect.xy[1], labels[i],
                      va='center', ha='center', fontsize=9, color=text_color,
                      bbox=dict(facecolor=color, lw=0))
```

As we just saw, the coordinate values of the x and y axes in the variable `boxes` have been divided by the width and height of the image, respectively. When drawing anchor boxes, we need to restore their original coordinate values; thus, we define variable `bbox_scale` below. Now, we can draw all the anchor boxes centered on (250, 250) in the image. As you can see, the blue anchor box with a scale of 0.75 and an aspect ratio of 1 well surrounds the dog in the image.

```
d2l.set_figsize()
bbox_scale = tf.constant((w, h, w, h), dtype=tf.float32)
fig = d2l.plt.imshow(img)
show_bboxes(fig.axes, boxes[250, 250, :, :] * bbox_scale,
            ['s=0.75, r=1', 's=0.5, r=1', 's=0.25, r=1', 's=0.75, r=2',
             's=0.75, r=0.5'])
```



32.4.2 Intersection over Union (IoU)

We just mentioned that an anchor box "well" surrounds the dog in the image. If the ground-truth bounding box of the object is known, how can "well" here be quantified? Intuitively, we can measure the similarity between the anchor box and the ground-truth bounding box. We know that the *Jaccard index* can measure the similarity between two sets. Given sets $\mathcal{A}$ and $\mathcal{B}$, their Jaccard index is the size of their intersection divided by the size of their union:

$$J(\mathcal{A}, \mathcal{B}) = \frac{|\mathcal{A} \cap \mathcal{B}|}{|\mathcal{A} \cup \mathcal{B}|}. \tag{32.2}$$

In fact, we can consider the pixel area of any bounding box as a set of pixels. In this way, we can measure the similarity of the two bounding boxes by the Jaccard index of their pixel sets. For two bounding boxes, we usually refer their Jaccard index as *intersection over union* (*IoU*), which is the ratio of their intersection area to their union area, as shown in Figure 32.2. The range of an IoU is between 0 and 1: 0 means that two bounding boxes do not overlap at all, while 1 indicates that the two bounding boxes are equal.

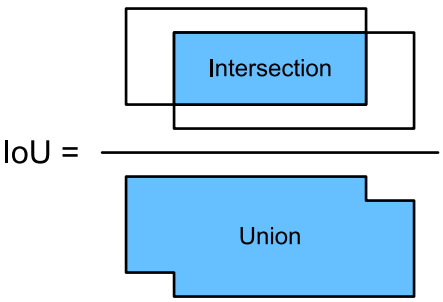


Figure 32.2: IoU is the ratio of the intersection area to the union area of two bounding boxes.

For the remainder of this section, we will use IoU to measure the similarity between anchor boxes and ground-truth bounding boxes, and between different anchor boxes. Given two

lists of anchor or bounding boxes, the following `box_iou` computes their pairwise IoU across these two lists.

```
def box_iou(boxes1, boxes2):
    """Compute pairwise IoU across two lists of anchor or bounding boxes."""
    box_area = lambda boxes: ((boxes[:, 2] - boxes[:, 0]) *
                              (boxes[:, 3] - boxes[:, 1]))
    # Shape of `boxes1`, `boxes2`, `areas1`, `areas2`: (no. of boxes1, 4),
    # (no. of boxes2, 4), (no. of boxes1,), (no. of boxes2,)
    areas1 = box_area(boxes1)
    areas2 = box_area(boxes2)
    # Shape of `inter_upperlefts`, `inter_lowerrights`, `inters`: (no. of
    # boxes1, no. of boxes2, 2)
    inter_upperlefts = tf.maximum(boxes1[:, None, :2], boxes2[:, :2])
    inter_lowerrights = tf.minimum(boxes1[:, None, 2:], boxes2[:, 2:])
    inters = tf.clip_by_value(inter_lowerrights - inter_upperlefts, 0,
                              float('inf'))
    # Shape of `inter_areas` and `union_areas`: (no. of boxes1, no. of boxes2)
    inter_areas = inters[:, :, 0] * inters[:, :, 1]
    union_areas = areas1[:, None] + areas2 - inter_areas
    return inter_areas / union_areas
```

32.4.3 Labeling Anchor Boxes in Training Data

In a training dataset, we consider each anchor box as a training example. In order to train an object detection model, we need *class* and *offset* labels for each anchor box, where the former is the class of the object relevant to the anchor box and the latter is the offset of the ground-truth bounding box relative to the anchor box. During the prediction, for each image we generate multiple anchor boxes, predict classes and offsets for all the anchor boxes, adjust their positions according to the predicted offsets to obtain the predicted bounding boxes, and finally only output those predicted bounding boxes that satisfy certain criteria.

As we know, an object detection training set comes with labels for locations of *ground-truth bounding boxes* and classes of their surrounded objects. To label any generated *anchor box*, we refer to the labeled location and class of its *assigned* ground-truth bounding box that is closest to the anchor box. In the following, we describe an algorithm for assigning closest ground-truth bounding boxes to anchor boxes.

32.4.3.1 Assigning Ground-Truth Bounding Boxes to Anchor Boxes

Given an image, suppose that the anchor boxes are $A_1, A_2, \ldots, A_{n_a}$ and the ground-truth bounding boxes are $B_1, B_2, \ldots, B_{n_b}$, where $n_a \geq n_b$. Let's define a matrix $\mathbf{X} \in \mathbb{R}^{n_a \times n_b}$, whose element x_{ij} in the i^{th} row and j^{th} column is the IoU of the anchor box A_i and the ground-truth bounding box B_j. The algorithm consists of the following steps:

1. Find the largest element in matrix $\mathbf{X}$ and denote its row and column indices as i_1 and j_1, respectively. Then the ground-truth bounding box B_{j_1} is assigned to the anchor box A_{i_1}. This is quite intuitive because A_{i_1} and B_{j_1} are the closest among all the pairs of anchor boxes and ground-truth bounding boxes. After the first assignment, discard all the elements in the ${i_1}^{\text{th}}$ row and the ${j_1}^{\text{th}}$ column in matrix $\mathbf{X}$.

2. Find the largest of the remaining elements in matrix $\mathbf{X}$ and denote its row and column indices as i_2 and j_2, respectively. We assign ground-truth bounding box B_{j_2} to anchor box A_{i_2} and discard all the elements in the ${i_2}^{\text{th}}$ row and the ${j_2}^{\text{th}}$ column in matrix $\mathbf{X}$.
3. At this point, elements in two rows and two columns in matrix $\mathbf{X}$ have been discarded. We proceed until all elements in n_b columns in matrix $\mathbf{X}$ are discarded. At this time, we have assigned a ground-truth bounding box to each of n_b anchor boxes.
4. Only traverse through the remaining $n_a - n_b$ anchor boxes. For example, given any anchor box A_i, find the ground-truth bounding box B_j with the largest IoU with A_i throughout the ${i}^{\text{th}}$ row of matrix $\mathbf{X}$, and assign B_j to A_i only if this IoU is greater than a predefined threshold.

Let's illustrate the above algorithm using a concrete example. As shown in Figure 32.3 (left), assuming that the maximum value in matrix $\mathbf{X}$ is x_{23}, we assign the ground-truth bounding box B_3 to the anchor box A_2. Then, we discard all the elements in row 2 and column 3 of the matrix, find the largest x_{71} in the remaining elements (shaded area), and assign the ground-truth bounding box B_1 to the anchor box A_7. Next, as shown in Figure 32.3 (middle), discard all the elements in row 7 and column 1 of the matrix, find the largest x_{54} in the remaining elements (shaded area), and assign the ground-truth bounding box B_4 to the anchor box A_5. Finally, as shown in Figure 32.3 (right), discard all the elements in row 5 and column 4 of the matrix, find the largest x_{92} in the remaining elements (shaded area), and assign the ground-truth bounding box B_2 to the anchor box A_9. After that, we only need to traverse through the remaining anchor boxes A_1, A_3, A_4, A_6, A_8 and determine whether to assign them ground-truth bounding boxes according to the threshold.

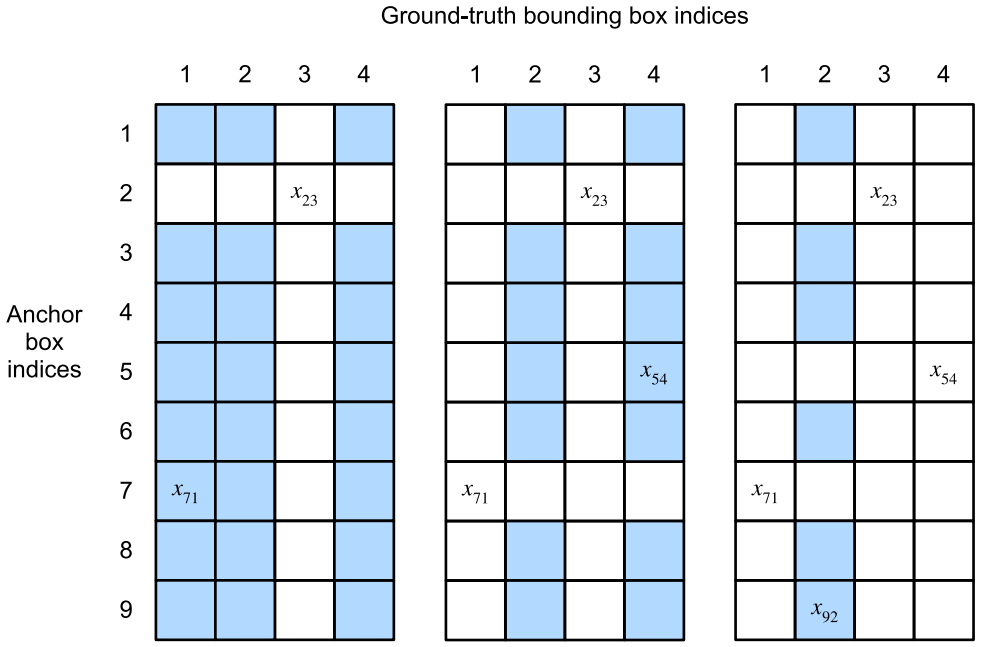

Figure 32.3: Assigning ground-truth bounding boxes to anchor boxes.

This algorithm is implemented in the following `assign_anchor_to_bbox` function. Note that this routine and the `nms` function below are written as explicit per-box Python loops to mirror the algorithm step by step for teaching; production code should instead use a vector-

ized/library routine, since each in-loop `argmax` forces a device-to-host synchronization on every iteration.

TensorFlow provides such a routine for non-maximum suppression as `tf.image.non_max_suppression`.

```
def assign_anchor_to_bbox(ground_truth, anchors, device, iou_threshold=0.5):
    """Assign closest ground-truth bounding boxes to anchor boxes."""
    num_anchors, num_gt_boxes = anchors.shape[0], ground_truth.shape[0]
    # Element x_ij in the i-th row and j-th column is the IoU of the anchor
    # box i and the ground-truth bounding box j
    jaccard = box_iou(anchors, ground_truth)
    # Initialize the tensor to hold the assigned ground-truth bounding box for
    # each anchor
    anchors_bbox_map = np.full((num_anchors,), -1, dtype=np.int32)
    # Assign ground-truth bounding boxes according to the threshold
    max_ious = tf.reduce_max(jaccard, axis=1).numpy()
    indices = tf.argmax(jaccard, axis=1).numpy()
    anc_i = np.nonzero(max_ious >= iou_threshold)[0]
    box_j = indices[max_ious >= iou_threshold]
    anchors_bbox_map[anc_i] = box_j
    # Use a plain Python loop — this runs once per sample, not in training
    col_discard = np.full((num_anchors,), -1.0)
    row_discard = np.full((num_gt_boxes,), -1.0)
    jaccard_np = jaccard.numpy()
    for _ in range(num_gt_boxes):
        max_idx = int(np.argmax(jaccard_np))
        box_idx = max_idx % num_gt_boxes
        anc_idx = max_idx // num_gt_boxes
        anchors_bbox_map[anc_idx] = box_idx
        jaccard_np[:, box_idx] = col_discard
        jaccard_np[anc_idx, :] = row_discard
    return tf.constant(anchors_bbox_map, dtype=tf.int32)
```

32.4.3.2 Labeling Classes and Offsets

Now we can label the class and offset for each anchor box. Suppose that an anchor box A is assigned a ground-truth bounding box B. On the one hand, the class of the anchor box A will be labeled as that of B. On the other hand, the offset of the anchor box A will be labeled according to the relative position between the central coordinates of B and A together with the relative size between these two boxes. Given varying positions and sizes of different boxes in the dataset, we can apply transformations to those relative positions and sizes that may lead to more uniformly distributed offsets that are easier to fit. Here we describe a common transformation. Given the central coordinates of A and B as (x_a, y_a) and (x_b, y_b), their widths as w_a and w_b, and their heights as h_a and h_b, respectively. We may label the offset of A as

$$\left(\frac{\frac{x_b - x_a}{w_a} - \mu_x}{\sigma_x}, \frac{\frac{y_b - y_a}{h_a} - \mu_y}{\sigma_y}, \frac{\log \frac{w_b}{w_a} - \mu_w}{\sigma_w}, \frac{\log \frac{h_b}{h_a} - \mu_h}{\sigma_h} \right), \tag{32.3}$$

where default values of the constants are $\mu_x = \mu_y = \mu_w = \mu_h = 0, \sigma_x = \sigma_y = 0.1$, and

$\sigma_w = \sigma_h = 0.2$. This transformation is implemented below in the `offset_boxes` function.

```
def offset_boxes(anchors, assigned_bb, eps=1e-6):
    """Transform for anchor box offsets."""
    c_anc = d2l.box_corner_to_center(anchors)
    c_assigned_bb = d2l.box_corner_to_center(assigned_bb)
    offset_xy = 10 * (c_assigned_bb[:, :2] - c_anc[:, :2]) / c_anc[:, 2:]
    offset_wh = 5 * d2l.log(eps + c_assigned_bb[:, 2:] / c_anc[:, 2:])
    offset = d2l.concat([offset_xy, offset_wh], axis=1)
    return offset
```

If an anchor box is not assigned a ground-truth bounding box, we just label the class of the anchor box as "background". Anchor boxes whose classes are background are often referred to as *negative* anchor boxes, and the rest are called *positive* anchor boxes. We implement the following `multibox_target` function to label classes and offsets for anchor boxes (the `anchors` argument) using ground-truth bounding boxes (the `labels` argument). This function sets the background class to zero and increments the integer index of a new class by one.

```
def multibox_target(anchors, labels):
    """Label anchor boxes using ground-truth bounding boxes."""
    batch_size, anchors = labels.shape[0], tf.squeeze(anchors, axis=0)
    batch_offset, batch_mask, batch_class_labels = [], [], []
    num_anchors = anchors.shape[0]
    for i in range(batch_size):
        label = labels[i, :, :]
        anchors_bbox_map = assign_anchor_to_bbox(
            label[:, 1:], anchors, None)
        bbox_mask = tf.tile(
            tf.expand_dims(
                tf.cast(anchors_bbox_map >= 0, dtype=tf.float32), axis=-1),
            [1, 4])
        # Initialize class labels and assigned bounding box coordinates with
        # zeros
        class_labels = tf.zeros(num_anchors, dtype=tf.int32)
        assigned_bb = tf.zeros((num_anchors, 4), dtype=tf.float32)
        # Label classes of anchor boxes using their assigned ground-truth
        # bounding boxes. If an anchor box is not assigned any, we label its
        # class as background (the value remains zero)
        indices_true = tf.cast(
            tf.squeeze(tf.where(anchors_bbox_map >= 0), axis=1), tf.int32)
        bb_idx = tf.gather(anchors_bbox_map, indices_true)
        class_labels = tf.tensor_scatter_nd_update(
            class_labels, tf.expand_dims(indices_true, 1),
            tf.cast(tf.gather(label[:, 0], bb_idx), tf.int32) + 1)
        assigned_bb = tf.tensor_scatter_nd_update(
            assigned_bb, tf.expand_dims(indices_true, 1),
            tf.gather(label[:, 1:], bb_idx))
        # Offset transformation
        offset = offset_boxes(anchors, assigned_bb) * bbox_mask
        batch_offset.append(tf.reshape(offset, [-1]))
        batch_mask.append(tf.reshape(bbox_mask, [-1]))
        batch_class_labels.append(class_labels)
```

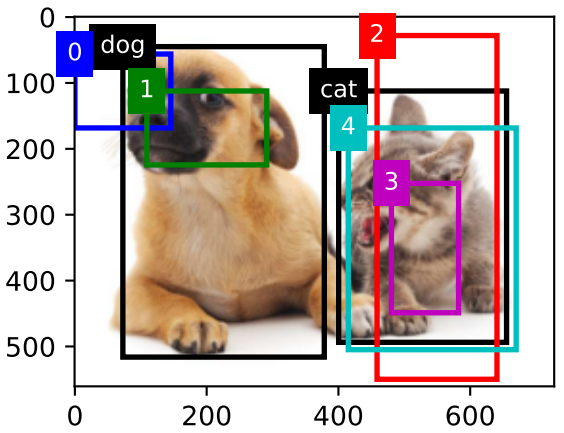
```
    bbox_offset = tf.stack(batch_offset)
    bbox_mask = tf.stack(batch_mask)
    class_labels = tf.stack(batch_class_labels)
    return (bbox_offset, bbox_mask, class_labels)
```

32.4.3.3 An Example

Let's illustrate anchor box labeling via a concrete example. We define ground-truth bounding boxes for the dog and cat in the loaded image, where the first element is the class (0 for dog and 1 for cat) and the remaining four elements are the (x, y)-axis coordinates at the upper-left corner and the lower-right corner (range is between 0 and 1). We also construct five anchor boxes to be labeled using the coordinates of the upper-left corner and the lower-right corner: $A_0, \ldots, A_4$ (the index starts from 0). Then we plot these ground-truth bounding boxes and anchor boxes in the image.

```
ground_truth = d2l.tensor([[0, 0.1, 0.08, 0.52, 0.92],
                           [1, 0.55, 0.2, 0.9, 0.88]])
anchors = d2l.tensor([[0, 0.1, 0.2, 0.3], [0.15, 0.2, 0.4, 0.4],
                      [0.63, 0.05, 0.88, 0.98], [0.66, 0.45, 0.8, 0.8],
                      [0.57, 0.3, 0.92, 0.9]])

fig = d2l.plt.imshow(img)
show_bboxes(fig.axes, ground_truth[:, 1:] * bbox_scale, ['dog', 'cat'], 'k')
show_bboxes(fig.axes, anchors * bbox_scale, ['0', '1', '2', '3', '4']);
```



Using the `multibox_target` function defined above, we can label classes and offsets of these anchor boxes based on the ground-truth bounding boxes for the dog and cat. In this example, indices of the background, dog, and cat classes are 0, 1, and 2, respectively. Below we add a dimension for examples of anchor boxes and ground-truth bounding boxes.

```
labels = multibox_target(tf.expand_dims(anchors, axis=0),
                         tf.expand_dims(ground_truth, axis=0))
```

There are three items in the returned result, all of which are in the tensor format. The third item contains the labeled classes of the input anchor boxes.

Let's analyze the returned class labels below based on anchor box and ground-truth bounding box positions in the image. First, among all the pairs of anchor boxes and ground-truth bounding boxes, the IoU of the anchor box A_4 and the ground-truth bounding box of the cat is the largest. Thus, the class of A_4 is labeled as the cat. Taking out pairs containing A_4 or the ground-truth bounding box of the cat, among the rest the pair of the anchor box A_1 and the ground-truth bounding box of the dog has the largest IoU. So the class of A_1 is labeled as the dog. Next, we need to traverse through the remaining three unlabeled anchor boxes: A_0, A_2, and A_3. For A_0, the class of the ground-truth bounding box with the largest IoU is the dog, but the IoU is below the predefined threshold (0.5), so the class is labeled as background; for A_2, the class of the ground-truth bounding box with the largest IoU is the cat and the IoU exceeds the threshold, so the class is labeled as the cat; for A_3, the class of the ground-truth bounding box with the largest IoU is the cat, but the value is below the threshold, so the class is labeled as background.

```
labels[2]
```

```
<tf.Tensor: shape=(1, 5), dtype=int32, numpy=array([[0, 1, 2, 0, 2]], dtype=int32)>
```

The second returned item is a mask variable of the shape (batch size, four times the number of anchor boxes). Every four elements in the mask variable correspond to the four offset values of each anchor box. Since we do not care about background detection, offsets of this negative class should not affect the objective function. Through elementwise multiplications, zeros in the mask variable will filter out negative class offsets before calculating the objective function.

```
labels[1]
```

```
<tf.Tensor: shape=(1, 20), dtype=float32, numpy=
array([[0., 0., 0., 0., 1., 1., 1., 1., 1., 1., 1., 0., 0., 0., 0.,
        1., 1., 1., 1.]], dtype=float32)>
```

The first returned item contains the four offset values labeled for each anchor box. Note that the offsets of negative-class anchor boxes are labeled as zeros.

```
labels[0]
```

```
<tf.Tensor: shape=(1, 20), dtype=float32, numpy=
array([[-0.00e+00, -0.00e+00, -0.00e+00, -0.00e+00,  1.40e+00,  1.00e+01,
         2.59e+00,  7.18e+00, -1.20e+00,  2.69e-01,  1.68e+00, -1.57e+00,
        -0.00e+00, -0.00e+00, -0.00e+00, -0.00e+00, -5.71e-01, -1.00e+00,
         4.17e-06,  6.26e-01]], dtype=float32)>
```

32.4.4 Predicting Bounding Boxes with Non-Maximum Suppression

During prediction, we generate multiple anchor boxes for the image and predict classes and offsets for each of them. A *predicted bounding box* is thus obtained according to an anchor box with its predicted offset. Below we implement the `offset_inverse` function that takes in

anchors and offset predictions as inputs and applies inverse offset transformations to return the predicted bounding box coordinates.

```
def offset_inverse(anchors, offset_preds):
    """Predict bounding boxes based on anchor boxes with predicted offsets."""
    anc = d2l.box_corner_to_center(anchors)
    pred_bbox_xy = (offset_preds[:, :2] * anc[:, 2:] / 10) + anc[:, :2]
    pred_bbox_wh = d2l.exp(offset_preds[:, 2:] / 5) * anc[:, 2:]
    pred_bbox = d2l.concat((pred_bbox_xy, pred_bbox_wh), axis=1)
    predicted_bbox = d2l.box_center_to_corner(pred_bbox)
    return predicted_bbox
```

When there are many anchor boxes, many similar (with significant overlap) predicted bounding boxes can be potentially output for surrounding the same object. To simplify the output, we can merge similar predicted bounding boxes that belong to the same object by using *non-maximum suppression* (NMS).

Here is how non-maximum suppression works. For a predicted bounding box B, the object detection model calculates the predicted likelihood for each class. Denoting by p the largest predicted likelihood, the class corresponding to this probability is the predicted class for B. Specifically, we refer to p as the *confidence* (score) of the predicted bounding box B. On the same image, all the predicted non-background bounding boxes are sorted by confidence in descending order to generate a list L. Then we manipulate the sorted list L in the following steps:

1. Select the predicted bounding box B_1 with the highest confidence from L as a basis and remove all non-basis predicted bounding boxes whose IoU with B_1 exceeds a predefined threshold ϵ from L. At this point, L keeps the predicted bounding box with the highest confidence but drops others that are too similar to it. In a nutshell, those with *non-maximum* confidence scores are *suppressed*.
2. Select the predicted bounding box B_2 with the second highest confidence from L as another basis and remove all non-basis predicted bounding boxes whose IoU with B_2 exceeds ϵ from L.
3. Repeat the above process until all the predicted bounding boxes in L have been used as a basis. At this time, the IoU of any pair of predicted bounding boxes in L is below the threshold ϵ; thus, no pair is too similar with each other.
4. Output all the predicted bounding boxes in the list L.

The following `nms` function sorts confidence scores in descending order and returns their indices.

```
def nms(boxes, scores, iou_threshold):
    """Sort confidence scores of predicted bounding boxes."""
    # Work in NumPy so the Python while-loop isn't forcing a host/device
    # sync every iteration.
    boxes_np = np.asarray(boxes)
    B = np.argsort(-np.asarray(scores))
    keep = []  # Indices of predicted bounding boxes that will be kept
    while B.size > 0:
        i = int(B[0])
        keep.append(i)
```

```
        if B.size == 1: break
        rest = B[1:]
        # Pairwise IoU between box i and every remaining box, in NumPy
        box_i, rest_boxes = boxes_np[i], boxes_np[rest]
        lt = np.maximum(box_i[:2], rest_boxes[:, :2])
        rb = np.minimum(box_i[2:], rest_boxes[:, 2:])
        inter = np.clip(rb - lt, 0, None).prod(axis=1)
        area_i = (box_i[2:] - box_i[:2]).prod()
        area_rest = (rest_boxes[:, 2:] - rest_boxes[:, :2]).prod(axis=1)
        iou = inter / (area_i + area_rest - inter)
        B = rest[iou <= iou_threshold]
    return tf.constant(keep, dtype=tf.int32)
```

We define the following `multibox_detection` to apply non-maximum suppression to predicting bounding boxes. Do not worry if you find the implementation a bit complicated: we will show how it works with a concrete example right after the implementation.

```
def multibox_detection(cls_probs, offset_preds, anchors, nms_threshold=0.5,
                       pos_threshold=0.009999999):
    """Predict bounding boxes using non-maximum suppression."""
    batch_size = cls_probs.shape[0]
    anchors = tf.squeeze(anchors, axis=0)
    num_classes, num_anchors = cls_probs.shape[1], cls_probs.shape[2]
    out = []
    for i in range(batch_size):
        cls_prob = cls_probs[i]
        offset_pred = tf.reshape(offset_preds[i], (-1, 4))
        conf = tf.reduce_max(cls_prob[1:], axis=0)
        class_id = tf.cast(tf.argmax(cls_prob[1:], axis=0), tf.int32)
        predicted_bb = offset_inverse(anchors, offset_pred)
        keep = nms(predicted_bb, conf, nms_threshold)
        # Find all non-`keep` indices and set the class to background
        all_idx = tf.cast(tf.range(num_anchors), tf.int32)
        combined = tf.concat((keep, all_idx), axis=0)
        unique, _, counts = tf.unique_with_counts(combined)
        non_keep = tf.boolean_mask(unique, counts == 1)
        all_id_sorted = tf.concat((keep, non_keep), axis=0)
        # Set non-kept boxes' class to -1
        updates = tf.fill([tf.shape(non_keep)[0]], -1)
        class_id = tf.tensor_scatter_nd_update(
            class_id, tf.expand_dims(non_keep, 1), updates)
        class_id = tf.cast(tf.gather(class_id, all_id_sorted), tf.float32)
        conf = tf.gather(conf, all_id_sorted)
        predicted_bb = tf.gather(predicted_bb, all_id_sorted)
        # Here `pos_threshold` is a threshold for positive (non-background)
        # predictions
        below_min_idx = conf < pos_threshold
        class_id = tf.where(below_min_idx, tf.fill(tf.shape(class_id), -1.0),
                            class_id)
        conf = tf.where(below_min_idx, 1 - conf, conf)
        pred_info = tf.concat((tf.expand_dims(class_id, axis=1),
                               tf.expand_dims(conf, axis=1),
```

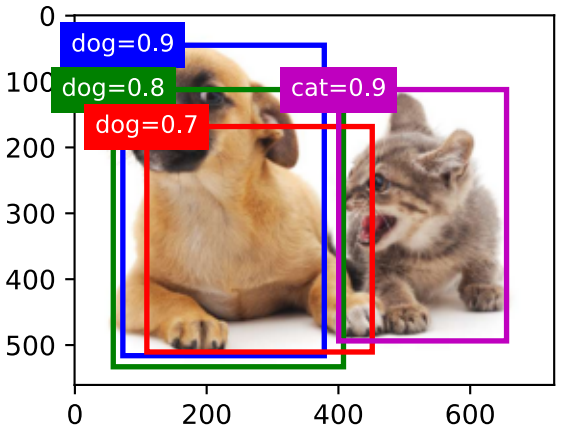
```
                                predicted_bb), axis=1)
        out.append(pred_info)
    return tf.stack(out)
```

Now let's apply the above implementations to a concrete example with four anchor boxes. For simplicity, we assume that the predicted offsets are all zeros. This means that the predicted bounding boxes are anchor boxes. For each class among the background, dog, and cat, we also define its predicted likelihood.

```
anchors = d2l.tensor([[0.1, 0.08, 0.52, 0.92], [0.08, 0.2, 0.56, 0.95],
                      [0.15, 0.3, 0.62, 0.91], [0.55, 0.2, 0.9, 0.88]])
# Use float zeros so offset_inverse arithmetic stays in float32
offset_preds = tf.zeros(d2l.size(anchors), dtype=tf.float32)
cls_probs = d2l.tensor([[0] * 4,  # Predicted background likelihood
                        [0.9, 0.8, 0.7, 0.1],  # Predicted dog likelihood
                        [0.1, 0.2, 0.3, 0.9]])  # Predicted cat likelihood
```

We can plot these predicted bounding boxes with their confidence on the image.

```
fig = d2l.plt.imshow(img)
show_bboxes(fig.axes, anchors * bbox_scale,
            ['dog=0.9', 'dog=0.8', 'dog=0.7', 'cat=0.9'])
```



Now we can invoke the `multibox_detection` function to perform non-maximum suppression, where the threshold is set to 0.5. Note that we add a dimension for examples in the tensor input.

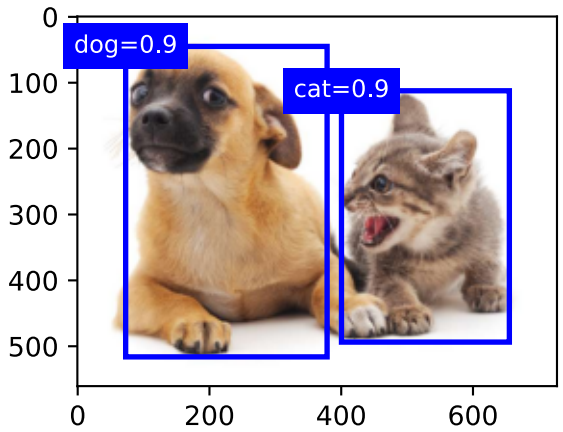
We can see that the shape of the returned result is (batch size, number of anchor boxes, 6). The six elements in the innermost dimension gives the output information for the same predicted bounding box. The first element is the predicted class index, which starts from 0 (0 is dog and 1 is cat). The value -1 indicates background or removal in non-maximum suppression. The second element is the confidence of the predicted bounding box. The remaining four elements are the (x, y)-axis coordinates of the upper-left corner and the lower-right corner of the predicted bounding box, respectively (range is between 0 and 1).

```
output = multibox_detection(tf.expand_dims(cls_probs, axis=0),
                            tf.expand_dims(offset_preds, axis=0),
                            tf.expand_dims(anchors, axis=0),
                            nms_threshold=0.5)
output
```

```
<tf.Tensor: shape=(1, 4, 6), dtype=float32, numpy=
array([[[ 0.  ,  0.9 ,  0.1 ,  0.08,  0.52,  0.92],
        [ 1.  ,  0.9 ,  0.55,  0.2 ,  0.9 ,  0.88],
        [-1.  ,  0.8 ,  0.08,  0.2 ,  0.56,  0.95],
        [-1.  ,  0.7 ,  0.15,  0.3 ,  0.62,  0.91]]], dtype=float32)>
```

After removing those predicted bounding boxes of class -1, we can output the final predicted bounding box kept by non-maximum suppression.

```
fig = d2l.plt.imshow(img)
for i in d2l.numpy(output[0]):
    if i[0] == -1:
        continue
    label = ('dog=', 'cat=')[int(i[0])] + str(i[1])
    show_bboxes(fig.axes, [d2l.tensor(i[2:]) * bbox_scale], label)
```



In practice, we can remove predicted bounding boxes with lower confidence even before performing non-maximum suppression, thereby reducing computation in this algorithm. We may also post-process the output of non-maximum suppression, for example, by only keeping results with higher confidence in the final output.

32.4.5 Summary

- We generate anchor boxes with different shapes centered on each pixel of the image.
- Intersection over union (IoU), also known as Jaccard index, measures the similarity of two bounding boxes. It is the ratio of their intersection area to their union area.
- In a training set, we need two types of labels for each anchor box. One is the class of the object relevant to the anchor box and the other is the offset of the ground-truth bounding box relative to the anchor box.

- During prediction, we can use non-maximum suppression (NMS) to remove similar predicted bounding boxes, thereby simplifying the output.

32.4.6 Exercises

1. Change values of `sizes` and `ratios` in the `multibox_prior` function. What are the changes to the generated anchor boxes?
2. Construct and visualize two bounding boxes with an IoU of 0.5. How do they overlap with each other?
3. Modify the variable `anchors` in Section 32.4.3 and Section 32.4.4. How do the results change?
4. Non-maximum suppression is a greedy algorithm that suppresses predicted bounding boxes by *removing* them. Is it possible that some of these removed ones are actually useful? How can this algorithm be modified to suppress *softly*? You may refer to Soft-NMS (Bodla et al. 2017).
5. Rather than being hand-crafted, can non-maximum suppression be learned?

32.5 Multiscale Object Detection

In Section 32.4, we generated multiple anchor boxes centered on each pixel of an input image. Essentially these anchor boxes represent samples of different regions of the image. However, we may end up with too many anchor boxes to compute if they are generated for *every* pixel. Think of a 561×728 input image. If five anchor boxes with varying shapes are generated for each pixel as their center, over two million anchor boxes ($561 \times 728 \times 5$) need to be labeled and predicted on the image.

32.5.1 Multiscale Anchor Boxes

You may realize that it is not difficult to reduce anchor boxes on an image. For instance, we can just uniformly sample a small portion of pixels from the input image to generate anchor boxes centered on them. In addition, at different scales we can generate different numbers of anchor boxes of different sizes. Intuitively, smaller objects are more likely to appear on an image than larger ones. As an example, 1×1, 1×2, and 2×2 objects can appear on a 2×2 image in 4, 2, and 1 possible ways, respectively. Therefore, when using smaller anchor boxes to detect smaller objects, we can sample more regions, while for larger objects we can sample fewer regions.

To demonstrate how to generate anchor boxes at multiple scales, let's read an image. Its height and width are 561 and 728 pixels, respectively.

```
img = d2l.plt.imread('../img/catdog.jpg')
h, w = img.shape[:2]
h, w
```

```
(561, 728)
```

Recall that in Section 6.2 we call a two-dimensional array output of a convolutional layer a feature map. By defining the feature map shape, we can determine centers of uniformly sampled anchor boxes on any image.

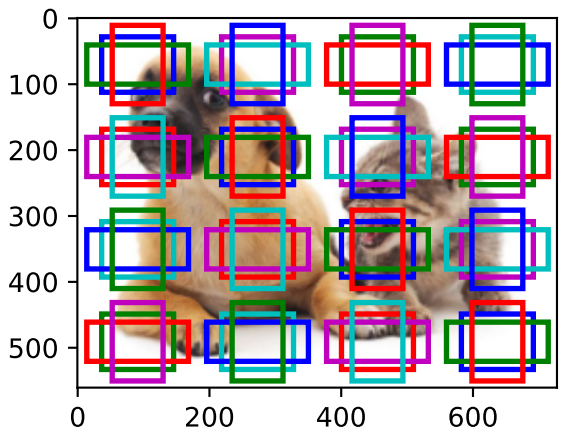
The `display_anchors` function is defined below. We generate anchor boxes (`anchors`) on the feature map (`fmap`) with each unit (pixel) as the anchor box center. Since the (x, y)-axis coordinate values in the anchor boxes (`anchors`) have been divided by the width and height of the feature map (`fmap`), these values are between 0 and 1, which indicate the relative positions of anchor boxes in the feature map.

Since centers of the anchor boxes (`anchors`) are spread over all units on the feature map (`fmap`), these centers must be *uniformly* distributed on any input image in terms of their relative spatial positions. More concretely, given the width and height of the feature map `fmap_w` and `fmap_h`, respectively, the following function will *uniformly* sample pixels in `fmap_h` rows and `fmap_w` columns on any input image. Centered on these uniformly sampled pixels, anchor boxes of scale `s` (assuming the length of the list `s` is 1) and different aspect ratios (`ratios`) will be generated.

```
def display_anchors(fmap_w, fmap_h, s):
    d2l.set_figsize()
    # Values on the first two dimensions do not affect the output
    fmap = tf.zeros((1, 10, fmap_h, fmap_w))
    anchors = d2l.multibox_prior(fmap, sizes=s, ratios=[1, 2, 0.5])
    bbox_scale = tf.constant((w, h, w, h), dtype=tf.float32)
    d2l.show_bboxes(d2l.plt.imshow(img).axes,
                    anchors[0] * bbox_scale)
```

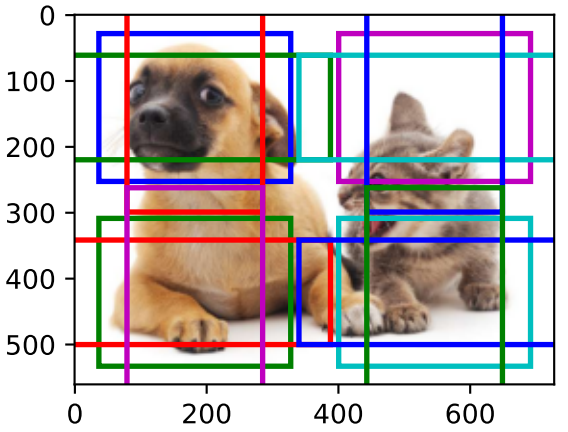
First, let's consider detection of small objects. In order to make it easier to distinguish when displayed, the anchor boxes with different centers here do not overlap: the anchor box scale is set to 0.15 and the height and width of the feature map are set to 4. We can see that the centers of the anchor boxes in 4 rows and 4 columns on the image are uniformly distributed.

```
display_anchors(fmap_w=4, fmap_h=4, s=[0.15])
```



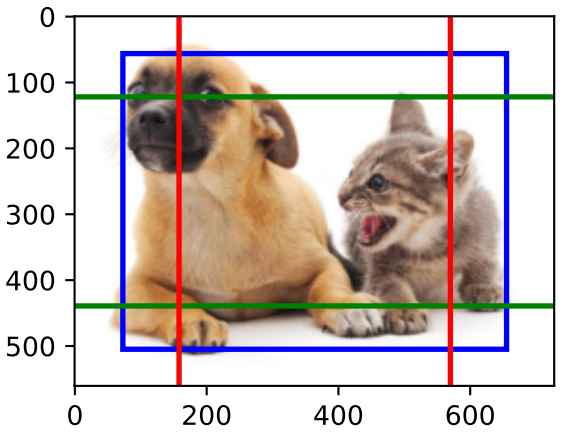
We move on to reduce the height and width of the feature map by half and use larger anchor boxes to detect larger objects. When the scale is set to 0.4, some anchor boxes will overlap with each other.

```
display_anchors(fmap_w=2, fmap_h=2, s=[0.4])
```



Finally, we further reduce the height and width of the feature map by half and increase the anchor box scale to 0.8. Now the center of the anchor box is the center of the image.

```
display_anchors(fmap_w=1, fmap_h=1, s=[0.8])
```



32.5.2 Multiscale Detection

Since we have generated multiscale anchor boxes, we will use them to detect objects of various sizes at different scales. In the following we introduce a CNN-based multiscale object detection method that we will implement in Section 32.7.

At some scale, say that we have c feature maps of shape $h \times w$. Using the method in Section 32.5.1, we generate hw sets of anchor boxes, where each set has a anchor boxes with the same center. For example, at the first scale in the experiments in Section 32.5.1, given ten (number of channels) 4×4 feature maps, we generated 16 sets of anchor boxes, where each set contains 3 anchor boxes with the same center. Next, each anchor box is labeled

with the class and offset based on ground-truth bounding boxes. At the current scale, the object detection model needs to predict the classes and offsets of hw sets of anchor boxes on the input image, where different sets have different centers.

Assume that the c feature maps here are the intermediate outputs obtained by the CNN forward propagation based on the input image. Since there are hw different spatial positions on each feature map, the same spatial position can be thought of as having c units. According to the definition of receptive field in Section 6.2, these c units at the same spatial position of the feature maps have the same receptive field on the input image: they represent the input image information in the same receptive field. Therefore, we can transform the c units of the feature maps at the same spatial position into the classes and offsets of the a anchor boxes generated using this spatial position. In essence, we use the information of the input image in a certain receptive field to predict the classes and offsets of the anchor boxes that are close to that receptive field on the input image.

When the feature maps at different layers have varying-size receptive fields on the input image, they can be used to detect objects of different sizes. For example, we can design a neural network where units of feature maps that are closer to the output layer have wider receptive fields, so they can detect larger objects from the input image.

In a nutshell, we can leverage layerwise representations of images at multiple levels by deep neural networks for multiscale object detection. We will show how this works through a concrete example in Section 32.7.

32.5.3 Summary

- At multiple scales, we can generate anchor boxes with different sizes to detect objects with different sizes.
- By defining the shape of feature maps, we can determine centers of uniformly sampled anchor boxes on any image.
- We use the information of the input image in a certain receptive field to predict the classes and offsets of the anchor boxes that are close to that receptive field on the input image.
- Through deep learning, we can leverage its layerwise representations of images at multiple levels for multiscale object detection.

32.5.4 Exercises

1. According to our discussions in Section 7.1, deep neural networks learn hierarchical features with increasing levels of abstraction for images. In multiscale object detection, do feature maps at different scales correspond to different levels of abstraction? Why or why not?
2. At the first scale (`fmap_w=4, fmap_h=4`) in the experiments in Section 32.5.1, generate uniformly distributed anchor boxes that may overlap.
3. Given a feature map variable with shape $1 \times c \times h \times w$, where c, h, and w are the number of channels, height, and width of the feature maps, respectively. How can you transform this variable into the classes and offsets of anchor boxes? What is the shape of the output?
4. Anchors on a coarse grid can miss an object even when their size matches it. Consider square anchors of side s in normalized coordinates, centered on an $f \times f$ grid as `display_anchors` generates them for ratio 1, and a square object of the same side whose center may lie anywhere.

1. Show that the smallest possible IoU between the object and its nearest anchor is $u^2/(2-u^2)$ with $u = \max(0, 1 - 1/(2fs))$.
2. Evaluate this for the three settings $(f, s) = (4, 0.15)$, $(2, 0.4)$, and $(1, 0.8)$ of Section 32.5.1. For $f = 1$, use the fact that the object has to lie inside the image.
3. How large must fs, the anchor side measured in grid steps, be for every such object to have an anchor with IoU at least 0.5, the threshold of `assign_anchor_to_bbox`?

5. Normalize `dog_bbox` and `cat_bbox` from Section 32.3 by the width and height of the image. For each of the three settings used with `display_anchors` in this section, compute with `d2l.box_iou` the largest IoU between each animal and the anchors, and report the six values in a table. Which setting fits each animal best? Then pool the 63 anchors of all three settings and label them with `d2l.multibox_target`. How many positive anchors does each animal get, and which step of the assignment algorithm in Section 32.4.3 produces them?

32.6 The Object Detection Dataset

There is no small dataset such as MNIST and Fashion-MNIST in the field of object detection. In order to quickly demonstrate object detection models, we collected and labeled a small dataset. First, we took photos of free bananas from our office and generated 1000 banana images with different rotations and sizes. Then we placed each banana image at a random position on some background image. In the end, we labeled bounding boxes for those bananas on the images.

32.6.1 Downloading the Dataset

The banana detection dataset with all the image and csv label files can be downloaded directly from the Internet.

```
import os
import pandas as pd
from PIL import Image
```

```
d2l.DATA_HUB['banana-detection'] = (
    d2l.DATA_URL + 'banana-detection.zip',
    '5de26c8fce5ccdea9f91267273464dc968d20d72')
```

32.6.2 Reading the Dataset

We are going to read the banana detection dataset in the `read_data_bananas` function below. The dataset includes a csv file for object class labels and ground-truth bounding box coordinates at the upper-left and lower-right corners.

```
def read_data_bananas(is_train=True):
    """Read the banana detection dataset images and labels."""
    from PIL import Image
    data_dir = d2l.download_extract('banana-detection')
```

```
    csv_fname = os.path.join(data_dir, 'bananas_train' if is_train
                             else 'bananas_val', 'label.csv')
    csv_data = pd.read_csv(csv_fname)
    csv_data = csv_data.set_index('img_name')
    images, targets = [], []
    for img_name, target in csv_data.iterrows():
        img = Image.open(
            os.path.join(data_dir, 'bananas_train' if is_train else
                         'bananas_val', 'images', f'{img_name}'))
        images.append(tf.constant(np.array(img), dtype=tf.float32))
        # Here `target` contains (class, upper-left x, upper-left y,
        # lower-right x, lower-right y), where all the images have the same
        # banana class (index 0)
        targets.append(list(target))
    return images, tf.expand_dims(tf.constant(targets, dtype=tf.float32),
                                  axis=1) / 256
```

By using the `read_data_bananas` function to read images and labels, the following `BananasDataset` class will allow us to create a customized dataset class for loading the banana detection dataset.

```
class BananasDataset:
    """A customized dataset to load the banana detection dataset."""
    def __init__(self, is_train):
        self.features, self.labels = read_data_bananas(is_train)
        print('read ' + str(len(self.features)) + (f' training examples' if
              is_train else f' validation examples'))

    def __getitem__(self, idx):
        return (self.features[idx], self.labels[idx])

    def __len__(self):
        return len(self.features)
```

Finally, we define the `load_data_bananas` function to return two data iterator instances for both the training and test sets. For the test dataset, there is no need to read it in random order.

```
def load_data_bananas(batch_size):
    """Load the banana detection dataset."""
    train_dataset = BananasDataset(is_train=True)
    val_dataset = BananasDataset(is_train=False)
    # Stack images: result shape is (N, H, W, C) — NHWC for TF
    train_images = tf.stack(train_dataset.features)
    val_images = tf.stack(val_dataset.features)
    train_iter = tf.data.Dataset.from_tensor_slices(
        (train_images, train_dataset.labels))
    # `drop_remainder=True` keeps every training minibatch the same
    # shape so the SSD `train_step` (`@tf.function`-wrapped at the call
    # site in :numref:`sec_ssd`) traces once per epoch shape instead of
    # retracing for the smaller last batch.
```

```
    train_iter = train_iter.shuffle(len(train_dataset.features)).batch(
        batch_size, drop_remainder=True).prefetch(tf.data.AUTOTUNE)
    val_iter = tf.data.Dataset.from_tensor_slices(
        (val_images, val_dataset.labels))
    val_iter = val_iter.batch(batch_size).prefetch(tf.data.AUTOTUNE)
    return train_iter, val_iter
```

Let's read a minibatch and print the shapes of both images and labels in this minibatch. The shape of the image minibatch looks familiar: it is the same as in our earlier image classification tasks. The shape of the label minibatch is (batch size, m, 5), where m is the largest possible number of bounding boxes that any image has in the dataset.

TensorFlow keeps the channels last, so the image minibatch has the shape (batch size, height, width, number of channels).

Although computation in minibatches is more efficient, it requires that all the image examples contain the same number of bounding boxes to form a minibatch via concatenation. In general, images may have a varying number of bounding boxes; thus, images with fewer than m bounding boxes will be padded with illegal bounding boxes until m is reached. Then the label of each bounding box is represented by an array of length 5. The first element in the array is the class of the object in the bounding box, where -1 indicates an illegal bounding box for padding. The remaining four elements of the array are the (x, y)-coordinate values of the upper-left corner and the lower-right corner of the bounding box (the range is between 0 and 1). For the banana dataset, since there is only one bounding box on each image, we have $m = 1$.

```
batch_size, edge_size = 32, 256
train_iter, _ = load_data_bananas(batch_size)
batch = next(iter(train_iter))
batch[0].shape, batch[1].shape
```

```
read 1000 training examples
read 100 validation examples
```

```
(TensorShape([32, 256, 256, 3]), TensorShape([32, 1, 5]))
```

32.6.3 Demonstration

Let's demonstrate ten images with their labeled ground-truth bounding boxes. We can see that the rotations, sizes, and positions of bananas vary across all these images. Of course, this is just a simple artificial dataset. In practice, real-world datasets are usually much more complicated.

```
# Images are already NHWC (H, W, C) in TF; normalize to [0, 1]
imgs = batch[0][:10] / 255
axes = d2l.show_images(imgs, 2, 5, scale=2)
for ax, label in zip(axes, batch[1][:10]):
    d2l.show_bboxes(ax, [label[0][1:5] * edge_size], colors=['w'])
```

32.6.4 Summary

- The banana detection dataset we collected can be used to demonstrate object detection models.
- The data loading for object detection is similar to that for image classification. However, in object detection the labels also contain information of ground-truth bounding boxes, which is missing in image classification.

32.6.5 Exercises

1. Demonstrate other images with ground-truth bounding boxes in the banana detection dataset. How do they differ with respect to bounding boxes and objects?
2. Say that we want to apply data augmentation, such as random cropping, to object detection. How can it be different from that in image classification? Hint: what if a cropped image only contains a small portion of an object?
3. Compute the width, height, aspect ratio (width divided by height), and area of every training box returned by `read_data_bananas`, in units of the image size. Plot their histograms and report the minimum, median, and maximum of each. Then generate one anchor per position (size 0.2, ratio 1) with `d2l.multibox_prior` on feature maps of size 4×4, 8×8, 16×16, and 32×32, and use `d2l.box_iou` to report for each the fraction of training boxes whose best anchor has IoU at least 0.5. What is the coarsest feature map that covers at least 99% of the boxes? On the 8×8 map, how much does adding the sizes and ratios of your choice raise the fraction, compared with halving the grid step?
4. Implement the random crop of problem 2 for the banana dataset: crop a random 192×192 window from each 256×256 training image, resize the window back to 256×256, and shift, clip, and rescale the box label accordingly. Plot a few augmented images with their boxes to check the labels. Report the fraction of training images in which less than half of the banana's area remains inside the window. What label would you give such an image?
5. Images with fewer than m boxes are padded with illegal boxes of class -1. Check what the implementation of `multibox_target` in Section 32.4 does with such a box: append the row `[-1, 0, 0, 0, 0]` to the dog and cat labels of the example in Section 32.4.3, and compare the returned class labels, masks, and offsets with and without it.
    1. Which anchor does the loop in `assign_anchor_to_bbox` assign to the padding box,

and why that one?
2. What class label, mask, and offset label does that anchor receive, and how would they affect the loss of a detector trained on these labels?
3. Modify `multibox_target` so that it ignores padding boxes, and check that its output then matches the unpadded case.

32.7 Single Shot Multibox Detection

In Section 32.3 to Section 32.6, we introduced bounding boxes, anchor boxes, multiscale object detection, and the dataset for object detection. Now we are ready to use such background knowledge to design an object detection model: single shot multibox detection (SSD) (W. Liu et al. 2016). This model is simple, fast, and widely used. Although this is just one of vast amounts of object detection models, some of the design principles and implementation details in this section are also applicable to other models.

32.7.1 Model

Figure 32.4 provides an overview of the design of single-shot multibox detection. This model mainly consists of a base network followed by several multiscale feature map blocks. The base network is for extracting features from the input image, so it can use a deep CNN. For example, the original single-shot multibox detection paper adopts a VGG network truncated before the classification layer (W. Liu et al. 2016), while ResNet has also been commonly used. Through our design we can make the base network output larger feature maps so as to generate more anchor boxes for detecting smaller objects. Subsequently, each multiscale feature map block reduces (e.g., by half) the height and width of the feature maps from the previous block, and enables each unit of the feature maps to increase its receptive field on the input image.

Recall the design of multiscale object detection through layerwise representations of images by deep neural networks in Section 32.5. Since multiscale feature maps closer to the top of Figure 32.4 are smaller but have larger receptive fields, they are suitable for detecting fewer but larger objects.

In a nutshell, via its base network and several multiscale feature map blocks, single-shot multibox detection generates a varying number of anchor boxes with different sizes, and detects varying-size objects by predicting classes and offsets of these anchor boxes (thus the bounding boxes); this is therefore a multiscale object detection model.

In the following, we will describe the implementation details of different blocks in Figure 32.4. To begin with, we discuss how to implement the class and bounding box prediction.

32.7.1.1 Class Prediction Layer

Let the number of object classes be q. Then anchor boxes have $q + 1$ classes, where class 0 is background. At some scale, suppose that the height and width of feature maps are h and w, respectively. When a anchor boxes are generated with each spatial position of these feature maps as their center, a total of hwa anchor boxes need to be classified. This often makes classification with fully connected layers infeasible due to likely heavy parametrization costs. Recall how we used channels of convolutional layers to predict classes in Sec-

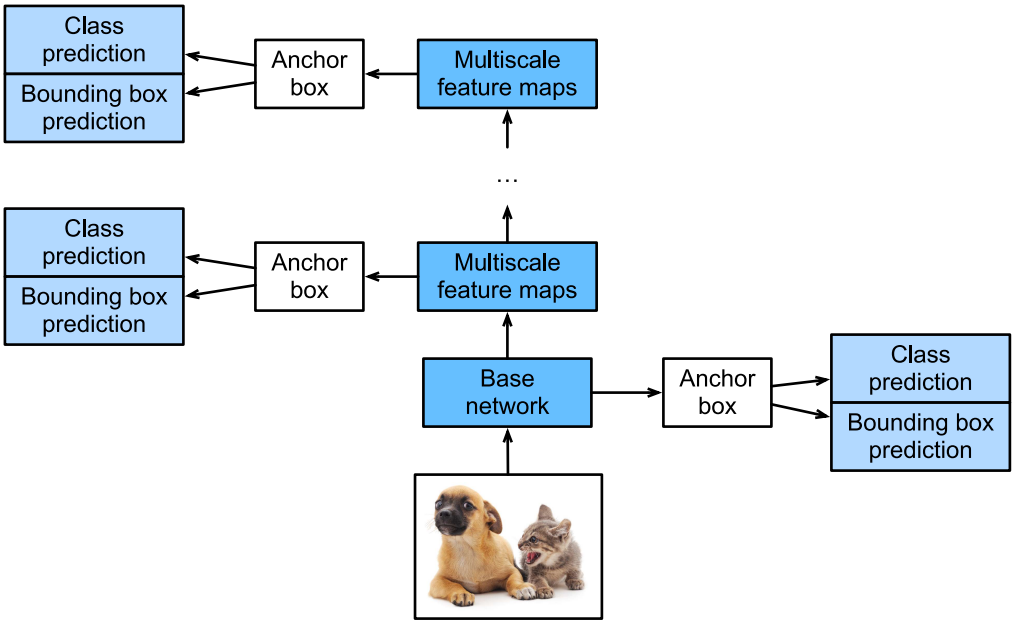


Figure 32.4: As a multiscale object detection model, single-shot multibox detection mainly consists of a base network followed by several multiscale feature map blocks.

tion 7.2.2. Single-shot multibox detection uses the same technique to reduce model complexity.

Specifically, the class prediction layer uses a convolutional layer without altering width or height of feature maps. In this way, there can be a one-to-one correspondence between outputs and inputs at the same spatial dimensions (width and height) of feature maps. More concretely, channels of the output feature maps at any spatial position (x, y) represent class predictions for all the anchor boxes centered on (x, y) of the input feature maps. To produce valid predictions, there must be $a(q+1)$ output channels, where for the same spatial position the output channel with index $i(q+1)+j$ represents the prediction of the class j $(0 \leq j \leq q)$ for the anchor box i $(0 \leq i < a)$.

Below we define such a class prediction layer, specifying a and q via arguments `num_anchors` and `num_classes`, respectively. This layer uses a 3×3 convolutional layer with a padding of 1. The width and height of the input and output of this convolutional layer remain unchanged.

```
from tensorflow import keras
```

```
def cls_predictor(num_anchors, num_classes):
    return keras.layers.Conv2D(num_anchors * (num_classes + 1),
                               kernel_size=3, padding='same')
```

32.7.1.2 Bounding Box Prediction Layer

The design of the bounding box prediction layer is similar to that of the class prediction layer. The only difference lies in the number of outputs for each anchor box: here we need

to predict four offsets rather than $q + 1$ classes.

```
def bbox_predictor(num_anchors):
    return keras.layers.Conv2D(num_anchors * 4, kernel_size=3, padding='same')
```

32.7.1.3 Concatenating Predictions for Multiple Scales

As we mentioned, single-shot multibox detection uses multiscale feature maps to generate anchor boxes and predict their classes and offsets. At different scales, the shapes of feature maps or the numbers of anchor boxes centered on the same unit may vary. Therefore, shapes of the prediction outputs at different scales may vary.

In the following example, we construct feature maps at two different scales, `Y1` and `Y2`, for the same minibatch, where the height and width of `Y2` are half of those of `Y1`. Let's take class prediction as an example. Suppose that 5 and 3 anchor boxes are generated for every unit in `Y1` and `Y2`, respectively. Suppose further that the number of object classes is 10. For feature maps `Y1` and `Y2` the numbers of channels in the class prediction outputs are $5\times(10+1) = 55$ and $3 \times (10 + 1) = 33$, respectively.

Either output shape is (batch size, height, width, number of channels), since Keras convolutions keep the channels last.

```
def forward(x, block):
    # Keras uses NHWC format; input shape: (N, H, W, C)
    return block(x)

Y1 = forward(tf.zeros((2, 20, 20, 8)), cls_predictor(5, 10))
Y2 = forward(tf.zeros((2, 10, 10, 16)), cls_predictor(3, 10))
Y1.shape, Y2.shape
```

```
(TensorShape([2, 20, 20, 55]), TensorShape([2, 10, 10, 33]))
```

As we can see, except for the batch size dimension, the other three dimensions all have different sizes. To concatenate these two prediction outputs for more efficient computation, we will transform these tensors into a more consistent format.

Note that the channel dimension holds the predictions for anchor boxes with the same center.

This dimension is already the innermost.

Since the batch size remains the same for different scales, we can transform the prediction output into a two-dimensional tensor with shape (batch size, height $\times$ width $\times$ number of channels). Then we can concatenate such outputs at different scales along dimension 1.

```
def flatten_pred(pred):
    # pred is (N, H, W, C); flatten H*W*C with channel innermost so that
    # the resulting layout matches multibox_prior's anchor ordering
    return tf.reshape(pred, (tf.shape(pred)[0], -1))

def concat_preds(preds):
    return tf.concat([flatten_pred(p) for p in preds], axis=1)
```

In this way, even though `Y1` and `Y2` have different sizes in channels, heights, and widths, we can still concatenate these two prediction outputs at two different scales for the same minibatch.

```
concat_preds([Y1, Y2]).shape
```

```
TensorShape([2, 25300])
```

32.7.1.4 Downsampling Block

In order to detect objects at multiple scales, we define the following downsampling block that halves the height and width of input feature maps. In fact, this block applies the design of VGG blocks in Section 7.2.1.1. More concretely, each downsampling block consists of two 3×3 convolutional layers with padding of 1 followed by a 2×2 max-pooling layer with stride of 2. As we know, 3×3 convolutional layers with padding of 1 do not change the shape of feature maps. However, the subsequent 2×2 max-pooling reduces the height and width of input feature maps by half. For both input and output feature maps of this downsampling block, because $1 \times 2 + (3 - 1) + (3 - 1) = 6$, each unit in the output has a 6×6 receptive field on the input. Therefore, the downsampling block enlarges the receptive field of each unit in its output feature maps.

```
def down_sample_blk(num_channels):
    blk = keras.Sequential()
    for _ in range(2):
        blk.add(keras.layers.Conv2D(num_channels, kernel_size=3,
                                    padding='same'))
        # Running averages decay 0.9 and epsilon is 1e-5
        blk.add(keras.layers.BatchNormalization(momentum=0.9, epsilon=1e-5))
        blk.add(keras.layers.ReLU())
    blk.add(keras.layers.MaxPool2D(pool_size=2, strides=2))
    return blk
```

In the following example, our constructed downsampling block changes the number of input channels and halves the height and width of the input feature maps.

```
forward(tf.zeros((2, 20, 20, 3)), down_sample_blk(10)).shape
```

```
TensorShape([2, 10, 10, 10])
```

32.7.1.5 Base Network Block

The base network block is used to extract features from input images. For simplicity, we construct a small base network consisting of three downsampling blocks that double the number of channels at each block. Given a 256×256 input image, this base network block outputs 32×32 feature maps ($256/2^3 = 32$).

```
def base_net():
    blk = keras.Sequential()
    for num_filters in [16, 32, 64]:
```

```
        blk.add(down_sample_blk(num_filters))
    return blk

forward(tf.zeros((2, 256, 256, 3)), base_net()).shape
```

```
TensorShape([2, 32, 32, 64])
```

32.7.1.6 The Complete Model

The complete single shot multibox detection model consists of five blocks. The feature maps produced by each block are used for both (i) generating anchor boxes and (ii) predicting classes and offsets of these anchor boxes. Among these five blocks, the first one is the base network block, the second to the fourth are downsampling blocks, and the last block uses global max-pooling to reduce both the height and width to 1. Technically, the second to the fifth blocks are all those multiscale feature map blocks in Figure 32.4.

```
def get_blk(i):
    if i == 0:
        return base_net()
    elif i == 4:
        return keras.layers.GlobalMaxPool2D(keepdims=True)
    else:
        return down_sample_blk(128)
```

Now we define the forward propagation for each block. Different from in image classification tasks, outputs here include (i) CNN feature maps `Y`, (ii) anchor boxes generated using `Y` at the current scale, and (iii) classes and offsets predicted (based on `Y`) for these anchor boxes.

```
def blk_forward(X, blk, size, ratio, cls_predictor, bbox_predictor,
                training=False):
    Y = blk(X, training=training)
    # Keras uses NHWC; multibox_prior expects NCHW (shape[-2:] = H, W)
    Y_nchw = tf.transpose(Y, (0, 3, 1, 2))
    anchors = d2l.multibox_prior(Y_nchw, sizes=size, ratios=ratio)
    # Keep cls_preds and bbox_preds in NHWC; flatten_pred relies on the
    # channel-last memory layout to align with multibox_prior's anchor order
    cls_preds = cls_predictor(Y, training=training)
    bbox_preds = bbox_predictor(Y, training=training)
    return (Y, anchors, cls_preds, bbox_preds)
```

Recall that in Figure 32.4 a multiscale feature map block that is closer to the top is for detecting larger objects; thus, it needs to generate larger anchor boxes. In the above forward propagation, at each multiscale feature map block we pass in a list of two scale values via the `sizes` argument of the invoked `multibox_prior` function (described in Section 32.4). In the following, the interval between 0.2 and 1.05 is split evenly into five sections to determine the smaller scale values at the five blocks: 0.2, 0.37, 0.54, 0.71, and 0.88. Then their larger scale values are given by $\sqrt{0.2 \times 0.37} = 0.272$, $\sqrt{0.37 \times 0.54} = 0.447$, and so on.

```
sizes = [[0.2, 0.272], [0.37, 0.447], [0.54, 0.619], [0.71, 0.79],
         [0.88, 0.961]]
ratios = [[1, 2, 0.5]] * 5
num_anchors = len(sizes[0]) + len(ratios[0]) - 1
```

Now we can define the complete model `TinySSD` as follows.

```
class TinySSD(keras.Model):
    def __init__(self, num_classes, **kwargs):
        super().__init__(**kwargs)
        self.num_classes = num_classes
        self.cls_loss = keras.losses.SparseCategoricalCrossentropy(
            from_logits=True)
        for i in range(5):
            # Equivalent to: self.blk_i, self.cls_i, self.bbox_i
            setattr(self, f'blk_{i}', get_blk(i))
            setattr(self, f'cls_{i}', cls_predictor(num_anchors, num_classes))
            setattr(self, f'bbox_{i}', bbox_predictor(num_anchors))

    def call(self, X, training=False):
        anchors_list = [None] * 5
        cls_preds_list = [None] * 5
        bbox_preds_list = [None] * 5
        # X is expected in NHWC layout (the Keras default)
        for i in range(5):
            blk = getattr(self, f'blk_{i}')
            cls_pred = getattr(self, f'cls_{i}')
            bbox_pred = getattr(self, f'bbox_{i}')
            X, anchors_list[i], cls_preds_list[i], bbox_preds_list[i] = \
                blk_forward(X, blk, sizes[i], ratios[i],
                            cls_pred, bbox_pred, training=training)
        anchors = tf.concat(anchors_list, axis=1)
        cls_preds = concat_preds(cls_preds_list)
        cls_preds = tf.reshape(cls_preds,
                               (tf.shape(cls_preds)[0], -1,
                                self.num_classes + 1))
        bbox_preds = concat_preds(bbox_preds_list)
        return anchors, cls_preds, bbox_preds

    def _compute_ssd_loss(self, cls_preds, cls_labels, bbox_preds,
                          bbox_labels, bbox_masks):
        num_classes = self.num_classes + 1
        cls = self.cls_loss(
            tf.reshape(cls_labels, [-1]),
            tf.reshape(cls_preds, [-1, num_classes]))
        bbox = tf.reduce_mean(
            tf.abs((bbox_preds * bbox_masks) -
                   (bbox_labels * bbox_masks)))
        return cls + bbox

    def train_step(self, data):
        features, target = data
```

```
        with tf.GradientTape() as tape:
            anchors, cls_preds, bbox_preds = self(features, training=True)
            bbox_labels, bbox_masks, cls_labels = d2l.multibox_target(
                anchors, target)
            loss = self._compute_ssd_loss(cls_preds, cls_labels,
                                          bbox_preds, bbox_labels, bbox_masks)
        grads = tape.gradient(loss, self.trainable_variables)
        self.optimizer.apply_gradients(zip(grads, self.trainable_variables))
        # Accumulate metrics without syncing large tensors to host
        cls_correct = tf.reduce_sum(
            tf.cast(tf.argmax(cls_preds, axis=-1) ==
                    tf.cast(cls_labels, tf.int64), tf.int64))
        cls_total = tf.cast(tf.size(cls_labels), tf.int64)
        bbox_abs = tf.reduce_sum(
            tf.abs((bbox_preds * bbox_masks) - (bbox_labels * bbox_masks)))
        bbox_total = tf.cast(tf.size(bbox_labels), tf.float32)
        return {'loss': loss,
                'cls_correct': cls_correct, 'cls_total': cls_total,
                'bbox_abs': bbox_abs, 'bbox_total': bbox_total}
```

We create a model instance and use it to perform forward propagation on a minibatch of 256×256 images `X`.

As shown earlier in this section, the first block outputs 32×32 feature maps. Recall that the second to fourth downsampling blocks halve the height and width and the fifth block uses global pooling. Since 4 anchor boxes are generated for each unit along spatial dimensions of feature maps, at all the five scales a total of $(32^2 + 16^2 + 8^2 + 4^2 + 1) \times 4 = 5444$ anchor boxes are generated for each image.

```
net = TinySSD(num_classes=1)
X = tf.zeros((32, 256, 256, 3))  # NHWC for Keras
anchors, cls_preds, bbox_preds = net(X)

print('output anchors:', anchors.shape)
print('output class preds:', cls_preds.shape)
print('output bbox preds:', bbox_preds.shape)
```

```
output anchors: (1, 5444, 4)
output class preds: (32, 5444, 2)
output bbox preds: (32, 21776)
```

32.7.2 Training

Now we will explain how to train the single shot multibox detection model for object detection.

32.7.2.1 Reading the Dataset and Initializing the Model

To begin with, let's read the banana detection dataset described in Section 32.6.

```
batch_size = 32
train_iter, _ = d2l.load_data_bananas(batch_size)
```

```
read 1000 training examples
read 100 validation examples
```

There is only one class in the banana detection dataset. After defining the model, we need to initialize its parameters and define the optimization algorithm.

```
net = TinySSD(num_classes=1)
net.compile(optimizer=keras.optimizers.SGD(learning_rate=0.2,
                                           weight_decay=5e-4))
```

32.7.2.2 Defining Loss and Evaluation Functions

Object detection has two types of losses. The first loss concerns classes of anchor boxes: its computation can simply reuse the cross-entropy loss function that we used for image classification. The second loss concerns offsets of positive (non-background) anchor boxes: this is a regression problem. For this regression problem, however, here we do not use the squared loss described in Section 2.1.3. Instead, we use the ℓ_1 norm loss, the absolute value of the difference between the prediction and the ground-truth. The mask variable `bbox_masks` filters out negative anchor boxes and illegal (padded) anchor boxes in the loss calculation. In the end, we sum up the anchor box class loss and the anchor box offset loss to obtain the loss function for the model.

```
# Loss functions are encapsulated in TinySSD._compute_ssd_loss and
# train_step; these module-level helpers mirror the other frameworks for
# use in evaluation after training.
_cls_loss = keras.losses.SparseCategoricalCrossentropy(
    from_logits=True, reduction='none')

def calc_loss(cls_preds, cls_labels, bbox_preds, bbox_labels, bbox_masks):
    batch_size = cls_preds.shape[0]
    num_classes = cls_preds.shape[2]
    # Per-example mean cross-entropy over anchors (shape: (batch_size,))
    cls = tf.reduce_mean(
        tf.reshape(_cls_loss(tf.reshape(cls_labels, [-1]),
                             tf.reshape(cls_preds, [-1, num_classes])),
                   [batch_size, -1]),
        axis=1)
    # Per-example mean L1 bbox loss (shape: (batch_size,)) to match PT/JAX
    bbox = tf.reduce_mean(
        tf.abs((bbox_preds - bbox_labels) * bbox_masks), axis=1)
    return cls + bbox
```

We can use accuracy to evaluate the classification results. Due to the used ℓ_1 norm loss for the offsets, we use the *mean absolute error* to evaluate the predicted bounding boxes. These prediction results are obtained from the generated anchor boxes and the predicted offsets for them.

```
def cls_eval(cls_preds, cls_labels):
    # Because the class prediction results are on the final dimension,
    # `argmax` needs to specify this dimension
    return float(tf.reduce_sum(
        tf.cast(tf.argmax(cls_preds, axis=-1) ==
                tf.cast(cls_labels, tf.int64), tf.int64)))

def bbox_eval(bbox_preds, bbox_labels, bbox_masks):
    return float(tf.reduce_sum(
        tf.abs((bbox_labels - bbox_preds) * bbox_masks)))
```

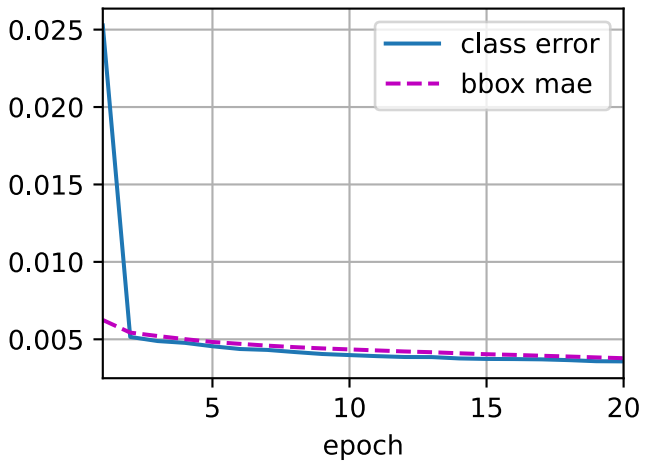
32.7.2.3 Training the Model

When training the model, we need to generate multiscale anchor boxes (`anchors`) and predict their classes (`cls_preds`) and offsets (`bbox_preds`) in the forward propagation. Then we label the classes (`cls_labels`) and offsets (`bbox_labels`) of such generated anchor boxes based on the label information `Y`. Finally, we calculate the loss function using the predicted and labeled values of the classes and offsets. For concise implementations, evaluation of the test dataset is omitted here.

```
num_epochs, timer = 20, d2l.Timer()
animator = d2l.Animator(xlabel='epoch', xlim=[1, num_epochs],
                        legend=['class error', 'bbox mae'])
# Anchors depend only on the input *shape*, so for a fixed input size
# they're constant across the epoch. Grab them once here and reuse
# them in every batch's multibox_target call — saves one forward pass
# per step.
sample_features, _ = next(iter(train_iter))
sample_features = tf.cast(sample_features, tf.float32)
anchors_static, _, _ = net(sample_features, training=False)
# `multibox_target` mixes TF ops with NumPy / `.numpy()` calls, which
# can't run inside `@tf.function`. We keep it eager and only put the
# pure-TF gradient step under @tf.function. The wrapper closes over
# `net` so its trainable variables aren't @tf.function arguments
# (which would re-trace each call) — same pattern that worked for
# gan / dcgan.
@tf.function(reduce_retracing=True)
def _grad_step(features, bbox_labels, bbox_masks, cls_labels):
    with tf.GradientTape() as tape:
        _, cls_preds, bbox_preds = net(features, training=True)
        loss = net._compute_ssd_loss(cls_preds, cls_labels, bbox_preds,
                                     bbox_labels, bbox_masks)
    grads = tape.gradient(loss, net.trainable_variables)
    net.optimizer.apply_gradients(zip(grads, net.trainable_variables))
    cls_correct = tf.reduce_sum(
        tf.cast(tf.argmax(cls_preds, axis=-1) ==
                tf.cast(cls_labels, tf.int64), tf.int64))
    cls_total = tf.cast(tf.size(cls_labels), tf.int64)
    bbox_abs = tf.reduce_sum(
        tf.abs((bbox_preds * bbox_masks) - (bbox_labels * bbox_masks)))
    bbox_total = tf.cast(tf.size(bbox_labels), tf.float32)
```

```
    return loss, cls_correct, cls_total, bbox_abs, bbox_total
for epoch in range(num_epochs):
    # Accumulate metrics as TF tensors so the inner loop never forces
    # a host sync (the per-batch `int(logs['cls_correct'])` was a
    # significant bottleneck before).
    cls_correct_sum = tf.zeros((), dtype=tf.int64)
    cls_total = tf.zeros((), dtype=tf.int64)
    bbox_abs_total = tf.zeros((), dtype=tf.float32)
    bbox_total = tf.zeros((), dtype=tf.float32)
    for features, target in train_iter:
        timer.start()
        features = tf.cast(features, tf.float32)
        target = tf.cast(target, tf.float32)
        bbox_labels, bbox_masks, cls_labels = d2l.multibox_target(
            anchors_static, target)
        _, cc, ct, ba, bt = _grad_step(features, bbox_labels,
                                       bbox_masks, cls_labels)
        cls_correct_sum += cc
        cls_total += ct
        bbox_abs_total += ba
        bbox_total += bt
    cls_err = float(1 - cls_correct_sum / cls_total)
    bbox_mae = float(bbox_abs_total / bbox_total)
    animator.add(epoch + 1, (cls_err, bbox_mae))
print(f'class err {cls_err:.2e}, bbox mae {bbox_mae:.2e}')
print(f'{len(train_iter) * batch_size / timer.stop():.1f} examples/sec')
```

```
class err 3.57e-03, bbox mae 3.78e-03
1878.9 examples/sec
```



32.7.3 Prediction

During prediction, the goal is to detect all the objects of interest on the image. Below we read and resize a test image, converting it to a four-dimensional tensor that is required by convolutional layers.

```
from PIL import Image as PILImage
img_pil = PILImage.open('../img/banana.jpg')
img = np.array(img_pil)
# img is (H, W, C); add batch dim for NHWC input
X = tf.expand_dims(tf.cast(img, tf.float32), axis=0)
```

Using the `multibox_detection` function below, the predicted bounding boxes are obtained from the anchor boxes and their predicted offsets. Then non-maximum suppression is used to remove similar predicted bounding boxes.

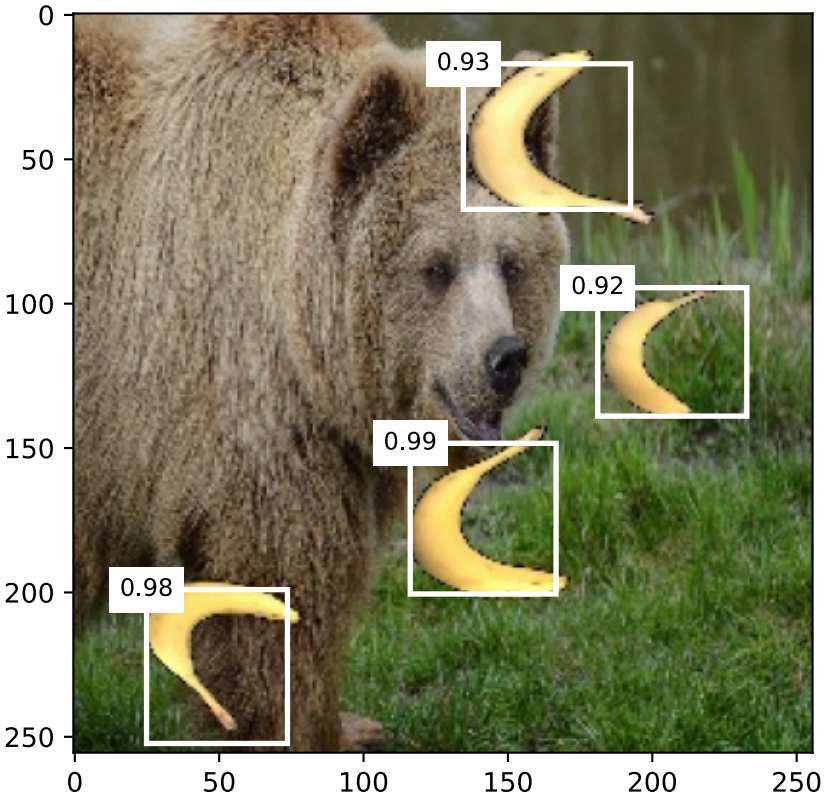
```
def predict(X):
    anchors, cls_preds, bbox_preds = net(X, training=False)
    # cls_preds: (batch, num_anchors, num_classes+1) -> softmax -> transpose
    # to (batch, num_classes+1, num_anchors) for multibox_detection
    cls_probs = tf.transpose(tf.nn.softmax(cls_preds, axis=-1), (0, 2, 1))
    output = d2l.multibox_detection(cls_probs, bbox_preds, anchors)
    # Drop padding rows (class index -1).
    mask = output[0, :, 0] != -1
    idx = tf.where(mask)[:, 0]
    return tf.gather(output[0], idx)

output = predict(X)
```

Finally, we display all the predicted bounding boxes with confidence 0.9 or above as output.

```
def display(img, output, threshold):
    d2l.set_figsize((5, 5))
    fig = d2l.plt.imshow(img)
    for row in output:
        score = float(row[1])
        if score < threshold:
            continue
        h, w = img.shape[:2]
        bbox = [row[2:6] * np.array((w, h, w, h), dtype=np.float32)]
        d2l.show_bboxes(fig.axes, bbox, '%.2f' % score, 'w')

display(img, output, threshold=0.9)
```



32.7.4 Summary

- Single shot multibox detection is a multiscale object detection model. Via its base network and several multiscale feature map blocks, single-shot multibox detection generates a varying number of anchor boxes with different sizes, and detects varying-size objects by predicting classes and offsets of these anchor boxes (thus the bounding boxes).
- When training the single-shot multibox detection model, the loss function is calculated based on the predicted and labeled values of the anchor box classes and offsets.

32.7.5 Exercises

1. Can you improve the single-shot multibox detection by improving the loss function? For example, replace ℓ_1 norm loss with smooth ℓ_1 norm loss for the predicted offsets. This loss function uses a square function around zero for smoothness, which is controlled by the hyperparameter σ:

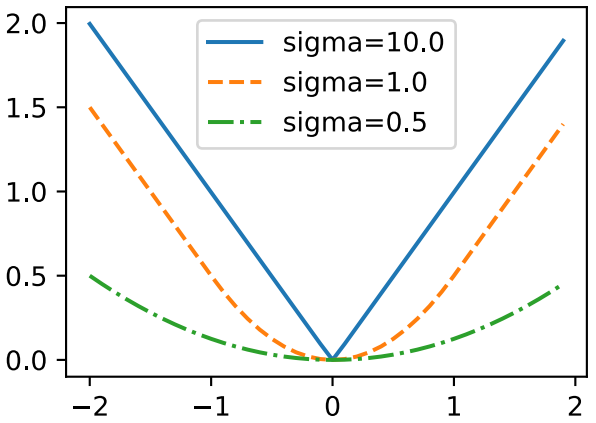
$$f(x) = \begin{cases} (\sigma x)^2/2, & \text{if } |x| < 1/\sigma^2 \\ |x| - 0.5/\sigma^2, & \text{otherwise} \end{cases}$$

When σ is very large, this loss is similar to the ℓ_1 norm loss. When its value is smaller, the loss function is smoother.

```
def smooth_l1(data, scalar):
    cond = tf.abs(data) < 1 / (scalar ** 2)
    quad = (scalar * data) ** 2 / 2
    lin = tf.abs(data) - 0.5 / (scalar ** 2)
    return tf.where(cond, quad, lin)

sigmas = [10, 1, 0.5]
lines = ['-', '--', '-.']
x = tf.range(-2.0, 2.0, 0.1)
d2l.set_figsize()

for l, s in zip(lines, sigmas):
    y = smooth_l1(x, scalar=s)
    d2l.plt.plot(x, y, l, label='sigma=%.1f' % s)
d2l.plt.legend();
```



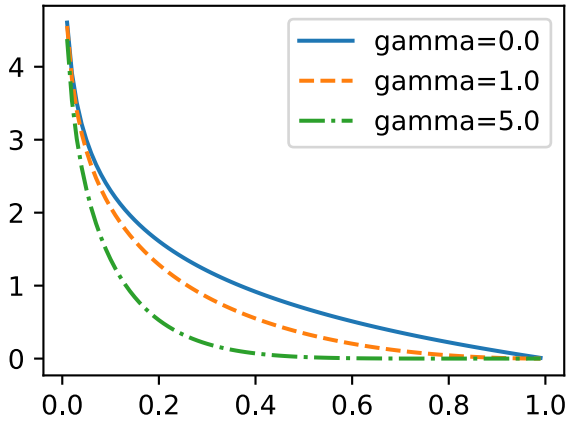
Besides, in the experiment we used cross-entropy loss for class prediction: denoting by p_j the predicted probability for the ground-truth class j, the cross-entropy loss is $-\log p_j$. We can also use the focal loss (T.-Y. Lin et al. 2017): given hyperparameters $\gamma > 0$ and $\alpha > 0$, this loss is defined as:

$$-\alpha(1-p_j)^\gamma \log p_j. \tag{32.4}$$

As we can see, increasing γ can effectively reduce the relative loss for well-classified examples (e.g., $p_j > 0.5$) so the training can focus more on those difficult examples that are misclassified.

```
def focal_loss(gamma, x):
    return -(1 - x) ** gamma * tf.math.log(x)

x = tf.range(0.01, 1.0, 0.01)
for l, gamma in zip(lines, [0, 1, 5]):
    y = d2l.plt.plot(x, focal_loss(gamma, x), l, label='gamma=%.1f' % gamma)
d2l.plt.legend();
```



2. Due to space limitations, we have omitted some implementation details of the single shot multibox detection model in this section. Can you further improve the model in the following aspects:
    1. When an object is much smaller compared with the image, the model could resize the input image bigger.
    2. There are typically a vast number of negative anchor boxes. To make the class distribution more balanced, we could downsample negative anchor boxes.
    3. In the loss function, assign different weight hyperparameters to the class loss and the offset loss.
    4. Use other methods to evaluate the object detection model, such as those in the single shot multibox detection paper (W. Liu et al. 2016).
3. Apply `d2l.multibox_target` to the anchors returned by `net` and to one minibatch of labels from `train_iter`, and count the positive (non-background) anchors of each image. What fraction of the 5444 anchors is positive? Compute the class error of a trivial model that labels every anchor as background, and compare it with the class error printed after training. What does the comparison say about class error as a measure of detection quality?
4. The text shows that one downsampling block gives each output unit a 6×6 receptive field. Extend the calculation to `TinySSD` with a 256×256 input, where `blk_0` consists of three downsampling blocks. A layer with kernel size k and stride s enlarges the receptive field by $k - 1$ times the accumulated stride j of its input and multiplies j by s. For the outputs of `blk_0` to `blk_3`, compute the stride j in input pixels and the receptive field of one unit of the 3×3 prediction layers applied to them. Compare each receptive field with the anchor sizes at that scale (256 times the entries of `sizes`). At which scales is the receptive field smaller than the largest anchor it has to classify? Why does `blk_4` need no such calculation?
5. The training loop omits evaluation. `d2l.load_data_bananas` also returns an iterator over the 100 validation images, each of which contains one banana. For each validation image, take the box with the highest confidence among the outputs of `predict` and compute its IoU with the ground-truth box using `d2l.box_iou`. Report the mean IoU and the fraction of images whose IoU is at least 0.5, and draw the three images with the lowest IoU together with both boxes. What do these failures have in common?

32.8 Region-based CNNs (R-CNNs)

Besides single shot multibox detection described in Section 32.7, region-based CNNs or regions with CNN features (R-CNNs) are also among many pioneering approaches of applying deep learning to object detection (Girshick et al. 2014). In this section, we will introduce the R-CNN and its series of improvements: the fast R-CNN (Girshick 2015), the faster R-CNN (Ren et al. 2015), and the mask R-CNN (K. He et al. 2017). Due to limited space, we will only focus on the design of these models.

32.8.1 R-CNNs

The *R-CNN* first extracts many (e.g., 2000) *region proposals* from the input image (e.g., anchor boxes can also be considered as region proposals), labeling their classes and bounding boxes (e.g., offsets). (Girshick et al. 2014) Then a CNN is used to perform forward propagation on each region proposal to extract its features. Next, features of each region proposal are used for predicting the class and bounding box of this region proposal.

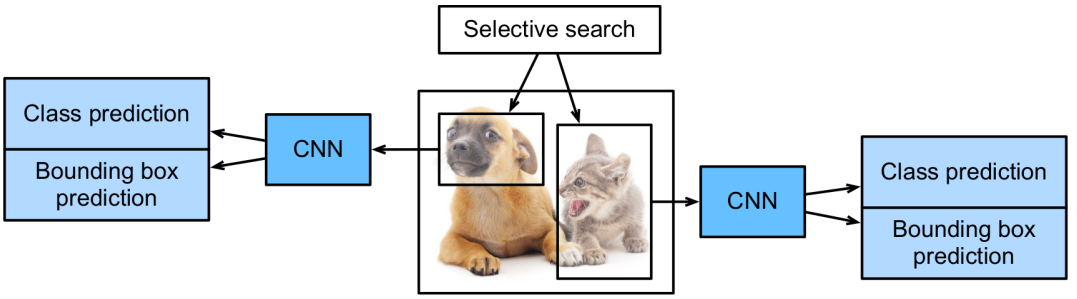


Figure 32.5: The R-CNN model.

Figure 32.5 shows the R-CNN model. More concretely, the R-CNN consists of the following four steps:

1. Perform *selective search* to extract multiple high-quality region proposals on the input image (Uijlings et al. 2013). These proposed regions are usually selected at multiple scales with different shapes and sizes. Each region proposal will be labeled with a class and a ground-truth bounding box.
2. Choose a pretrained CNN and truncate it before the output layer. Resize each region proposal to the input size required by the network, and output the extracted features for the region proposal through forward propagation.
3. Take the extracted features and labeled class of each region proposal as an example. Train multiple support vector machines to classify objects, where each support vector machine individually determines whether the example contains a specific class.
4. Take the extracted features and labeled bounding box of each region proposal as an example. Train a linear regression model to predict the ground-truth bounding box.

Although the R-CNN model uses pretrained CNNs to effectively extract image features, it is slow. Imagine that we select thousands of region proposals from a single input image: this requires thousands of CNN forward propagations to perform object detection. This massive computing load makes it infeasible to widely use R-CNNs in real-world applications.

32.8.2 Fast R-CNN

The main performance bottleneck of an R-CNN lies in the independent CNN forward propagation for each region proposal, without sharing computation. Since these regions usually have overlaps, independent feature extractions lead to much repeated computation. One of the major improvements of the *fast R-CNN* from the R-CNN is that the CNN forward propagation is only performed on the entire image (Girshick 2015).

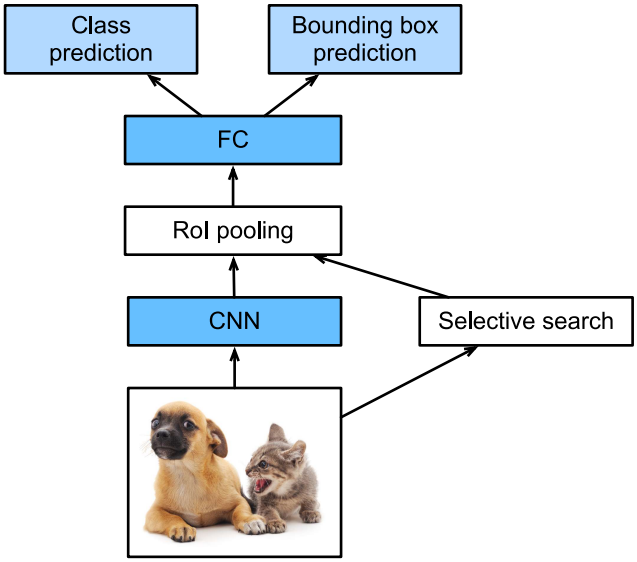

Figure 32.6: The fast R-CNN model.

Figure 32.6 describes the fast R-CNN model. Its major computations are as follows:

1. Compared with the R-CNN, in the fast R-CNN the input of the CNN for feature extraction is the entire image, rather than individual region proposals. Moreover, this CNN is trainable. Given an input image, let the shape of the CNN output be $1 \times c \times h_1 \times w_1$.
2. Suppose that selective search generates n region proposals. These region proposals (of different shapes) mark regions of interest (of different shapes) on the CNN output. Then these regions of interest further extract features of the same shape (say height h_2 and width w_2 are specified) in order to be easily concatenated. To achieve this, the fast R-CNN introduces the *region of interest (RoI) pooling* layer: the CNN output and region proposals are input into this layer, outputting concatenated features of shape $n \times c \times h_2 \times w_2$ that are further extracted for all the region proposals.
3. Using a fully connected layer, transform the concatenated features into an output of shape $n \times d$, where d depends on the model design.
4. Predict the class and bounding box for each of the n region proposals. More concretely, in class and bounding box prediction, transform the fully connected layer output into an output of shape $n \times q$ (q is the number of classes) and an output of shape $n \times 4$, respectively. The class prediction uses softmax regression.

The region of interest pooling layer proposed in the fast R-CNN is different from the pooling layer introduced in Section 6.5. In the pooling layer, we indirectly control the output shape by specifying sizes of the pooling window, padding, and stride. In contrast, we can directly specify the output shape in the region of interest pooling layer.

For example, let's specify the output height and width for each region as h_2 and w_2, respectively. For any region of interest window of shape $h \times w$, this window is divided into a $h_2 \times w_2$ grid of subwindows, where the shape of each subwindow is approximately $(h/h_2) \times (w/w_2)$. In practice, the height and width of any subwindow shall be rounded up, and the largest element shall be used as output of the subwindow. Therefore, the region of interest pooling layer can extract features of the same shape even when regions of interest have different shapes.

As an illustrative example, in Figure 32.7, the upper-left 3×3 region of interest is selected on a 4×4 input. For this region of interest, we use a 2×2 region of interest pooling layer to obtain a 2×2 output. Note that each of the four divided subwindows contains elements 0, 1, 4, and 5 (5 is the maximum); 2 and 6 (6 is the maximum); 8 and 9 (9 is the maximum); and 10.

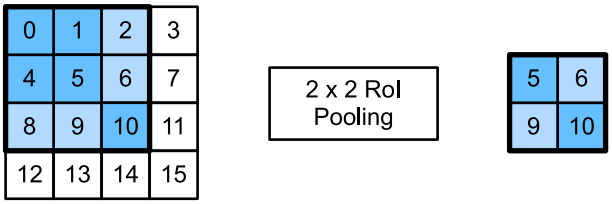

Figure 32.7: A 2×2 region of interest pooling layer.

Below we demonstrate the computation of the region of interest pooling layer. Suppose that the height and width of the CNN-extracted features `X` are both 4, and there is only a single channel.

```
# TF uses NHWC; we store the 4x4 feature map as (1, 4, 4, 1)
X = tf.cast(tf.reshape(tf.range(16), (1, 4, 4, 1)), tf.float32)
X
```

```
<tf.Tensor: shape=(1, 4, 4, 1), dtype=float32, numpy=
array([[[[ 0.],
         [ 1.],
         [ 2.],
         [ 3.]],

        [[ 4.],
         [ 5.],
         [ 6.],
         [ 7.]],

        [[ 8.],
         [ 9.],
         [10.],
         [11.]],

        [[12.],
         [13.],
         [14.],
         [15.]]], dtype=float32)>
```

Let's further suppose that the height and width of the input image are both 40 pixels and

that selective search generates two region proposals on this image. Each region proposal is expressed as five elements: its object class followed by the (x, y)-coordinates of its upper-left and lower-right corners.

```
rois = np.array([[0, 0, 0, 20, 20], [0, 0, 10, 30, 30]], dtype=np.float32)
```

Because the height and width of `X` are $1/10$ of the height and width of the input image, the coordinates of the two region proposals are multiplied by 0.1 according to the specified `spatial_scale` argument. Then the two regions of interest are marked on `X` as `X[:, :, 0:3, 0:3]` and `X[:, :, 1:4, 0:4]`, respectively. Finally in the 2×2 region of interest pooling, each region of interest is divided into a grid of sub-windows to further extract features of the same shape 2×2.

TensorFlow stores `X` in NHWC layout, so these regions are `X[:, 0:3, 0:3, :]` and `X[:, 1:4, 0:4, :]`.

```
# TensorFlow does not ship a built-in RoI pooling op in the public API,
# so we implement max-RoI pooling manually.  X is NHWC here.
def roi_pool(X, rois, pooled_size, spatial_scale):
    """RoI max-pooling for NHWC tensors."""
    height, width, c = X.shape[1:]
    ph, pw = pooled_size
    outputs = []
    for roi in np.asarray(rois):
        batch_idx = int(roi[0])
        # Round the scaled corners; both corners belong to the region
        x1, y1, x2, y2 = [int(math.floor(v * spatial_scale + 0.5))
                          for v in roi[1:]]
        bin_h = max(y2 - y1 + 1, 1) / ph
        bin_w = max(x2 - x1 + 1, 1) / pw
        rows = []
        for pi in range(ph):
            # A subwindow starts at the floor and ends at the ceiling
            hs = min(max(y1 + math.floor(pi * bin_h), 0), height)
            he = min(max(y1 + math.ceil((pi + 1) * bin_h), 0), height)
            row = []
            for pj in range(pw):
                ws = min(max(x1 + math.floor(pj * bin_w), 0), width)
                we = min(max(x1 + math.ceil((pj + 1) * bin_w), 0), width)
                if hs < he and ws < we:
                    sub = X[batch_idx, hs:he, ws:we, :]
                    row.append(tf.reduce_max(sub, axis=[0, 1]))
                else:  # empty subwindows output 0
                    row.append(tf.zeros((c,), X.dtype))
            rows.append(tf.stack(row, axis=0))  # (pw, C)
        outputs.append(tf.stack(rows, axis=0))  # (ph, pw, C)
    # (num_rois, ph, pw, C)
    return tf.stack(outputs, axis=0)

roi_pool(X, rois, pooled_size=(2, 2), spatial_scale=0.1)
```

```
<tf.Tensor: shape=(2, 2, 2, 1), dtype=float32, numpy=
array([[[[ 5.],
```

```
        [ 6.]],

       [[ 9.],
        [10.]]],

      [[[ 9.],
        [11.]],

       [[13.],
        [15.]]], dtype=float32)>
```

32.8.3 Faster R-CNN

To be more accurate in object detection, the fast R-CNN model usually has to generate a lot of region proposals in selective search. To reduce region proposals without loss of accuracy, the *faster R-CNN* proposes to replace selective search with a *region proposal network* (Ren et al. 2015).

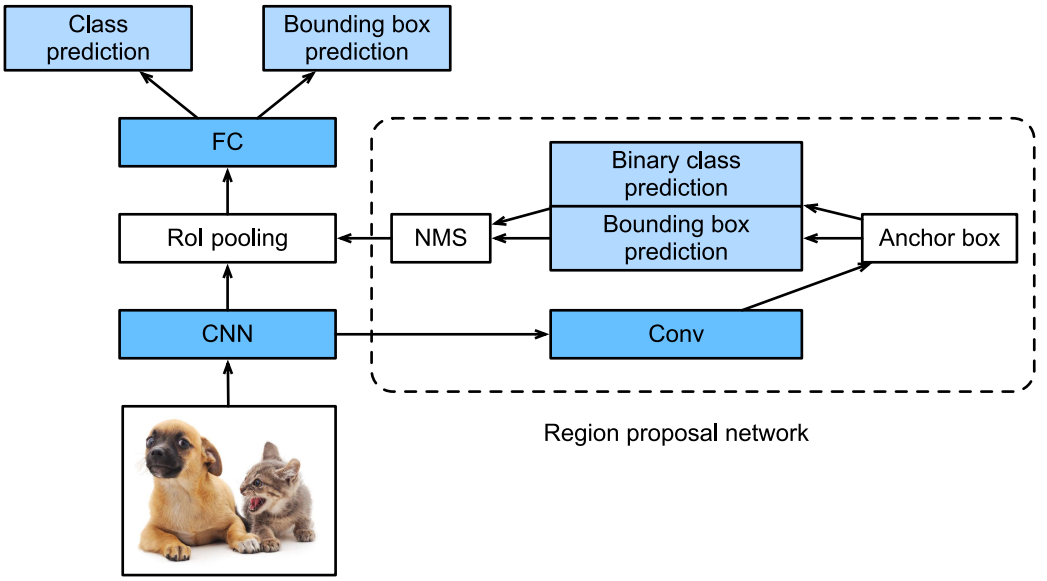

Figure 32.8: The faster R-CNN model.

Figure 32.8 shows the faster R-CNN model. Compared with the fast R-CNN, the faster R-CNN only changes the region proposal method from selective search to a region proposal network. The rest of the model remains unchanged. The region proposal network works in the following steps:

1. Use a 3×3 convolutional layer with padding of 1 to transform the CNN output to a new output with c channels. In this way, each unit along the spatial dimensions of the CNN-extracted feature maps gets a new feature vector of length c.
2. Centered on each pixel of the feature maps, generate multiple anchor boxes of different scales and aspect ratios and label them.
3. Using the length-c feature vector at the center of each anchor box, predict the binary class (background or objects) and bounding box for this anchor box.

4. Consider those predicted bounding boxes whose predicted classes are objects. Remove overlapped results using non-maximum suppression. The remaining predicted bounding boxes for objects are the region proposals required by the region of interest pooling layer.

It is worth noting that, as part of the faster R-CNN model, the region proposal network is jointly trained with the rest of the model. In other words, the objective function of the faster R-CNN includes not only the class and bounding box prediction in object detection, but also the binary class and bounding box prediction of anchor boxes in the region proposal network. As a result of the end-to-end training, the region proposal network learns how to generate high-quality region proposals, so as to stay accurate in object detection with a reduced number of region proposals that are learned from data.

32.8.4 Mask R-CNN

In the training dataset, if pixel-level positions of object are also labeled on images, the *mask R-CNN* can effectively leverage such detailed labels to further improve the accuracy of object detection (K. He et al. 2017).

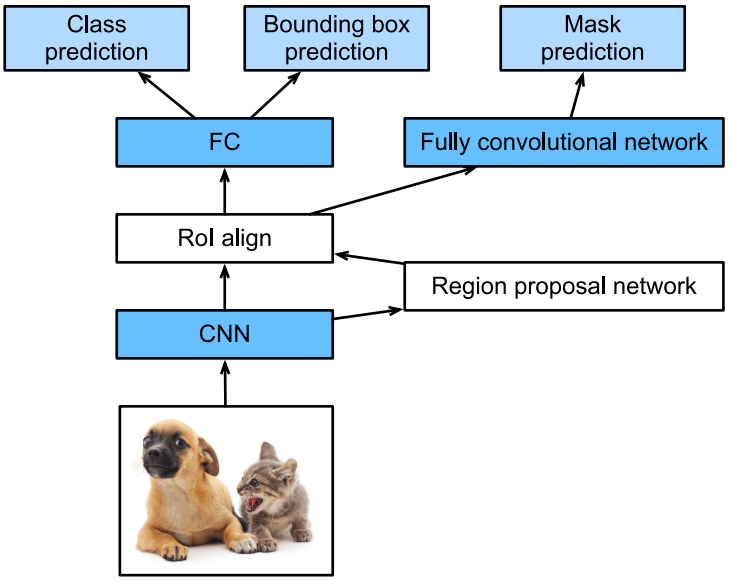

Figure 32.9: The mask R-CNN model.

As shown in Figure 32.9, the mask R-CNN is modified based on the faster R-CNN. Specifically, the mask R-CNN replaces the region of interest pooling layer with the *region of interest (RoI) alignment* layer. This region of interest alignment layer uses bilinear interpolation to preserve the spatial information on the feature maps, which is more suitable for pixel-level prediction. The output of this layer contains feature maps of the same shape for all the regions of interest. They are used to predict not only the class and bounding box for each region of interest, but also the pixel-level position of the object through an additional fully convolutional network. More details on using a fully convolutional network to predict pixel-level semantics of an image will be provided in subsequent sections of this chapter.

32.8.5 Summary

- The R-CNN extracts many region proposals from the input image, uses a CNN to perform forward propagation on each region proposal to extract its features, then uses these features to predict the class and bounding box of this region proposal.
- One of the major improvements of the fast R-CNN from the R-CNN is that the CNN forward propagation is only performed on the entire image. It also introduces the region of interest pooling layer, so that features of the same shape can be further extracted for regions of interest that have different shapes.
- The faster R-CNN replaces the selective search used in the fast R-CNN with a jointly trained region proposal network, so that the former can stay accurate in object detection with a reduced number of region proposals.
- Based on the faster R-CNN, the mask R-CNN additionally introduces a fully convolutional network, so as to leverage pixel-level labels to further improve the accuracy of object detection.

32.8.6 Exercises

1. Work through region of interest pooling by hand for the two regions `X[:, :, 0:3, 0:3]` and `X[:, :, 1:4, 0:4]` named in the text.
    1. Using the rule that subwindow heights and widths are rounded up, list the elements of the four subwindows of each region and write down the two 2×2 outputs. Compare them with the output of the section's code.
    2. Let L be the sum of the eight pooled values. List the entries of `X` whose partial derivative $\partial L/\partial x_{ij}$ is nonzero, together with the values of these derivatives. Explain why one entry receives a derivative of 2, and check your answer with automatic differentiation.
2. Estimate the cost of the R-CNN family on one 600×1000 image with 2000 region proposals. Assume that the backbone CNN costs about 300 multiply-adds per input pixel, regardless of the image size (roughly the cost of VGG-16), that the R-CNN resizes every proposal to 224×224 before running the backbone on it, and that the fast R-CNN pools each region to a $512 \times 7 \times 7$ feature and then applies two fully connected layers with 4096 outputs each, as in the VGG networks of Section 7.2.1.
    1. Compute the ratio of the backbone cost of the R-CNN to that of the fast R-CNN.
    2. Count the multiply-adds of the two fully connected layers for one region and for all 2000 regions, and compare the total with the backbone cost of the fast R-CNN.
    3. The faster R-CNN keeps about 300 proposals from its region proposal network. Compute its total cost under the same assumptions and state which part of the computation the smaller number of proposals reduces.
3. Can we frame object detection as a single regression problem, such as predicting bounding boxes and class probabilities? You may refer to the design of the YOLO model (Redmon et al. 2016).
4. Compare single shot multibox detection with the methods introduced in this section. What are their major differences? You may refer to Figure 2 of Zhao et al. (2019) .
5. The region of interest alignment layer of the mask R-CNN does not round coordinates. Implement a function `roi_align(X, rois, pooled_size, spatial_scale)` that scales each region to real-valued coordinates on the feature map, divides it into a grid of equal subwindows, and outputs the bilinear interpolation of `X` at the center of each subwindow, treating `X[0, 0, i, j]` as the value at the point $(x, y) = (j, i)$.
    1. Apply it to `X` and `rois` of this section and report the two 2×2 outputs. The entries

of `X` satisfy $x_{ij} = 4i + j$; check that each output equals $4y + x$ at the center (x, y) of its subwindow, and explain why bilinear interpolation gives this value exactly.
2. Shift the first region proposal to the right by 2, 4, 6, and 8 pixels in the input image, that is, by 0.2 to 0.8 cells of `X`. Tabulate the outputs of region of interest pooling and of your `roi_align` for each shift. State which of the two changes continuously with the shift, and explain why this matters for predicting pixel-level masks.

In TensorFlow, `X` is NHWC: read the regions `X[:, :, 0:3, 0:3]` and `X[:, :, 1:4, 0:4]` as `X[:, 0:3, 0:3, :]` and `X[:, 1:4, 0:4, :]`, and `X[0, 0, i, j]` as `X[0, i, j, 0]`.

32.9 Semantic Segmentation and the Dataset

When discussing object detection tasks in Section 32.3 to Section 32.8, rectangular bounding boxes are used to label and predict objects in images. This section will discuss the problem of *semantic segmentation*, which focuses on how to divide an image into regions belonging to different semantic classes. Different from object detection, semantic segmentation recognizes and understands what are in images in pixel level: its labeling and prediction of semantic regions are in pixel level. Figure 32.10 shows the labels of the dog, cat, and background of the image in semantic segmentation. Compared with in object detection, the pixel-level borders labeled in semantic segmentation are obviously more fine-grained.

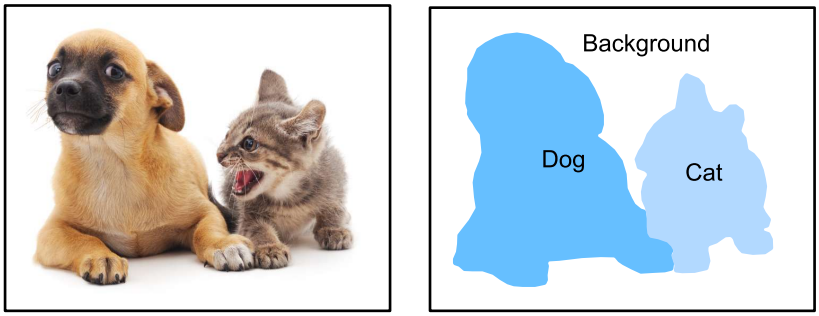

Figure 32.10: Labels of the dog, cat, and background of the image in semantic segmentation.

32.9.1 Image Segmentation and Instance Segmentation

There are also two important tasks in the field of computer vision that are similar to semantic segmentation, namely image segmentation and instance segmentation. We will briefly distinguish them from semantic segmentation as follows.

- *Image segmentation* divides an image into several constituent regions. The methods for this type of problem usually make use of the correlation between pixels in the image. It does not need label information about image pixels during training, and it cannot guarantee that the segmented regions will have the semantics that we hope to obtain during prediction. Taking the image in Figure 32.10 as input, image segmentation may divide the dog into two regions: one covers the mouth and eyes which are mainly black, and the other covers the rest of the body which is mainly yellow.
- *Instance segmentation* is also called *simultaneous detection and segmentation*. It studies how to recognize the pixel-level regions of each object instance in an image. Different from semantic segmentation, instance segmentation needs to distinguish not only

semantics, but also different object instances. For example, if there are two dogs in the image, instance segmentation needs to distinguish which of the two dogs a pixel belongs to.

32.9.2 The Pascal VOC2012 Semantic Segmentation Dataset

One of the most important semantic segmentation dataset is Pascal VOC2012. In the following, we will take a look at this dataset.

```
import os
```

The tar file of the dataset is about 2 GB, so it may take a while to download the file. The extracted dataset is located at `../data/VOCdevkit/VOC2012`.

```
d2l.DATA_HUB['voc2012'] = (d2l.DATA_URL + 'VOCtrainval_11-May-2012.tar',
                           '4e443f8a2eca6b1dac8a6c57641b67dd40621a49')

voc_dir = d2l.download_extract('voc2012', 'VOCdevkit/VOC2012')
```

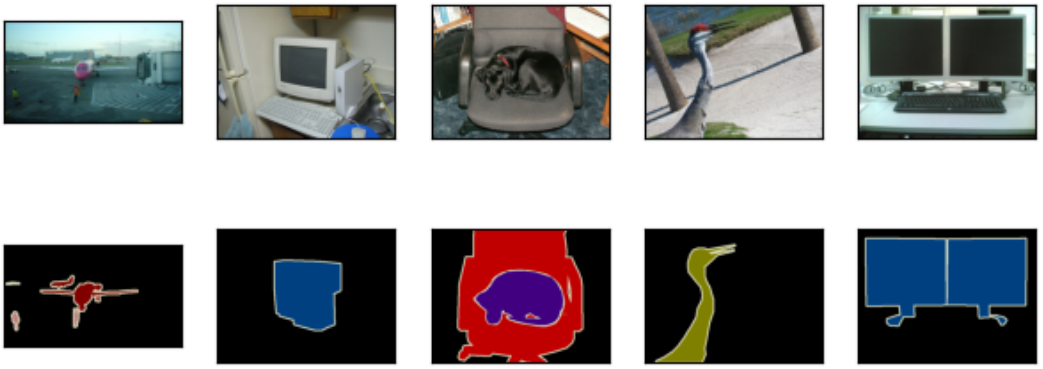
After entering the path `../data/VOCdevkit/VOC2012`, we can see the different components of the dataset. The `ImageSets/Segmentation` path contains text files that specify training and test samples, while the `JPEGImages` and `SegmentationClass` paths store the input image and label for each example, respectively. The label here is also in the image format, with the same size as its labeled input image. Besides, pixels with the same color in any label image belong to the same semantic class. The following defines the `read_voc_images` function to read all the input images and labels into the memory.

```
def read_voc_images(voc_dir, is_train=True):
    """Read all VOC feature and label images."""
    from PIL import Image
    txt_fname = os.path.join(voc_dir, 'ImageSets', 'Segmentation',
                             'train.txt' if is_train else 'val.txt')
    with open(txt_fname, 'r') as f:
        images = f.read().split()
    features, labels = [], []
    for i, fname in enumerate(images):
        features.append(np.array(Image.open(os.path.join(
            voc_dir, 'JPEGImages', f'{fname}.jpg'))))
        labels.append(np.array(Image.open(os.path.join(
            voc_dir, 'SegmentationClass', f'{fname}.png')).convert('RGB')))
    return features, labels

train_features, train_labels = read_voc_images(voc_dir, True)
```

We draw the first five input images and their labels. In the label images, white and black represent borders and background, respectively, while the other colors correspond to different classes.

```
n = 5
imgs = train_features[:n] + train_labels[:n]
d2l.show_images(imgs, 2, n);
```



Next, we enumerate the RGB color values and class names for all the labels in this dataset.

```
VOC_COLORMAP = [[0, 0, 0], [128, 0, 0], [0, 128, 0], [128, 128, 0],
                [0, 0, 128], [128, 0, 128], [0, 128, 128], [128, 128, 128],
                [64, 0, 0], [192, 0, 0], [64, 128, 0], [192, 128, 0],
                [64, 0, 128], [192, 0, 128], [64, 128, 128], [192, 128, 128],
                [0, 64, 0], [128, 64, 0], [0, 192, 0], [128, 192, 0],
                [0, 64, 128]]

VOC_CLASSES = ['background', 'aeroplane', 'bicycle', 'bird', 'boat',
               'bottle', 'bus', 'car', 'cat', 'chair', 'cow',
               'diningtable', 'dog', 'horse', 'motorbike', 'person',
               'potted plant', 'sheep', 'sofa', 'train', 'tv/monitor']
```

With the two constants defined above, we can conveniently find the class index for each pixel in a label. We define the `voc_colormap2label` function to build the mapping from the above RGB color values to class indices, and the `voc_label_indices` function to map any RGB values to their class indices in this Pascal VOC2012 dataset.

```
def voc_colormap2label():
    """Build the mapping from RGB to class indices for VOC labels."""
    colormap2label = np.zeros(256 ** 3, dtype=np.int32)
    for i, colormap in enumerate(VOC_COLORMAP):
        colormap2label[
            (colormap[0] * 256 + colormap[1]) * 256 + colormap[2]] = i
    return colormap2label

def voc_label_indices(colormap, colormap2label):
    """Map any RGB values in VOC labels to their class indices."""
    colormap = colormap.astype(np.int32)
    idx = ((colormap[:, :, 0] * 256 + colormap[:, :, 1]) * 256
```

```
            + colormap[:, :, 2])
    return colormap2label[idx]
```

For example, in the first example image, the class index for the front part of the airplane is 1, while the background index is 0.

```
y = voc_label_indices(train_labels[0], voc_colormap2label())
y[105:115, 130:140], VOC_CLASSES[1]
```

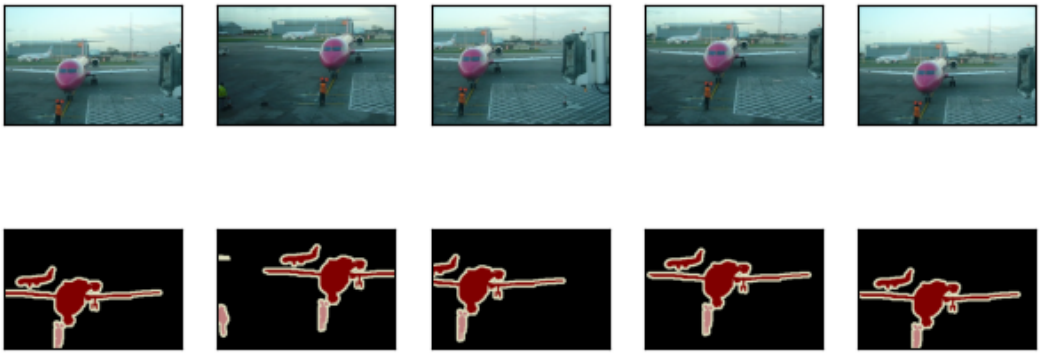
```
(array([[0, 0, 0, 0, 0, 0, 0, 0, 0, 1],
        [0, 0, 0, 0, 0, 0, 0, 1, 1, 1],
        [0, 0, 0, 0, 0, 0, 1, 1, 1, 1],
        [0, 0, 0, 0, 0, 1, 1, 1, 1, 1],
        [0, 0, 0, 0, 0, 1, 1, 1, 1, 1],
        [0, 0, 0, 0, 1, 1, 1, 1, 1, 1],
        [0, 0, 0, 0, 0, 1, 1, 1, 1, 1],
        [0, 0, 0, 0, 0, 1, 1, 1, 1, 1],
        [0, 0, 0, 0, 0, 0, 1, 1, 1, 1],
        [0, 0, 0, 0, 0, 0, 0, 0, 1, 1]], dtype=int32),
 'aeroplane')
```

32.9.2.1 Data Preprocessing

In previous experiments such as in Section 7.1 to Section 7.2.3, images are rescaled to fit the model's required input shape. However, in semantic segmentation, doing so requires rescaling the predicted pixel classes back to the original shape of the input image. Such rescaling may be inaccurate, especially for segmented regions with different classes. To avoid this issue, we crop the image to a *fixed* shape instead of rescaling. Specifically, using random cropping from image augmentation, we crop the same area of the input image and the label.

```
def voc_rand_crop(feature, label, height, width):
    """Randomly crop both feature and label images."""
    # Use NumPy for the random crop so this is safe to run from worker
    # threads (tf.image.random_crop holds graph-side state that breaks
    # under tf.data parallel py_function calls).
    H, W = feature.shape[0], feature.shape[1]
    top = int(np.random.randint(0, H - height + 1))
    left = int(np.random.randint(0, W - width + 1))
    feat = feature[top:top + height, left:left + width, :]
    lab = label[top:top + height, left:left + width, :]
    return feat, lab
```

```
imgs = []
for _ in range(n):
    imgs += voc_rand_crop(train_features[0], train_labels[0], 200, 300)
d2l.show_images(imgs[::2] + imgs[1::2], 2, n);
```



32.9.2.2 Custom Semantic Segmentation Dataset Class

We define a custom semantic segmentation dataset class `VOCSegDataset` by inheriting the `Dataset` class provided by high-level APIs. By implementing the `__getitem__` function, we can arbitrarily access the input image indexed as `idx` in the dataset and the class index of each pixel in this image. Since some images in the dataset have a smaller size than the output size of random cropping, these examples are filtered out by a custom `filter` function. In addition, we also define the `normalize_image` function to standardize the values of the three RGB channels of input images.

```
class VOCSegDataset:
    """A customized dataset to load the VOC dataset."""

    def __init__(self, is_train, crop_size, voc_dir):
        self.rgb_mean = np.array([0.485, 0.456, 0.406], dtype=np.float32)
        self.rgb_std = np.array([0.229, 0.224, 0.225], dtype=np.float32)
        self.crop_size = crop_size
        features, labels = read_voc_images(voc_dir, is_train=is_train)
        self.features = [self.normalize_image(feature)
                         for feature in self.filter(features)]
        self.labels = self.filter(labels)
        self.colormap2label = voc_colormap2label()
        print('read ' + str(len(self.features)) + ' examples')

    def normalize_image(self, img):
        return (img.astype(np.float32) / 255 - self.rgb_mean) / self.rgb_std

    def filter(self, imgs):
        return [img for img in imgs if (
            img.shape[0] >= self.crop_size[0] and
            img.shape[1] >= self.crop_size[1])]

    def __getitem__(self, idx):
        feature, label = voc_rand_crop(self.features[idx], self.labels[idx],
                                       *self.crop_size)
        # feature: HWC float32; label: HWC uint8 RGB -> class indices HW int32
        label_idx = voc_label_indices(label, self.colormap2label)
        return (feature.astype(np.float32),
```

```
                label_idx.astype(np.int32))

    def __len__(self):
        return len(self.features)
```

32.9.2.3 Reading the Dataset

We use the custom `VOCSegDataset` class to create instances of the training set and test set, respectively. Suppose that we specify that the output shape of randomly cropped images is 320×480. Below we can view the number of examples that are retained in the training set and test set.

```
crop_size = (320, 480)
voc_train = VOCSegDataset(True, crop_size, voc_dir)
voc_test = VOCSegDataset(False, crop_size, voc_dir)
```

```
read 1114 examples
read 1078 examples
```

Setting the batch size to 64, we define the data iterator for the training set. Let's print the shape of the first minibatch. Different from in image classification or object detection, labels here are three-dimensional tensors.

```
batch_size = 64
indices = np.random.permutation(len(voc_train))
batch = [voc_train[i] for i in indices[:batch_size]]
X = tf.stack([b[0] for b in batch])
Y = tf.stack([b[1] for b in batch])
print(X.shape)
print(Y.shape)
```

```
(64, 320, 480, 3)
(64, 320, 480)
```

32.9.2.4 Putting It All Together

Finally, we define the following `load_data_voc` function to download and read the Pascal VOC2012 semantic segmentation dataset. It returns data iterators for both the training and test datasets.

```
def load_data_voc(batch_size, crop_size):
    """Load the VOC semantic segmentation dataset."""
    voc_dir = d2l.download_extract('voc2012', os.path.join(
        'VOCdevkit', 'VOC2012'))
    train_dataset = VOCSegDataset(True, crop_size, voc_dir)
    test_dataset = VOCSegDataset(False, crop_size, voc_dir)
    n_train = len(train_dataset)
    n_test = len(test_dataset)
    # Drop last partial batch
    n_train = (n_train // batch_size) * batch_size
```

```
    n_test = (n_test // batch_size) * batch_size
    def make_tf_dataset(dataset, n, shuffle):
        # Cropping/labeling is plain NumPy; wrap in tf.py_function and run it
        # in parallel so the GPU isn't starved between batches. We use
        # from_tensor_slices(indices) + map(parallel) instead of a single
        # serial Python generator.
        feat0, label0 = dataset[0]
        feat_shape, label_shape = feat0.shape, label0.shape
        def load(i):
            feat, label = dataset[int(i)]
            return feat, label
        def tf_load(i):
            feat, label = tf.py_function(
                load, [i], (tf.float32, tf.int32))
            feat.set_shape(feat_shape)
            label.set_shape(label_shape)
            return feat, label
        ds = tf.data.Dataset.from_tensor_slices(
            np.arange(len(dataset), dtype=np.int64))
        if shuffle:
            ds = ds.shuffle(buffer_size=min(n, 1000),
                            reshuffle_each_iteration=True)
        ds = ds.take(n)
        ds = ds.map(tf_load, num_parallel_calls=tf.data.AUTOTUNE)
        ds = ds.batch(batch_size, drop_remainder=True)
        ds = ds.prefetch(tf.data.AUTOTUNE)
        return ds
    train_iter = make_tf_dataset(train_dataset, n_train, shuffle=True)
    test_iter = make_tf_dataset(test_dataset, n_test, shuffle=False)
    return train_iter, test_iter
```

32.9.3 Summary

- Semantic segmentation recognizes and understands what are in an image in pixel level by dividing the image into regions belonging to different semantic classes.
- One of the most important semantic segmentation dataset is Pascal VOC2012.
- In semantic segmentation, since the input image and label correspond one-to-one on the pixel, the input image is randomly cropped to a fixed shape rather than rescaled.

32.9.4 Exercises

1. How can semantic segmentation be applied in autonomous vehicles and medical image diagnostics? Can you think of other applications?
2. Recall the descriptions of data augmentation in Section 32.1. Which of the image augmentation methods used in image classification would be infeasible to be applied in semantic segmentation?
3. Use `voc_label_indices` to compute, over all training labels returned by `read_voc_images`, the fraction of pixels in each of the 21 classes and the number of images in which each class occurs. Report the background fraction and the class with the fewest pixels. Which pixel accuracy does a model attain that predicts background everywhere? The intersection over union (IoU) of class c is the number of pixels both predicted and

labeled as c, divided by the number predicted or labeled as c. Compute this model's IoU for every class and the mean over the 21 classes, and explain why the mean IoU separates this model from a useful one while the pixel accuracy does not.

4. The text crops images instead of rescaling them because rescaling a label image is inaccurate.
    1. Two neighboring label pixels belong to the classes cat (index 8) and dog (index 12). Interpolating the class indices linearly halfway between them gives which index, and which class does it name? Interpolating their colors from `VOC_COLORMAP` instead gives which color, and which index does `voc_label_indices` return for it?
    2. Implement a random-scale augmentation that resizes the input image with bilinear interpolation and the label image with nearest-neighbor interpolation, by a common factor drawn uniformly from $[1, 2]$, before calling `voc_rand_crop`. Check that every pixel of the resulting labels has a color in `VOC_COLORMAP`, and count the pixels that fail this check when the label image is resized with bilinear interpolation instead.
5. In the label images, object borders and regions that are hard to label are drawn in the color $(224, 224, 192)$, which is not in `VOC_COLORMAP`.
    1. From the way `voc_colormap2label` builds its lookup table, determine the class index that `voc_label_indices` assigns to these pixels. Compute the fraction of such pixels in the training labels.
    2. Change `voc_colormap2label` so that this color maps to the index 255, and state how the per-pixel cross-entropy loss and the pixel accuracy must treat pixels with this index.
    3. With such an index available, `VOCSegDataset` no longer needs to discard the training images that are smaller than `crop_size`. Modify it to pad the image and the label instead, state the label value of the padded pixels, and report the number of training examples the dataset then contains for `crop_size = (320, 480)`.

32.10 Transposed Convolution

The CNN layers we have seen so far, such as convolutional layers (Section 6.2) and pooling layers (Section 6.5), typically reduce (downsample) the spatial dimensions (height and width) of the input, or keep them unchanged. In semantic segmentation that classifies at pixel-level, it will be convenient if the spatial dimensions of the input and output are the same. For example, the channel dimension at one output pixel can hold the classification results for the input pixel at the same spatial position.

To achieve this, especially after the spatial dimensions are reduced by CNN layers, we can use another type of CNN layers that can increase (upsample) the spatial dimensions of intermediate feature maps. In this section, we will introduce *transposed convolution*, which is also called *fractionally-strided convolution* (Dumoulin and Visin 2016), for reversing downsampling operations by the convolution.

32.10.1 Basic Operation

Ignoring channels for now, let's begin with the basic transposed convolution operation with stride of 1 and no padding. Suppose that we are given a $n_h \times n_w$ input tensor and a $k_h \times k_w$ kernel. Sliding the kernel window with stride of 1 for n_w times in each row and n_h times in each column yields a total of $n_h n_w$ intermediate results. Each intermediate result is a $(n_h + k_h - 1) \times (n_w + k_w - 1)$ tensor that are initialized as zeros. To compute each

intermediate tensor, each element in the input tensor is multiplied by the kernel so that the resulting $k_h \times k_w$ tensor replaces a portion in each intermediate tensor. Note that the position of the replaced portion in each intermediate tensor corresponds to the position of the element in the input tensor used for the computation. In the end, all the intermediate results are summed over to produce the output.

As an example, Figure 32.11 illustrates how transposed convolution with a 2×2 kernel is computed for a 2×2 input tensor.

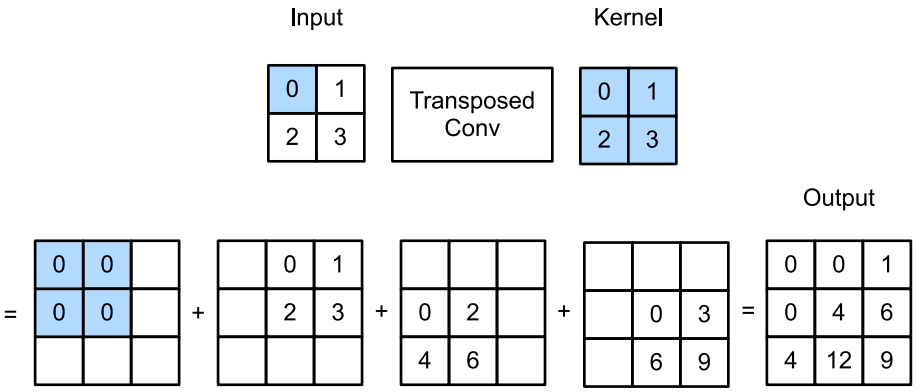


Figure 32.11: Transposed convolution with a 2×2 kernel. The shaded portions are a portion of an intermediate tensor as well as the input and kernel tensor elements used for the computation.

We can implement this basic transposed convolution operation `trans_conv` for a input matrix `X` and a kernel matrix `K`.

```
def trans_conv(X, K):
    n_h, n_w = X.shape
    # Add each scaled kernel X[i, j] * K, zero-padded into place at (i, j)
    return tf.add_n([tf.pad(X[i, j] * K, [[i, n_h - 1 - i], [j, n_w - 1 - j]])
                     for i in range(n_h) for j in range(n_w)])
```

In contrast to the regular convolution (in Section 6.2) that *reduces* input elements via the kernel, the transposed convolution *broadcasts* input elements via the kernel, thereby producing an output that is larger than the input. We can construct the input tensor `X` and the kernel tensor `K` from Figure 32.11 to validate the output of the above implementation of the basic two-dimensional transposed convolution operation.

```
X = d2l.tensor([[0.0, 1.0], [2.0, 3.0]])
K = d2l.tensor([[0.0, 1.0], [2.0, 3.0]])
trans_conv(X, K)
```

```
<tf.Tensor: shape=(3, 3), dtype=float32, numpy=
array([[ 0.,  0.,  1.],
       [ 0.,  4.,  6.],
       [ 4., 12.,  9.]], dtype=float32)>
```

Alternatively, when the input `X` and kernel `K` are both four-dimensional tensors, we can use high-level APIs to obtain the same results.

```
X, K = tf.reshape(X, (1, 2, 2, 1)), tf.reshape(K, (2, 2, 1, 1))
tconv = tf.keras.layers.Conv2DTranspose(1, kernel_size=2, use_bias=False)
tconv.build(X.shape)
tconv.kernel.assign(K)
tconv(X)
```

```
<tf.Tensor: shape=(1, 3, 3, 1), dtype=float32, numpy=
array([[[[ 0.],
         [ 0.],
         [ 1.]],

        [[ 0.],
         [ 4.],
         [ 6.]],

        [[ 4.],
         [12.],
         [ 9.]]]], dtype=float32)>
```

32.10.2 Padding, Strides, and Multiple Channels

Different from in the regular convolution where padding is applied to input, it is applied to output in the transposed convolution. For example, when specifying the padding number on either side of the height and width as 1, the first and last rows and columns will be removed from the transposed convolution output.

Keras's `Conv2DTranspose` takes no numeric padding, so we remove the first and last rows and columns by slicing its output.

```
# Keras has no numeric padding here: apply, then remove the outer border
tconv(X)[:, 1:-1, 1:-1, :]
```

```
<tf.Tensor: shape=(1, 1, 1, 1), dtype=float32, numpy=array([[[[4.]]]], dtype=float32)>
```

In the transposed convolution, strides are specified for intermediate results (thus output), not for input. Using the same input and kernel tensors from Figure 32.11, changing the stride from 1 to 2 increases both the height and width of intermediate tensors, hence the output tensor in Figure 32.12.

The following code snippet can validate the transposed convolution output for stride of 2 in Figure 32.12.

```
tconv = tf.keras.layers.Conv2DTranspose(1, kernel_size=2, strides=2,
                                        use_bias=False)
tconv.build(X.shape)
tconv.kernel.assign(K)
tconv(X)
```

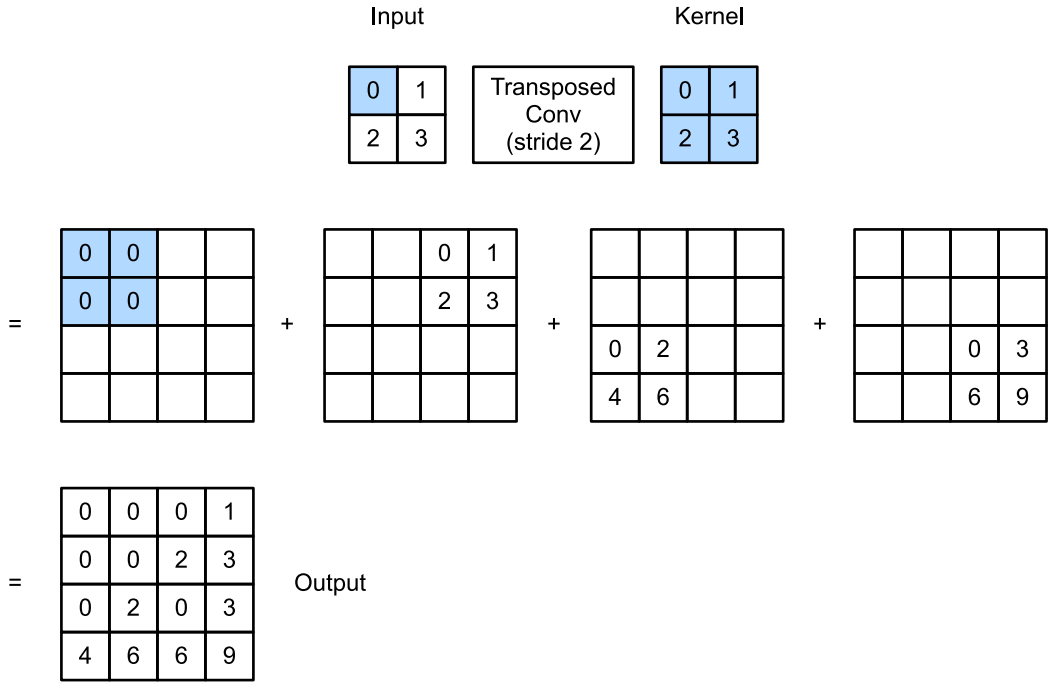

Figure 32.12: Transposed convolution with a 2×2 kernel with stride of 2. The shaded portions are a portion of an intermediate tensor as well as the input and kernel tensor elements used for the computation.

```
<tf.Tensor: shape=(1, 4, 4, 1), dtype=float32, numpy=
array([[[[0.],
         [0.],
         [0.],
         [1.]],

        [[0.],
         [0.],
         [2.],
         [3.]],

        [[0.],
         [2.],
         [0.],
         [3.]],

        [[4.],
         [6.],
         [6.],
         [9.]]], dtype=float32)>
```

For multiple input and output channels, the transposed convolution works in the same way as the regular convolution. Suppose that the input has c_i channels, and that the transposed convolution assigns a $k_h \times k_w$ kernel tensor to each input channel. When multiple output channels are specified, we will have a $c_i \times k_h \times k_w$ kernel for each output channel.

As in all, if we feed `X` into a convolutional layer f to output $\mathtt{Y} = f(\mathtt{X})$ and create a transposed convolutional layer g with the same hyperparameters as f except for the number of output channels being the number of channels in `X`, then $g(Y)$ will have the same shape as `X`. This can be illustrated in the following example. Note that when the stride is greater than 1, multiple input shapes can map to the same output shape under convolution, so the shape match is not guaranteed in general. In such cases, an additional output padding can be used to resolve the ambiguity.

`tf.keras.layers.Conv2DTranspose` takes it as the `output_padding` argument.

```
# Channels last: (batch, height, width, channels)
X = tf.random.uniform((1, 16, 16, 10))
conv = tf.keras.Sequential([tf.keras.layers.ZeroPadding2D(2),
                            tf.keras.layers.Conv2D(20, kernel_size=5,
                                                   strides=3)])
tconv = tf.keras.layers.Conv2DTranspose(10, kernel_size=5, strides=3)
# Padding 2 on the transposed side removes two rows/columns per border
tconv(conv(X))[:, 2:-2, 2:-2, :].shape == X.shape
```

```
True
```

32.10.3 Connection to Matrix Transposition

The transposed convolution is named after the matrix transposition. To explain, let's first see how to implement convolutions using matrix multiplications. In the example below, we define a 3×3 input `X` and a 2×2 convolution kernel `K`, and then use the `corr2d` function to compute the convolution output `Y`.

```
X = d2l.reshape(d2l.arange(9.0), (3, 3))
K = d2l.tensor([[1.0, 2.0], [3.0, 4.0]])
Y = d2l.corr2d(X, K)
Y
```

```
<tf.Tensor: shape=(2, 2), dtype=float32, numpy=
array([[27., 37.],
       [57., 67.]], dtype=float32)>
```

Next, we rewrite the convolution kernel `K` as a sparse weight matrix `W` containing a lot of zeros. The shape of the weight matrix is $(4, 9)$, where the non-zero elements come from the convolution kernel `K`.

```
def kernel2matrix(K):
    k = tf.concat([K[0, :], d2l.zeros(1), K[1, :]], 0)  # length 5
    # Row r holds k shifted right by the r-th window offset 0, 1, 3, 4
    return tf.stack([tf.pad(k, [[s, 4 - s]]) for s in (0, 1, 3, 4)])

W = kernel2matrix(K)
W
```

```
<tf.Tensor: shape=(4, 9), dtype=float32, numpy=
array([[1., 2., 0., 3., 4., 0., 0., 0., 0.],
       [0., 1., 2., 0., 3., 4., 0., 0., 0.],
       [0., 0., 0., 1., 2., 0., 3., 4., 0.],
       [0., 0., 0., 0., 1., 2., 0., 3., 4.]], dtype=float32)>
```

Concatenate the input `X` row by row to get a vector of length 9. Then the matrix multiplication of `W` and the vectorized `X` gives a vector of length 4. After reshaping it, we can obtain the same result `Y` from the original convolution operation above: we just implemented convolutions using matrix multiplications.

```
Y == d2l.reshape(d2l.matmul(W, d2l.reshape(X, (-1, 1))), (2, 2))
```

```
<tf.Tensor: shape=(2, 2), dtype=bool, numpy=
array([[ True,  True],
       [ True,  True]])>
```

Likewise, we can implement transposed convolutions using matrix multiplications. In the following example, we take the 2×2 output `Y` from the above regular convolution as input to the transposed convolution. To implement this operation by multiplying matrices, we only need to transpose the weight matrix `W` with the new shape $(9, 4)$.

```
Z = trans_conv(Y, K)
Z == d2l.reshape(d2l.matmul(d2l.transpose(W), d2l.reshape(Y, (-1, 1))), (3, 3))
```

```
<tf.Tensor: shape=(3, 3), dtype=bool, numpy=
array([[ True,  True,  True],
       [ True,  True,  True],
       [ True,  True,  True]])>
```

Consider implementing the convolution by multiplying matrices. Given an input vector $\mathbf{x}$ and a weight matrix $\mathbf{W}$, the forward propagation function of the convolution can be implemented by multiplying its input with the weight matrix and outputting a vector $\mathbf{y} = \mathbf{W}\mathbf{x}$. Since backpropagation follows the chain rule and $\nabla_{\mathbf{x}}\mathbf{y} = \mathbf{W}^\top$, the backpropagation function of the convolution can be implemented by multiplying its input with the transposed weight matrix $\mathbf{W}^\top$. Therefore, the transposed convolutional layer can just exchange the forward propagation function and the backpropagation function of the convolutional layer: its forward propagation and backpropagation functions multiply their input vector with $\mathbf{W}^\top$ and $\mathbf{W}$, respectively.

32.10.4 Summary

- In contrast to the regular convolution that reduces input elements via the kernel, the transposed convolution broadcasts input elements via the kernel, thereby producing an output that is larger than the input.
- If we feed `X` into a convolutional layer f to output `Y` $= f(\mathtt{X})$ and create a transposed convolutional layer g with the same hyperparameters as f except for the number of output channels being the number of channels in `X`, then $g(Y)$ will have the same shape as `X`. This holds when the stride is 1; for stride > 1, an additional `output_padding` may be needed since multiple input shapes can share the same convolution output shape.
- We can implement convolutions using matrix multiplications. The transposed convolutional layer can just exchange the forward propagation function and the backpropagation function of the convolutional layer.

32.10.5 Exercises

1. In Section 32.10.3, the convolution input `X` and the transposed convolution output `Z` have the same shape. Do they have the same value? Why?
2. Is it efficient to use matrix multiplications to implement convolutions? Why?
3. Derive the output height of a transposed convolution with input height n, kernel height k, padding p, and stride s from the description in this section: the intermediate results are placed s rows apart, and padding removes p rows at each border. Check the formula on `conv` and `tconv` of this section (kernel 5, padding 2, stride 3): compute the height of `conv(X)` for the 16×16 input, then the height of `tconv(conv(X))`. List all input heights that `conv` maps to the same output height, and give the number of extra rows (the `output_padding`) that `tconv` needs to restore each of them.
4. Apply a transposed convolution with a 3×3 kernel of ones and stride 2, without padding, to a 4×4 input of ones, and report the 9×9 output. Explain its checkerboard pattern by counting, for each output position, the input elements that contribute to it. Prove that for stride s the interior of the output is constant if and only if s divides the kernel size k, and check which of the kernel sizes 2, 3, and 4 give a constant interior for stride 2.
5. Extend `trans_conv` with a `stride` argument and check it against the output in Figure 32.12. Then show that the same output results from three steps: insert $s - 1$ zeros between neighboring input elements along rows and columns, pad the result with $k - 1$ zeros on every side, and apply `d2l.corr2d` with the kernel rotated by 180 degrees. Prove the equivalence, verify it numerically for random inputs and kernels, and explain from it the name *fractionally-strided convolution*.

32.11 Fully Convolutional Networks

As discussed in Section 32.9, semantic segmentation classifies images in pixel level. A fully convolutional network (FCN) uses a convolutional neural network to transform image pixels to pixel classes (Long et al. 2015). Unlike the CNNs that we encountered earlier for image classification or object detection, a fully convolutional network transforms the height and width of intermediate feature maps back to those of the input image: this is achieved by the transposed convolutional layer introduced in Section 32.10. As a result, the classification output and the input image have a one-to-one correspondence in pixel level: the channel dimension at any output pixel holds the classification results for the input pixel at the same spatial position.

```
import keras
from PIL import Image
from safetensors.numpy import load_file
```

32.11.1 The Model

Here we describe the basic design of the fully convolutional network model. As shown in Figure 32.13, this model first uses a CNN to extract image features, then transforms the number of channels into the number of classes via a 1×1 convolutional layer, and finally transforms the height and width of the feature maps to those of the input image via the transposed convolution introduced in Section 32.10. As a result, the model output has the same height and width as the input image, where the output channel contains the predicted classes for the input pixel at the same spatial position.

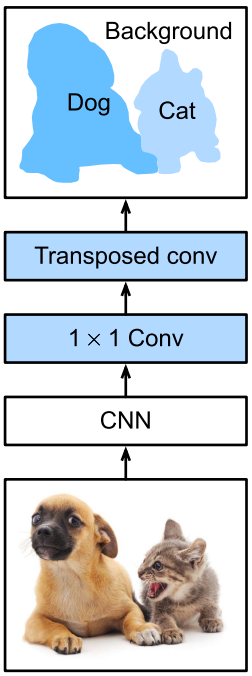

Figure 32.13: Fully convolutional network.

Below, we use a ResNet model pretrained on the ImageNet dataset to extract image features and denote the model instance as `pretrained_net`. The last few layers of this model include a global average pooling layer and a fully connected layer: they are not needed in the fully convolutional network.

```
# keras.applications ships no ResNet-18, so we build one as a Functional
# model and load ImageNet weights from the Hugging Face checkpoint
# microsoft/resnet-18. `hf` maps each checkpoint prefix to its (conv, bn).
hf = {}

def _conv_bn(x, prefix, num_channels, kernel_size, strides=1):
    # Pad k//2 on every side: 'same' pads only right and bottom when the
    # stride is 2 and the sizes are even
    if kernel_size > 1:
        x = keras.layers.ZeroPadding2D(kernel_size // 2)(x)
    conv = keras.layers.Conv2D(num_channels, kernel_size, strides=strides,
                               use_bias=False)
    # Running averages decay 0.9, epsilon 1e-5
    bn = keras.layers.BatchNormalization(momentum=0.9, epsilon=1e-5)
    hf[prefix] = (conv, bn)
    return bn(conv(x))

def _resnet_block(x, prefix, num_channels, strides=1, use_1x1conv=False):
    y = keras.layers.ReLU()(_conv_bn(x, prefix + '.layer.0', num_channels, 3,
                                     strides))
    y = _conv_bn(y, prefix + '.layer.1', num_channels, 3)
    if use_1x1conv:
        x = _conv_bn(x, prefix + '.shortcut', num_channels, 1, strides)
    return keras.layers.ReLU()(y + x)

inputs = keras.Input(shape=(None, None, 3))
x = _conv_bn(inputs, 'resnet.embedder.embedder', 64, 7, strides=2)
x = keras.layers.ReLU()(x)
x = keras.layers.ZeroPadding2D(1)(x)  # Zeros are safe after a ReLU
x = keras.layers.MaxPool2D(pool_size=3, strides=2)(x)
for i, (num_channels, strides) in enumerate(
        [(64, 1), (128, 2), (256, 2), (512, 2)]):
    stage = f'resnet.encoder.stages.{i}.layers'
    x = _resnet_block(x, f'{stage}.0', num_channels, strides,
                      use_1x1conv=strides > 1)
    x = _resnet_block(x, f'{stage}.1', num_channels)
features = x
pooled = keras.layers.GlobalAveragePooling2D()(features)
dense = keras.layers.Dense(1000)
pretrained_net = keras.Model(inputs=inputs, outputs=dense(pooled))

weights = load_file(d2l.download(
    'https://huggingface.co/microsoft/resnet-18/resolve/'
    '65a5785d9156231087c481e0c7dd33a5ff6f7e3e/model.safetensors',
    '../data/resnet-18', 'd905ba97ebcd156c13e528cd1731bd23406979e3'))
for prefix, (conv, bn) in hf.items():
    # Checkpoint kernels are (out, in, h, w); Keras expects (h, w, in, out)
    conv.set_weights([weights[f'{prefix}.convolution.weight'].transpose(
```

```
        2, 3, 1, 0)])
    bn.set_weights([weights[f'{prefix}.normalization.{name}'] for name in
                    ('weight', 'bias', 'running_mean', 'running_var')])
dense.set_weights([weights['classifier.1.weight'].T,
                   weights['classifier.1.bias']])
# Show the last few layers
pretrained_net.layers[-3:]
```

```
[<ReLU name=re_lu_16, built=True>,
 <GlobalAveragePooling2D name=global_average_pooling2d, built=True>,
 <Dense name=dense, built=True>]
```

Next, we create the fully convolutional network instance `net`. It copies all the pretrained convolutional layers in the ResNet except for the final global average pooling layer and the fully connected layer that are closest to the output.

```
# Build the FCN feature extractor: all layers up to (but not including)
# the global average pooling and dense head — i.e., the full conv body.
# The last conv-block output (`features`) is the 1/32-resolution feature
# map; we use it as the new model output, dropping GAP + Dense.
net = keras.Model(inputs=pretrained_net.input, outputs=features)
```

Given an input with height and width of 320 and 480 respectively, the forward propagation of `net` reduces the input height and width to 1/32 of the original, namely 10 and 15.

```
X = tf.random.uniform(shape=(1, 320, 480, 3))
net(X).shape
```

```
TensorShape([1, 10, 15, 512])
```

Next, we use a 1×1 convolutional layer to transform the number of output channels into the number of classes (21) of the Pascal VOC2012 dataset. Finally, we need to increase the height and width of the feature maps by 32 times to change them back to the height and width of the input image. Recall how to calculate the output shape of a convolutional layer in Section 6.3. Since $(320-64+16\times2+32)/32 = 10$ and $(480-64+16\times2+32)/32 = 15$, we construct a transposed convolutional layer with stride of 32, setting the height and width of the kernel to 64, the padding to 16. In general, we can see that for stride s, padding $s/2$ (assuming $s/2$ is an integer), and the height and width of the kernel $2s$, the transposed convolution will increase the height and width of the input by s times.

Keras's `Conv2DTranspose` takes `padding='same'` here instead of a padding of 16; it makes the output exactly 32 times as high and wide as the input.

```
num_classes = 21
# 1x1 conv to reduce channels to num_classes
final_conv = keras.layers.Conv2D(num_classes, kernel_size=1,
                                 kernel_initializer='glorot_uniform')
# Transposed conv: stride=32, kernel=64, padding='same' upsamples 32x
# (for input height/width divisible by 32, output equals input spatial size)
transpose_conv = keras.layers.Conv2DTranspose(
    num_classes, kernel_size=64, strides=32, padding='same', use_bias=False)
```

```
inputs = net.input
x = net.output
x = final_conv(x)
x = transpose_conv(x)
fcn_net = keras.Model(inputs=inputs, outputs=x)
print('FCN output shape:', fcn_net(tf.random.uniform((1, 320, 480, 3))).shape)
```

```
FCN output shape: (1, 320, 480, 21)
```

32.11.2 Initializing Transposed Convolutional Layers

We already know that transposed convolutional layers can increase the height and width of feature maps. In image processing, we may need to scale up an image, i.e., *upsampling*. *Bilinear interpolation* is one of the commonly used upsampling techniques. It is also often used for initializing transposed convolutional layers.

To explain bilinear interpolation, say that given an input image we want to calculate each pixel of the upsampled output image. In order to calculate the pixel of the output image at coordinate (x, y), first map (x, y) to coordinate (x', y') on the input image, for example, according to the ratio of the input size to the output size. Note that the mapped x' and y' are real numbers. Then, find the four pixels closest to coordinate (x', y') on the input image. Finally, the pixel of the output image at coordinate (x, y) is calculated based on these four closest pixels on the input image and their relative distance from (x', y').

Upsampling of bilinear interpolation can be implemented by the transposed convolutional layer with the kernel constructed by the following `bilinear_kernel` function. Due to space limitations, we only provide the implementation of the `bilinear_kernel` function below without discussions on its algorithm design.

```
def bilinear_kernel(in_channels, out_channels, kernel_size):
    factor = (kernel_size + 1) // 2
    if kernel_size % 2 == 1:
        center = factor - 1
    else:
        center = factor - 0.5
    og = (np.arange(kernel_size).reshape(-1, 1),
          np.arange(kernel_size).reshape(1, -1))
    filt = (1 - np.abs(og[0] - center) / factor) * \
           (1 - np.abs(og[1] - center) / factor)
    # Keras Conv2DTranspose uses HWIO kernel format (height, width, out, in)
    weight = np.zeros((kernel_size, kernel_size, out_channels, in_channels),
                      dtype=np.float32)
    for i in range(min(in_channels, out_channels)):
        weight[:, :, i, i] = filt
    return weight
```

Let's experiment with upsampling of bilinear interpolation that is implemented by a transposed convolutional layer. We construct a transposed convolutional layer that doubles the height and weight, and initialize its kernel with the `bilinear_kernel` function.

```
# Build a transposed conv layer with bilinear initialization to double H and W
bilinear_w = bilinear_kernel(3, 3, 4)
conv_trans = keras.layers.Conv2DTranspose(
    3, kernel_size=4, strides=2, padding='same', use_bias=False,
    kernel_initializer=tf.constant_initializer(bilinear_w))
# Build the layer by passing a dummy input
_ = conv_trans(tf.zeros((1, 1, 1, 3)))
```

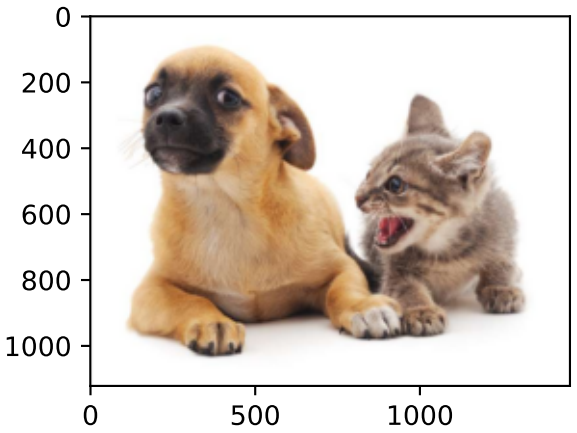
Read the image `X` and assign the upsampling output to `Y`.

```
img = np.array(Image.open('../img/catdog.jpg')).astype(np.float32) / 255
X = tf.expand_dims(tf.constant(img), axis=0)  # NHWC
Y = conv_trans(X)
out_img = Y[0].numpy()
```

As we can see, the transposed convolutional layer increases both the height and width of the image by a factor of two. Except for the different scales in coordinates, the image scaled up by bilinear interpolation and the original image printed in Section 32.3 look the same.

```
d2l.set_figsize()
print('input image shape:', img.shape)
d2l.plt.imshow(img);
print('output image shape:', out_img.shape)
d2l.plt.imshow(np.clip(out_img, 0, 1));
```

```
input image shape: (561, 728, 3)
output image shape: (1122, 1456, 3)
```



In a fully convolutional network, we initialize the transposed convolutional layer with upsampling of bilinear interpolation. For the 1×1 convolutional layer, we use Xavier initialization.

```
# Initialize the transpose conv kernel with bilinear upsampling weights.
# The 1x1 conv was already initialized with Glorot (Xavier) uniform above.
```

```
W = bilinear_kernel(num_classes, num_classes, 64)
# Find the Conv2DTranspose layer in fcn_net and set its weights
for layer in fcn_net.layers:
    if isinstance(layer, keras.layers.Conv2DTranspose):
        layer.set_weights([W])
        break
```

32.11.3 Reading the Dataset

We read the semantic segmentation dataset as introduced in Section 32.9. The output image shape of random cropping is specified as 320×480: both the height and width are divisible by 32.

```
batch_size, crop_size = 32, (320, 480)
train_iter, test_iter = d2l.load_data_voc(batch_size, crop_size)
```

```
read 1114 examples
read 1078 examples
```

32.11.4 Training

Now we can train our constructed fully convolutional network. The loss function and accuracy calculation here are not essentially different from those in image classification of earlier chapters. Because we use the output channel of the transposed convolutional layer to predict the class for each pixel, the channel dimension is specified in the loss calculation. In addition, the accuracy is calculated based on correctness of the predicted class for all the pixels.

```
# Each image's loss is the mean of its per-pixel cross-entropies, and an SGD
# step follows the gradient of the minibatch SUM of these image losses. Keras
# therefore logs `loss` per minibatch; the per-pixel cross-entropy is
# reported as a metric. The whole network (backbone + head) is fine-tuned.
class PixelLoss(keras.losses.Loss):
    def call(self, y, logits):
        return tf.reduce_mean(keras.losses.sparse_categorical_crossentropy(
            y, logits, from_logits=True), axis=(1, 2))

num_epochs, lr, wd = 5, 0.001, 1e-3
fcn_net.compile(
    optimizer=keras.optimizers.SGD(learning_rate=lr, weight_decay=wd),
    loss=PixelLoss(reduction='sum'),
    metrics=['accuracy', keras.metrics.SparseCategoricalCrossentropy(
        name='pixel_ce', from_logits=True)],
    # Keras may otherwise select XLA automatically. For this unusually large
    # transposed convolution, XLA's cuDNN autotuning can take tens of minutes
    # before the first training step and offers no benefit to this example.
    jit_compile=False)
fcn_net.fit(train_iter, epochs=num_epochs, validation_data=test_iter,
            verbose=2)
```

```
Epoch 1/5
34/34 - 74s - 2s/step - accuracy: 0.7443 - loss: 37.4598 - pixel_ce: 1.1706 - val_accuracy: 0.8138 -

```

32.11.5 Prediction

When predicting, we need to standardize the input image in each channel and transform the image into the four-dimensional input format required by the CNN.

```
def predict(img):
    rgb_mean = np.array([0.485, 0.456, 0.406], dtype=np.float32)
    rgb_std = np.array([0.229, 0.224, 0.225], dtype=np.float32)
    X = (img.astype(np.float32) / 255 - rgb_mean) / rgb_std
    X = tf.expand_dims(tf.constant(X), axis=0)  # NHWC
    pred = fcn_net(X, training=False)  # (1, H, W, num_classes)
    return tf.reshape(tf.argmax(pred, axis=-1), pred.shape[1:3])
```

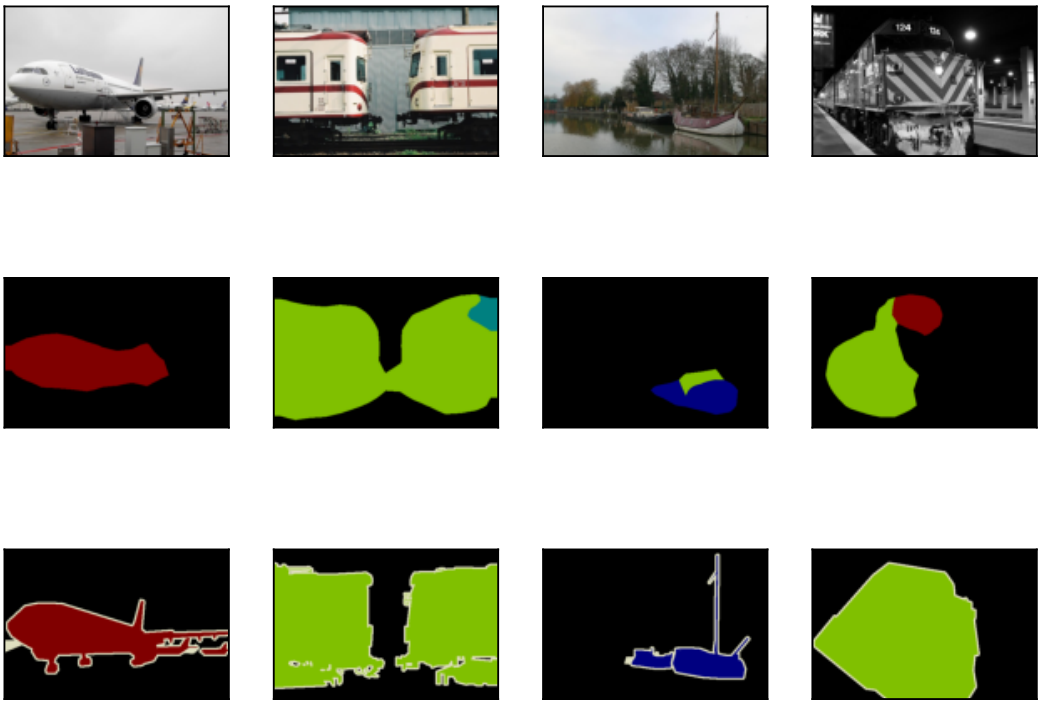
To visualize the predicted class of each pixel, we map the predicted class back to its label color in the dataset.

```
def label2image(pred):
    colormap = tf.constant(d2l.VOC_COLORMAP, dtype=tf.uint8)
    X = tf.cast(pred, tf.int32)
    return tf.gather(colormap, X)
```

Images in the test dataset vary in size and shape. Since the model uses a transposed convolutional layer with stride of 32, when the height or width of an input image is indivisible by 32, the output height or width of the transposed convolutional layer will deviate from the shape of the input image. In order to address this issue, we can crop multiple rectangular areas with height and width that are integer multiples of 32 in the image, and perform forward propagation on the pixels in these areas separately. Note that the union of these rectangular areas needs to completely cover the input image. When a pixel is covered by multiple rectangular areas, the average of the transposed convolution outputs in separate areas for this same pixel can be input to the softmax operation to predict the class.

For simplicity, we only read a few larger test images, and crop a 320×480 area for prediction starting from the upper-left corner of an image. For these test images, we print their cropped areas, prediction results, and ground-truth row by row.

```
voc_dir = d2l.download_extract('voc2012', 'VOCdevkit/VOC2012')
test_images, test_labels = d2l.read_voc_images(voc_dir, False)
n, imgs = 4, []
for i in range(n):
    # Crop HWC arrays: top=0, left=0, height=320, width=480
    X = test_images[i][:320, :480, :]
    pred = label2image(predict(X))
    label_crop = test_labels[i][:320, :480, :]
    imgs += [X, pred.numpy(), label_crop]
d2l.show_images(imgs[::3] + imgs[1::3] + imgs[2::3], 3, n, scale=2);
```



32.11.6 Summary

- The fully convolutional network first uses a CNN to extract image features, then transforms the number of channels into the number of classes via a 1×1 convolutional layer, and finally transforms the height and width of the feature maps to those of the input image via the transposed convolution.
- In a fully convolutional network, we can use upsampling of bilinear interpolation to initialize the transposed convolutional layer.

32.11.7 Exercises

1. If we use Xavier initialization for the transposed convolutional layer in the experiment, how does the result change?
2. The text uses `bilinear_kernel` without deriving it. Work it out for `bilinear_kernel(1, 1, 4)`, the kernel of the layer `conv_trans` with stride 2 and an output twice the size of its

input.

   1. Show that the 4×4 kernel is the outer product of a vector with itself, and give the vector.
   2. In one dimension, compute the six outputs of this transposed convolution for the input (a, b, c). Show that the four interior outputs are the linear interpolations of the input at $1/4$ and $3/4$ of the way between neighboring input pixels, and find the factor by which the first and the last output differ from the neighboring input pixel.
   3. Predict the ratio between the upper-left pixel of the two-dimensional output and the upper-left pixel of the input, and check it for each of the three color channels by applying `conv_trans` to the cat-and-dog image of this section.
3. Can you further improve the accuracy of the model by tuning the hyperparameters?
4. Predict the classes of all pixels in test images.
5. Pixel accuracy is dominated by the background class. For the trained network, compute the intersection over union (IoU) of every class on the test crops of `test_iter`: the number of pixels that are both predicted and labeled as class c, divided by the number of pixels that are predicted or labeled as c, with both counts accumulated over the whole test set. Report the mean IoU over the 21 classes next to the test pixel accuracy, list the five classes with the lowest IoU, and describe what these classes have in common.
6. The original fully convolutional network paper also uses outputs of some intermediate CNN layers (Long et al. 2015). Try to implement this idea.

32.12 Neural Style Transfer

If you are a photography enthusiast, you may be familiar with filters. It can change the color style of photos so that landscape photos become sharper or portrait photos have whitened skins. However, one filter usually only changes one aspect of the photo. To apply an ideal style to a photo, you probably need to try many different filter combinations. This process is as complex as tuning the hyperparameters of a model.

In this section, we will leverage layerwise representations of a CNN to automatically apply the style of one image to another image, i.e., *style transfer* (Gatys et al. 2016). This task needs two input images: one is the *content image* and the other is the *style image*. We will use neural networks to modify the content image to make it close to the style image in style. For example, the content image in Figure 32.14 is a landscape photo taken by us in Mount Rainier National Park in the suburbs of Seattle, while the style image is an oil painting with the theme of autumn oak trees. In the output synthesized image, the oil brush strokes of the style image are applied, leading to more vivid colors, while preserving the main shape of the objects in the content image.

32.12.1 Method

Figure 32.15 illustrates the CNN-based style transfer method with a simplified example. First, we initialize the synthesized image, for example, into the content image. This synthesized image is the only variable that needs to be updated during the style transfer process, i.e., the model parameters to be updated during training. Then we choose a pretrained CNN to extract image features and freeze its model parameters during training. This deep CNN uses multiple layers to extract hierarchical features for images. We can choose the output

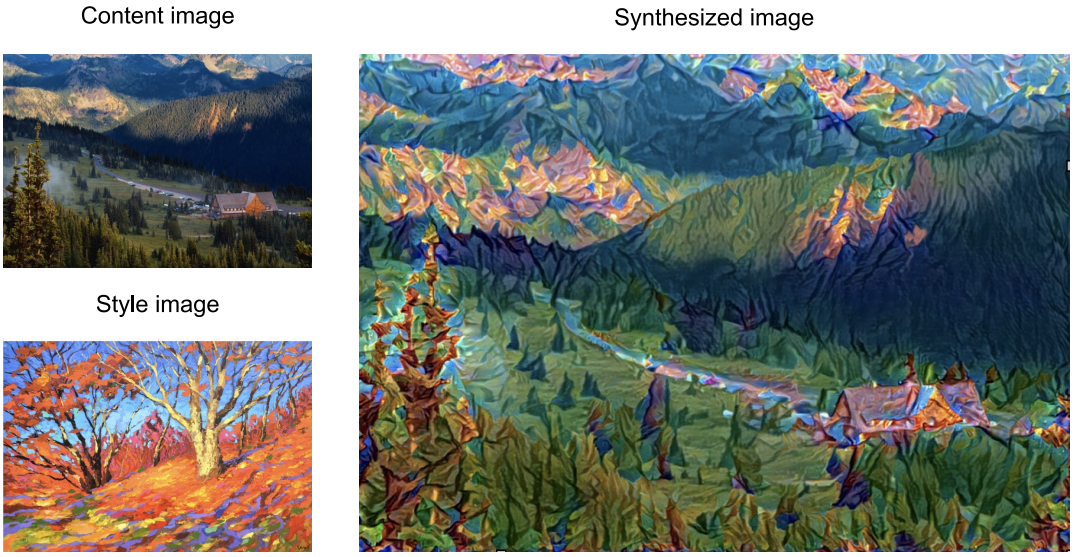


Figure 32.14: Given content and style images, style transfer outputs a synthesized image.

of some of these layers as content features or style features. Take Figure 32.15 as an example. The pretrained neural network here has 3 convolutional layers, where the second layer outputs the content features, and the first and third layers output the style features.

Next, we calculate the loss function of style transfer through forward propagation (direction of solid arrows), and update the model parameters (the synthesized image for output) through backpropagation (direction of dashed arrows). The loss function commonly used in style transfer consists of three parts: (i) *content loss* makes the synthesized image and the content image close in content features; (ii) *style loss* makes the synthesized image and style image close in style features; and (iii) *total variation loss* helps to reduce the noise in the synthesized image. Finally, when the model training is over, we output the model parameters of the style transfer to generate the final synthesized image.

In the following, we will explain the technical details of style transfer via a concrete experiment.

32.12.2 Reading the Content and Style Images

First, we read the content and style images. From their printed coordinate axes, we can tell that these images have different sizes.

```
# Cap cuDNN's convolution workspace. At 300x450 the default algorithm picker
# reserves ~9 GiB for a single VGG-19 forward pass; a 2 GiB cap keeps the true
# footprint near 1.4 GiB with the same result. TensorFlow reads the variable
# when it starts cuDNN, so this cell runs before the imports.
import os
os.environ['TF_CUDNN_WORKSPACE_LIMIT_IN_MB'] = '2048'
```

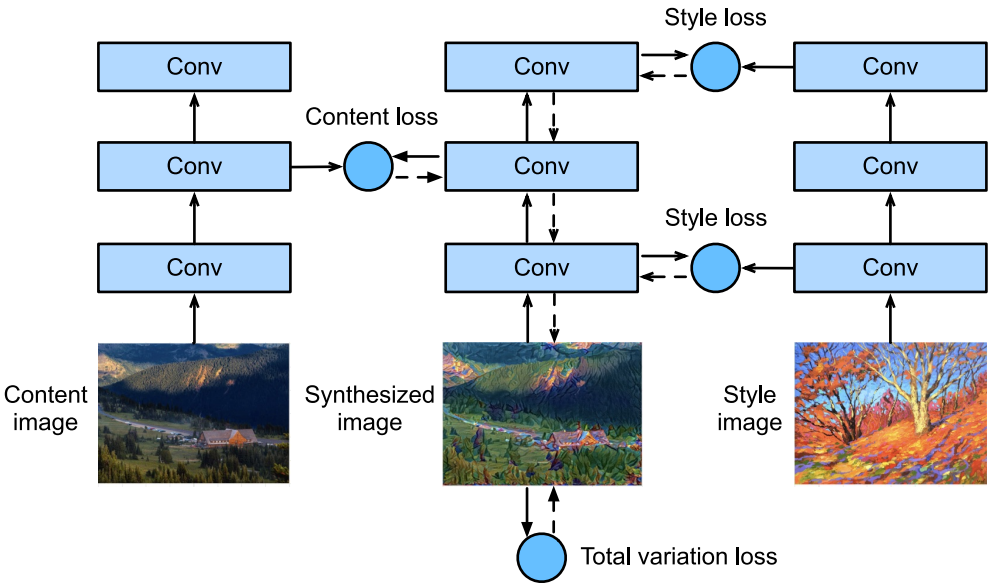

Figure 32.15: CNN-based style transfer process. Solid lines show the direction of forward propagation and dotted lines show backward propagation.

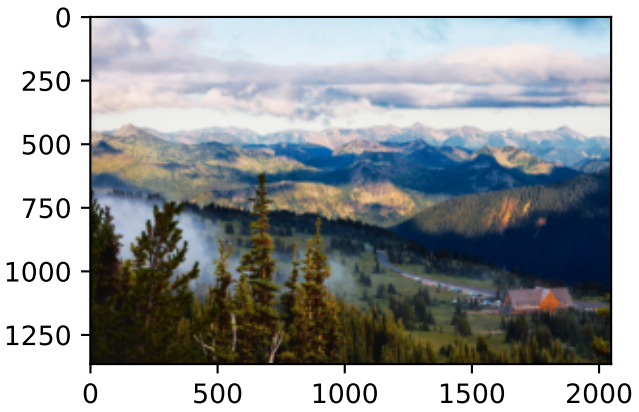
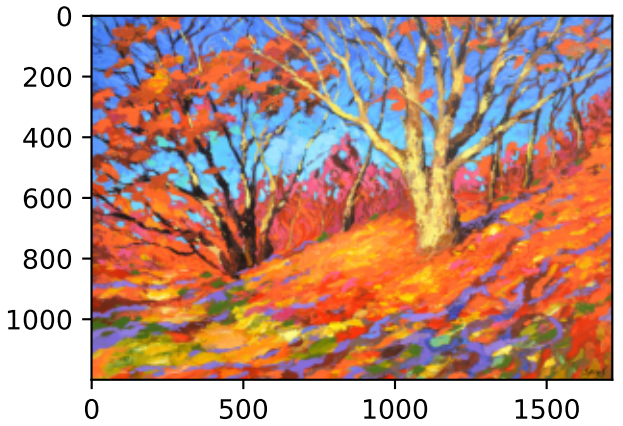
```
import keras
from PIL import Image
```

```
d2l.set_figsize()
content_img = Image.open('../img/rainier.jpg')
d2l.plt.imshow(content_img);
```



```
style_img = Image.open('../img/autumn-oak.jpg')
d2l.plt.imshow(style_img);
```



32.12.3 Preprocessing and Postprocessing

Below, we define two functions for preprocessing and postprocessing images. The `preprocess` function standardizes each of the three RGB channels of the input image and transforms the results into the CNN input format. The `postprocess` function restores the pixel values in the output image to their original values before standardization. Since the image printing function requires that each pixel has a floating point value from 0 to 1, we replace any value smaller than 0 or greater than 1 with 0 or 1, respectively.

```
# We keep the synthesized image in NCHW layout internally (matching PT/JAX
# so the #@tab-all gram/tv_loss/compute_loss cells work unchanged).
# VGG-19 expects NHWC, so we transpose when calling the feature extractor.
rgb_mean = tf.constant([0.485, 0.456, 0.406], dtype=tf.float32)
rgb_std  = tf.constant([0.229, 0.224, 0.225], dtype=tf.float32)

def preprocess(img, image_shape):
    img = img.resize((image_shape[1], image_shape[0]))  # PIL: (w, h)
    img = np.array(img, dtype=np.float32) / 255.0       # (H, W, C)
    img = img.transpose(2, 0, 1)                        # (C, H, W)
    img = (img - rgb_mean.numpy().reshape(3, 1, 1)) / rgb_std.numpy().reshape(
        3, 1, 1)
    return tf.expand_dims(tf.constant(img, dtype=tf.float32), axis=0)

def postprocess(img):
    img = img[0].numpy()                                # (C, H, W)
    img = np.clip(img.transpose(1, 2, 0) * rgb_std.numpy() +
                  rgb_mean.numpy(), 0, 1)
    return img
```

32.12.4 Extracting Features

We use the VGG-19 model pretrained on the ImageNet dataset to extract image features (Gatys et al. 2016).

```
pretrained_net = keras.applications.VGG19(weights='imagenet', include_top=False)
```

In order to extract the content features and style features of the image, we can select the output of certain layers in the VGG network. Generally speaking, the closer to the input layer, the easier to extract details of the image, and vice versa, the easier to extract the global information of the image. In order to avoid excessively retaining the details of the content image in the synthesized image, we choose a VGG layer that is closer to the output as the *content layer* to output the content features of the image. We also select the output of different VGG layers for extracting local and global style features. These layers are also called *style layers*. As mentioned in Section 7.2.1, the VGG network uses 5 convolutional blocks. In the experiment, we choose the last convolutional layer of the fourth convolutional block as the content layer, and the first convolutional layer of each convolutional block as the style layer. The indices of these layers can be obtained by printing the `pretrained_net` instance.

```
style_layers, content_layers = [0, 5, 10, 19, 28], [25]
```

When extracting features using VGG layers, we only need to use all those from the input layer to the content layer or style layer that is closest to the output layer. Let's construct a new network instance `net`, which only retains all the VGG layers to be used for feature extraction.

```
# The #@tab-all indices match torchvision's VGG-19 `features` numbering.
# Keras VGG-19 has a different layer order, so we remap.
_torch_to_tf = {0: 1, 5: 4, 10: 7, 19: 12, 25: 15, 28: 17}
style_layers  = [_torch_to_tf[i] for i in style_layers]
content_layers = [_torch_to_tf[i] for i in content_layers]
# Build a multi-output feature-extraction model (skips InputLayer at index 0)
_vgg_layers = pretrained_net.layers
net = keras.Model(
    inputs=pretrained_net.input,
    outputs=[_vgg_layers[i].output
             for i in sorted(set(content_layers + style_layers))])
```

Given the input `X`, if we simply invoke the forward propagation `net(X)`, we can only get the output of the last layer. Since we also need the outputs of intermediate layers, we need to perform layer-by-layer computation and keep the content and style layer outputs.

```
def _to_vgg_input(X_nchw):
    """Convert NCHW tensor (ImageNet-normalised) to VGG-19 NHWC input."""
    X_nhwc = tf.transpose(X_nchw, (0, 2, 3, 1))
    X_raw = (X_nhwc * tf.reshape(rgb_std, (1, 1, 1, 3))
             + tf.reshape(rgb_mean, (1, 1, 1, 3))) * 255.0
    return keras.applications.vgg19.preprocess_input(X_raw)

# _sorted_layers maps the sorted output index → original layer index
_sorted_layer_ids = sorted(set(content_layers + style_layers))

def extract_features(X, content_layers, style_layers):
    """Run VGG-19 and return (contents, styles) as NCHW tensors."""
```

```
    X_vgg = _to_vgg_input(X)
    all_outputs = net(X_vgg, training=False)  # list of NHWC tensors
    # all_outputs[i] corresponds to _sorted_layer_ids[i]
    layer_map = {lid: out for lid, out in zip(_sorted_layer_ids, all_outputs)}
    contents = [tf.transpose(layer_map[i], (0, 3, 1, 2)) for i in content_layers]
    styles   = [tf.transpose(layer_map[i], (0, 3, 1, 2)) for i in style_layers]
    return contents, styles
```

Two functions are defined below: the `get_contents` function extracts content features from the content image, and the `get_styles` function extracts style features from the style image. Since there is no need to update the model parameters of the pretrained network during training, we can extract the content and the style features even before the training starts. Since the synthesized image is a set of model parameters to be updated for style transfer, we can only extract the content and style features of the synthesized image by calling the `extract_features` function during training.

```
def get_contents(image_shape):
    content_X = preprocess(content_img, image_shape)
    contents_Y, _ = extract_features(content_X, content_layers, style_layers)
    return content_X, contents_Y

def get_styles(image_shape):
    style_X = preprocess(style_img, image_shape)
    _, styles_Y = extract_features(style_X, content_layers, style_layers)
    return style_X, styles_Y
```

32.12.5 Defining the Loss Function

Now we will describe the loss function for style transfer. The loss function consists of the content loss, style loss, and total variation loss.

32.12.5.1 Content Loss

Similar to the loss function in linear regression, the content loss measures the difference in content features between the synthesized image and the content image via the squared loss function. The two inputs of the squared loss function are both outputs of the content layer computed by the `extract_features` function.

```
def content_loss(Y_hat, Y):
    return tf.reduce_mean(tf.square(Y_hat - tf.stop_gradient(Y)))
```

32.12.5.2 Style Loss

Style loss, similar to content loss, also uses the squared loss function to measure the difference in style between the synthesized image and the style image. To express the style output of any style layer, we first use the `extract_features` function to compute the style layer output. Suppose that the output has 1 example, c channels, height h, and width w, we can transform this output into matrix $\mathbf{X}$ with c rows and hw columns. This matrix can

be thought of as the concatenation of c vectors $\mathbf{x}_1, \ldots, \mathbf{x}_c$, each of which has a length of hw. Here, vector $\mathbf{x}_i$ represents the style feature of channel i.

In the *Gram matrix* of these vectors $\mathbf{X}\mathbf{X}^\top \in \mathbb{R}^{c \times c}$, element x_{ij} in row i and column j is the dot product of vectors $\mathbf{x}_i$ and $\mathbf{x}_j$. It represents the correlation of the style features of channels i and j. We use this Gram matrix to represent the style output of any style layer. Note that when the value of hw is larger, it likely leads to larger values in the Gram matrix. Note also that the height and width of the Gram matrix are both the number of channels c. To allow style loss not to be affected by these values, the `gram` function below divides the Gram matrix by the number of its elements, i.e., chw.

```
def gram(X):
    num_channels, n = X.shape[1], d2l.size(X) // X.shape[1]
    X = d2l.reshape(X, (num_channels, n))
    return d2l.matmul(X, d2l.transpose(X)) / (num_channels * n)
```

Obviously, the two Gram matrix inputs of the squared loss function for style loss are based on the style layer outputs for the synthesized image and the style image. It is assumed here that the Gram matrix `gram_Y` based on the style image has been precomputed.

```
def style_loss(Y_hat, gram_Y):
    return tf.reduce_mean(tf.square(gram(Y_hat) - tf.stop_gradient(gram_Y)))
```

32.12.5.3 Total Variation Loss

Sometimes, the learned synthesized image has a lot of high-frequency noise, i.e., particularly bright or dark pixels. One common noise reduction method is *total variation denoising*. Denote by $x_{i,j}$ the pixel value at coordinate (i, j). Reducing total variation loss

$$\sum_{i,j} |x_{i,j} - x_{i+1,j}| + |x_{i,j} - x_{i,j+1}| \tag{32.5}$$

makes values of neighboring pixels on the synthesized image closer.

```
def tv_loss(Y_hat):
    return 0.5 * (d2l.reduce_mean(
        d2l.abs(Y_hat[:, :, 1:, :] - Y_hat[:, :, :-1, :])) +
                  d2l.reduce_mean(
        d2l.abs(Y_hat[:, :, :, 1:] - Y_hat[:, :, :, :-1])))
```

32.12.5.4 Loss Function

The loss function of style transfer is the weighted sum of content loss, style loss, and total variation loss. By adjusting these weight hyperparameters, we can balance among content retention, style transfer, and noise reduction on the synthesized image.

```
content_weight, style_weight, tv_weight = 1, 1e4, 10
```

```
def compute_loss(X, contents_Y_hat, styles_Y_hat, contents_Y, styles_Y_gram):
    # Calculate the content, style, and total variance losses respectively
    contents_l = [content_loss(Y_hat, Y) * content_weight for Y_hat, Y in zip(
        contents_Y_hat, contents_Y)]
    styles_l = [style_loss(Y_hat, Y) * style_weight for Y_hat, Y in zip(
        styles_Y_hat, styles_Y_gram)]
    tv_l = tv_loss(X) * tv_weight
    # Add up all the losses
    l = sum(styles_l + contents_l + [tv_l])
    return contents_l, styles_l, tv_l, l
```

32.12.6 Initializing the Synthesized Image

In style transfer, the synthesized image is the only variable that needs to be updated during training. Thus, we can treat the synthesized image as the model parameters.

No model class is needed: we optimize the synthesized image as a `tf.Variable` directly.

```
# In TF, we optimize the synthesized image as a tf.Variable directly
```

Next, we define the `get_inits` function. This function creates the synthesized image and initializes it to the image `X`. Gram matrices for the style image at various style layers, `styles_Y_gram`, are computed prior to training.

```
def get_inits(X, lr, styles_Y):
    # Initialize synthesized image to the content image (NCHW tf.Variable)
    gen_img = tf.Variable(tf.cast(X, tf.float32))
    lr_schedule = keras.optimizers.schedules.ExponentialDecay(
        initial_learning_rate=lr, decay_steps=50, decay_rate=0.8)
    trainer = keras.optimizers.Adam(learning_rate=lr_schedule)
    styles_Y_gram = [gram(Y) for Y in styles_Y]
    return gen_img, styles_Y_gram, trainer
```

32.12.7 Training

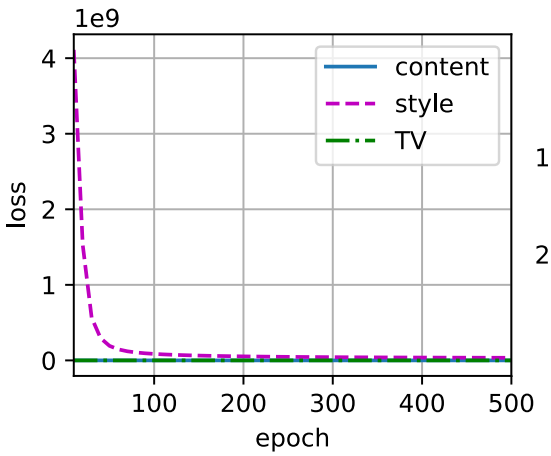
When training the model for style transfer, we continuously extract content features and style features of the synthesized image, and calculate the loss function. Below defines the training loop.

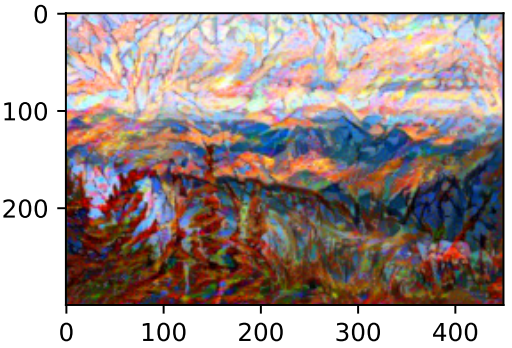
```
def train(X, contents_Y, styles_Y, lr, num_epochs, lr_decay_epoch):
    X, styles_Y_gram, trainer = get_inits(X, lr, styles_Y)
    animator = d2l.Animator(xlabel='epoch', ylabel='loss',
                            xlim=[10, num_epochs],
                            legend=['content', 'style', 'TV'],
                            ncols=2, figsize=(7, 2.5))
    for epoch in range(num_epochs):
        with tf.GradientTape() as tape:
            contents_Y_hat, styles_Y_hat = extract_features(
                X, content_layers, style_layers)
```

```
            contents_l, styles_l, tv_l, l = compute_loss(
                X, contents_Y_hat, styles_Y_hat, contents_Y, styles_Y_gram)
        grads = tape.gradient(l, [X])
        trainer.apply_gradients(zip(grads, [X]))
        if (epoch + 1) % 10 == 0:
            animator.axes[1].imshow(postprocess(X))
            animator.add(epoch + 1, [float(sum(contents_l)),
                                     float(sum(styles_l)), float(tv_l)])
    return X
```

Now we start to train the model. We rescale the height and width of the content and style images to 300 by 450 pixels. We use the content image to initialize the synthesized image.

```
image_shape = (300, 450)  # (h, w)
content_X, contents_Y = get_contents(image_shape)
_, styles_Y = get_styles(image_shape)
output = train(content_X, contents_Y, styles_Y, 0.3, 500, 50)
```





We can see that the synthesized image retains the scenery and objects of the content image, and transfers the color of the style image at the same time. For example, the synthesized image has blocks of color like those in the style image. Some of these blocks even have the subtle texture of brush strokes.

32.12.8 Summary

- The loss function commonly used in style transfer consists of three parts: (i) content loss makes the synthesized image and the content image close in content features; (ii) style loss makes the synthesized image and style image close in style features; and (iii) total variation loss helps to reduce the noise in the synthesized image.
- We can use a pretrained CNN to extract image features and minimize the loss function to continuously update the synthesized image as model parameters during training.
- We use Gram matrices to represent the style outputs from the style layers.

32.12.9 Exercises

1. How does the output change when you select different content and style layers?
2. Adjust the weight hyperparameters in the loss function. Does the output retain more content or have less noise?
3. Use different content and style images. Can you create more interesting synthesized images?
4. Evaluate `tv_loss` by hand for three single-channel $h \times w$ images: a constant image, a checkerboard with values ± 1, and an image that steps from 0 to 1 between two neighboring columns. Then take an image that ramps linearly from 0 to 1 over m columns. Show that `tv_loss` takes the same value for the step and for every ramp, while a penalty on squared differences of neighboring pixels decreases as $1/m$ for the ramp. Based on these results, state which of the two penalties removes isolated noisy pixels while keeping sharp edges, and why.
5. The style loss compares Gram matrices.
    1. Show that `gram(Y)` does not change when the hw spatial positions of a feature map `Y` are permuted, and verify this numerically for the style features `styles_Y` at one style layer.
    2. Set `content_weight` to 0, initialize the synthesized image with random noise instead of the content image, and train. Describe the output. Using the first part, explain which properties of the style image it reproduces and which it does not.
6. Can we apply style transfer for text? Hint: you may refer to the survey paper by Hu et al. (2022).

32.13 Image Classification (CIFAR-10) on Kaggle

So far, we have been using high-level APIs of deep learning frameworks to directly obtain image datasets in tensor format. However, custom image datasets often come in the form of image files. In this section, we will start from raw image files, and organize, read, then transform them into tensor format step by step.

We experimented with the CIFAR-10 dataset in Section 32.1, which is an important dataset in computer vision. In this section, we will apply the knowledge we learned in previous sections to practice the Kaggle competition of CIFAR-10 image classification. The web address of the competition is https://www.kaggle.com/c/cifar-10

Figure 32.16 shows the information on the competition's webpage. In order to submit the results, you need to register a Kaggle account.

```
import collections
import keras
import os
import pandas as pd
import shutil
```

32.13.1 Obtaining and Organizing the Dataset

The competition dataset is divided into a training set and a test set, which contain 50000 and 300000 images, respectively. In the test set, 10000 images will be used for evaluation, while the remaining 290000 images will not be evaluated: they are included just to make it hard

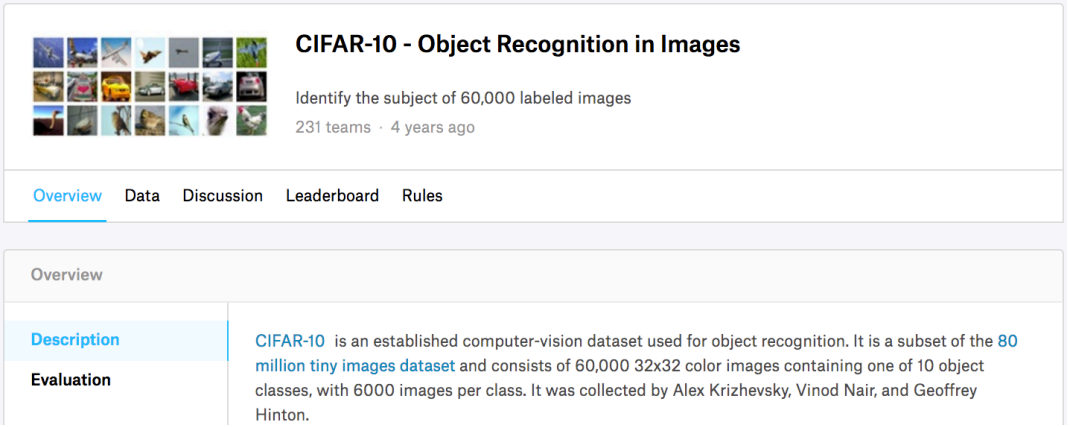


Figure 32.16: CIFAR-10 image classification competition webpage information. The competition dataset can be obtained by clicking the "Data" tab.

to cheat with *manually* labeled results of the test set. The images in this dataset are all png color (RGB channels) image files, whose height and width are both 32 pixels. The images cover a total of 10 categories, namely airplanes, cars, birds, cats, deer, dogs, frogs, horses, boats, and trucks. The upper-left corner of Figure 32.16 shows some images of airplanes, cars, and birds in the dataset.

32.13.1.1 Downloading the Dataset

After logging in to Kaggle, we can click the "Data" tab on the CIFAR-10 image classification competition webpage shown in Figure 32.16 and download the dataset by clicking the "Download All" button. After unzipping the downloaded file in `../data`, and unzipping `train.7z` and `test.7z` inside it, you will find the entire dataset in the following paths:

- `../data/cifar-10/train/[1-50000].png`
- `../data/cifar-10/test/[1-300000].png`
- `../data/cifar-10/trainLabels.csv`
- `../data/cifar-10/sampleSubmission.csv`

where the `train` and `test` directories contain the training and testing images, respectively, `trainLabels.csv` provides labels for the training images, and `sampleSubmission.csv` is a sample submission file.

To make it easier to get started, we provide a small-scale sample of the dataset that contains the first 1000 training images and 5 random testing images. To use the full dataset of the Kaggle competition, you need to set the following `demo` variable to `False`.

```
d2l.DATA_HUB['cifar10_tiny'] = (d2l.DATA_URL + 'kaggle_cifar10_tiny.zip',
                                '2068874e4b9a9f0fb07ebe0ad2b29754449ccacd')

# If you use the full dataset downloaded for the Kaggle competition, set
# `demo` to False
demo = True
```

```
if demo:
    data_dir = d2l.download_extract('cifar10_tiny')
else:
    data_dir = '../data/cifar-10/'
```

32.13.1.2 Organizing the Dataset

We need to organize datasets to facilitate model training and testing. Let's first read the labels from the csv file. The following function returns a dictionary that maps the non-extension part of the filename to its label.

```
def read_csv_labels(fname):
    """Read `fname` to return a filename to label dictionary."""
    with open(fname, 'r') as f:
        # Skip the file header line (column name)
        lines = f.readlines()[1:]
    tokens = [l.rstrip().split(',') for l in lines]
    return dict(((name, label) for name, label in tokens))

labels = read_csv_labels(os.path.join(data_dir, 'trainLabels.csv'))
print('# training examples:', len(labels))
print('# classes:', len(set(labels.values())))
```

```
# training examples: 1000
# classes: 10
```

Next, we define the `reorg_train_valid` function to split the validation set out of the original training set. The argument `valid_ratio` in this function is the ratio of the number of examples in the validation set to the number of examples in the original training set. More concretely, let n be the number of images of the class with the least examples, and r be the ratio. The validation set will split out $\max(\lfloor nr \rfloor, 1)$ images for each class. Let's use `valid_ratio=0.1` as an example. Since the original training set has 50000 images, there will be 45000 images used for training in the path `train_valid_test/train`, while the other 5000 images will be split out as validation set in the path `train_valid_test/valid`. After organizing the dataset, images of the same class will be placed under the same folder.

```
def copyfile(filename, target_dir):
    """Copy a file into a target directory."""
    os.makedirs(target_dir, exist_ok=True)
    shutil.copy(filename, target_dir)

def reorg_train_valid(data_dir, labels, valid_ratio):
    """Split the validation set out of the original training set."""
    # The number of examples of the class that has the fewest examples in the
    # training dataset
    n = collections.Counter(labels.values()).most_common()[-1][1]
    # The number of examples per class for the validation set
    n_valid_per_label = max(1, math.floor(n * valid_ratio))
    label_count = {}
```

```
    for train_file in os.listdir(os.path.join(data_dir, 'train')):
        label = labels[train_file.split('.')[0]]
        fname = os.path.join(data_dir, 'train', train_file)
        copyfile(fname, os.path.join(data_dir, 'train_valid_test',
                                     'train_valid', label))
        if label not in label_count or label_count[label] < n_valid_per_label:
            copyfile(fname, os.path.join(data_dir, 'train_valid_test',
                                         'valid', label))
            label_count[label] = label_count.get(label, 0) + 1
        else:
            copyfile(fname, os.path.join(data_dir, 'train_valid_test',
                                         'train', label))
    return n_valid_per_label
```

The `reorg_test` function below organizes the testing set for data loading during prediction.

```
def reorg_test(data_dir):
    """Organize the testing set for data loading during prediction."""
    for test_file in os.listdir(os.path.join(data_dir, 'test')):
        copyfile(os.path.join(data_dir, 'test', test_file),
                 os.path.join(data_dir, 'train_valid_test', 'test',
                              'unknown'))
```

Finally, we use a function to invoke the `read_csv_labels`, `reorg_train_valid`, and `reorg_test` functions defined above.

```
def reorg_cifar10_data(data_dir, valid_ratio):
    labels = read_csv_labels(os.path.join(data_dir, 'trainLabels.csv'))
    reorg_train_valid(data_dir, labels, valid_ratio)
    reorg_test(data_dir)
```

Here we only set the batch size to 32 for the small-scale sample of the dataset. When training and testing the complete dataset of the Kaggle competition, `batch_size` should be set to a larger integer, such as 128. We split out 10% of the training examples as the validation set for tuning hyperparameters.

```
batch_size = 32 if demo else 128
valid_ratio = 0.1
reorg_cifar10_data(data_dir, valid_ratio)
```

32.13.2 Image Augmentation

We use image augmentation to address overfitting. For example, images can be flipped horizontally at random during training. We can also perform standardization for the three RGB channels of color images. Below lists some of these operations that you can tweak.

```
CIFAR_MEAN = tf.constant([0.4914, 0.4822, 0.4465], dtype=tf.float32)
CIFAR_STD = tf.constant([0.2023, 0.1994, 0.2010], dtype=tf.float32)
```

```
def transform_train_fn(image, label):
    """Training augmentation: resize, random crop, flip, normalize."""
    image = tf.cast(image, tf.float32)
    image = tf.image.resize(image, [40, 40])
    image = tf.image.random_crop(image, size=[32, 32, 3])
    image = tf.image.random_flip_left_right(image)
    image = image / 255.0
    image = (image - CIFAR_MEAN) / CIFAR_STD
    return image, label

def transform_test_fn(image, label):
    """Test preprocessing: normalize only."""
    image = tf.cast(image, tf.float32) / 255.0
    image = (image - CIFAR_MEAN) / CIFAR_STD
    return image, label
```

During testing, we only perform standardization on images so as to remove randomness in the evaluation results.

```
# Test transform is defined above as transform_test_fn
```

32.13.3 Reading the Dataset

Next, we read the organized dataset consisting of raw image files. Each example includes an image and a label.

```
def _load_image_folder_tf(folder_path):
    """Load images from a class-subfolder directory into a tf.data.Dataset
    of (image, label) where image is uint8 [H, W, 3] and label is int."""
    ds = keras.utils.image_dataset_from_directory(
        folder_path, label_mode='int', image_size=(32, 32),
        batch_size=None, shuffle=False)
    return ds

train_ds = _load_image_folder_tf(
    os.path.join(data_dir, 'train_valid_test', 'train'))
train_valid_ds = _load_image_folder_tf(
    os.path.join(data_dir, 'train_valid_test', 'train_valid'))
valid_ds = _load_image_folder_tf(
    os.path.join(data_dir, 'train_valid_test', 'valid'))
test_ds = _load_image_folder_tf(
    os.path.join(data_dir, 'train_valid_test', 'test'))
```

```
Found 959 files belonging to 10 classes.
Found 1000 files belonging to 10 classes.
Found 119 files belonging to 10 classes.
Found 5 files belonging to 1 classes.
```

During training, we need to specify all the image augmentation operations defined above. When the validation set is used for model evaluation during hyperparameter tuning, no randomness from image augmentation should be introduced. Before final prediction, we

train the model on the combined training set and validation set to make full use of all the labeled data.

```
train_iter = (train_ds.map(transform_train_fn, num_parallel_calls=tf.data.AUTOTUNE)
              .shuffle(10000).batch(batch_size)
              .prefetch(tf.data.AUTOTUNE))
train_valid_iter = (train_valid_ds.map(transform_train_fn,
                    num_parallel_calls=tf.data.AUTOTUNE)
                    .shuffle(10000).batch(batch_size)
                    .prefetch(tf.data.AUTOTUNE))
valid_iter = (valid_ds.map(transform_test_fn, num_parallel_calls=tf.data.AUTOTUNE)
              .batch(batch_size)
              .prefetch(tf.data.AUTOTUNE))
test_iter = (test_ds.map(transform_test_fn, num_parallel_calls=tf.data.AUTOTUNE)
             .batch(batch_size)
             .prefetch(tf.data.AUTOTUNE))
```

32.13.4 Defining the Model

We use the ResNet-18 model `d2l.resnet18` with a three-channel input. Its weights start from He initialization (Section 4.4.2.2), which suits networks with ReLU activations.

```
def get_net():
    return d2l.resnet18(10, 3)

loss = keras.losses.SparseCategoricalCrossentropy(
    from_logits=True, reduction='none')
```

32.13.5 Defining the Training Function

We will select models and tune hyperparameters according to the model's performance on the validation set. In the following, we define the model training function `train`.

```
def train(net, train_iter, valid_iter, num_epochs, lr, wd, lr_period,
          lr_decay):
    # Keras's `ExponentialDecay` counts gradient-update steps, not epochs.
    # Scale by `num_batches` so that the learning rate decays every
    # `lr_period` epochs.
    num_batches = sum(1 for _ in train_iter)
    lr_schedule = keras.optimizers.schedules.ExponentialDecay(
        initial_learning_rate=lr,
        decay_steps=lr_period * num_batches,
        decay_rate=lr_decay,
        staircase=True)
    optimizer = keras.optimizers.SGD(learning_rate=lr_schedule, momentum=0.9,
                                     weight_decay=wd)
    timer = d2l.Timer()
    legend = ['train loss', 'train acc']
    if valid_iter is not None:
        legend.append('valid acc')
```

```
    animator = d2l.Animator(xlabel='epoch', xlim=[1, num_epochs],
                            legend=legend)
    for epoch in range(num_epochs):
        metric = d2l.Accumulator(3)
        for i, (features, labels) in enumerate(train_iter):
            timer.start()
            with tf.GradientTape() as tape:
                logits = net(features, training=True)
                l = loss(labels, logits)
            grads = tape.gradient(l, net.trainable_variables)
            optimizer.apply_gradients(zip(grads, net.trainable_variables))
            acc = tf.reduce_sum(tf.cast(
                tf.argmax(logits, axis=1) == tf.cast(labels, tf.int64),
                tf.float32))
            metric.add(float(tf.reduce_sum(l)), float(acc), len(labels))
            timer.stop()
            if (i + 1) % (num_batches // 5) == 0 or i == num_batches - 1:
                animator.add(epoch + (i + 1) / num_batches,
                             (metric[0] / metric[2], metric[1] / metric[2],
                              None))
        if valid_iter is not None:
            valid_metric = d2l.Accumulator(2)
            for features, labels in valid_iter:
                logits = net(features, training=False)
                valid_metric.add(
                    float(tf.reduce_sum(tf.cast(
                        tf.argmax(logits, axis=1) == tf.cast(labels, tf.int64),
                        tf.float32))),
                    len(labels))
            valid_acc = valid_metric[0] / valid_metric[1]
            animator.add(epoch + 1, (None, None, valid_acc))
    measures = (f'train loss {metric[0] / metric[2]:.3f}, '
                f'train acc {metric[1] / metric[2]:.3f}')
    if valid_iter is not None:
        measures += f', valid acc {valid_acc:.3f}'
    print(measures + f'\n{metric[2] * num_epochs / timer.sum():.1f}'
          f' examples/sec')
    return net
```

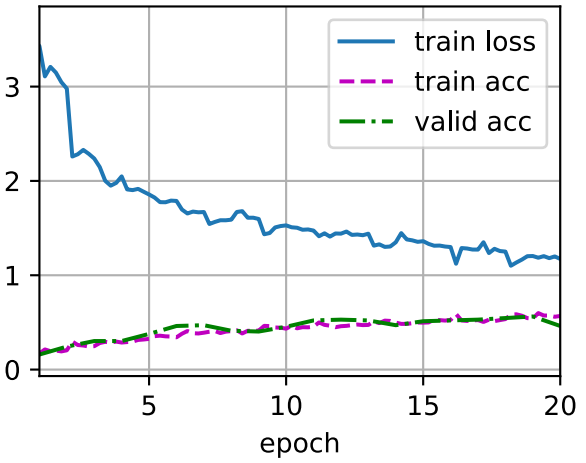
32.13.6 Training and Validating the Model

Now, we can train and validate the model. All the following hyperparameters can be tuned. For example, we can increase the number of epochs. When `lr_period` and `lr_decay` are set to 4 and 0.9, respectively, the learning rate of the optimization algorithm will be multiplied by 0.9 after every 4 epochs. Just for ease of demonstration, we only train 20 epochs here. When `demo=True`, the tiny sample has only a few validation images per class, so the validation accuracy is a noisy smoke test of the pipeline rather than a meaningful competition score. Use the full dataset (`demo=False`) and the longer recipe in the exercises to assess model quality.

```
num_epochs, lr, wd = 20, 0.001, 5e-4
lr_period, lr_decay = 4, 0.9
```

```
net = get_net()
net = train(net, train_iter, valid_iter, num_epochs, lr, wd, lr_period,
            lr_decay)
```

```
train loss 1.173, train acc 0.568, valid acc 0.462
82.8 examples/sec
```

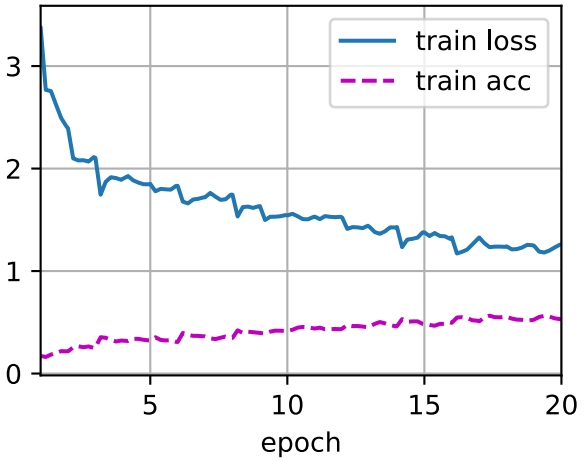


32.13.7 Classifying the Testing Set and Submitting Results on Kaggle

After obtaining a promising model with hyperparameters, we use all the labeled data (including the validation set) to retrain the model and classify the testing set.

```
net = get_net()
net = train(net, train_valid_iter, None, num_epochs, lr, wd, lr_period,
            lr_decay)
preds = []
for X, _ in test_iter:
    y_hat = net(X, training=False)
    preds.extend(tf.argmax(y_hat, axis=1).numpy())
# Get class names from the train_valid dataset directory
class_names = sorted(os.listdir(
    os.path.join(data_dir, 'train_valid_test', 'train_valid')))
sorted_ids = list(range(1, sum(1 for _ in test_ds) + 1))
sorted_ids.sort(key=lambda x: str(x))
df = pd.DataFrame({'id': sorted_ids, 'label': preds})
df['label'] = df['label'].apply(lambda x: class_names[x])
df.to_csv('submission.csv', index=False)
```

```
train loss 1.260, train acc 0.530
88.8 examples/sec
```



The above code will generate a `submission.csv` file, whose format meets the requirement of the Kaggle competition. The method for submitting results to Kaggle is similar to that in Section 4.7.

32.13.8 Summary

- We can read datasets containing raw image files after organizing them into the required format.
- We can use convolutional neural networks and image augmentation in an image classification competition.

32.13.9 Exercises

1. `reorg_train_valid` puts $\max(\lfloor nr \rfloor, 1)$ images of each class into the validation set. Compute the size of the validation set for the demo data (find n from `labels`) and for the full dataset, both with `valid_ratio = 0.1`. Treat each validation image as an independent Bernoulli trial and compute the standard error of the validation accuracy at an accuracy of 50% for the demo split and of 90% for the full split. Taking twice the standard error of the difference of two independent estimates as the threshold, decide which of the differences of 0.5, 2, and 10 percentage points between two runs each split can distinguish from noise.
2. Before writing `submission.csv`, the code sorts the test ids as strings. Explain why by determining the order in which the test images are read from `train_valid_test/test/unknown`, and write down the first eight ids of the full test set of 300000 images in that order. If the ids were left in numeric order, what score would a classifier with perfect predictions receive, approximately, and why?
3. Use the complete CIFAR-10 dataset for this Kaggle competition. Set hyperparameters as `batch_size = 128`, `num_epochs = 100`, `lr = 0.1`, `lr_period = 50`, and `lr_decay = 0.1`. See what accuracy and ranking you can achieve in this competition. Can you further improve them?
4. What accuracy can you get when not using image augmentation?
5. The ResNet-18 of this section starts with a 3×3 convolution of stride 1 and has no max-pooling layer, whereas the ResNet-18 for ImageNet in Section 7.4 starts with a 7×7

convolution of stride 2 followed by 3×3 max-pooling of stride 2. For 32×32 inputs, compute the height and width of the feature maps after each of the four residual stages in both networks. Then replace the stem of the section's network by the ImageNet stem, train both networks on the full dataset with the same schedule, and compare their validation accuracies. Explain the result from the feature-map sizes.

6. Test-time augmentation averages the predictions for several transformed copies of each test image. For a network trained on the full dataset, average the softmax outputs for each validation image and its horizontal flip, and compare the resulting validation accuracy with that of the unflipped images alone. Using the standard error of the validation accuracy, state whether the difference exceeds the noise of the validation set, and explain why horizontal flips are a suitable transformation for this purpose while vertical flips are not.

32.14 Dog Breed Identification (ImageNet Dogs) on Kaggle

In this section, we will practice the dog breed identification problem on Kaggle. The web address of this competition is https://www.kaggle.com/c/dog-breed-identification

In this competition, 120 different breeds of dogs will be recognized. In fact, the dataset for this competition is a subset of the ImageNet dataset. Unlike the images in the CIFAR-10 dataset in Section 32.13, the images in the ImageNet dataset are both higher and wider in varying dimensions. Figure 32.17 shows the information on the competition's webpage. You need a Kaggle account to submit your results.

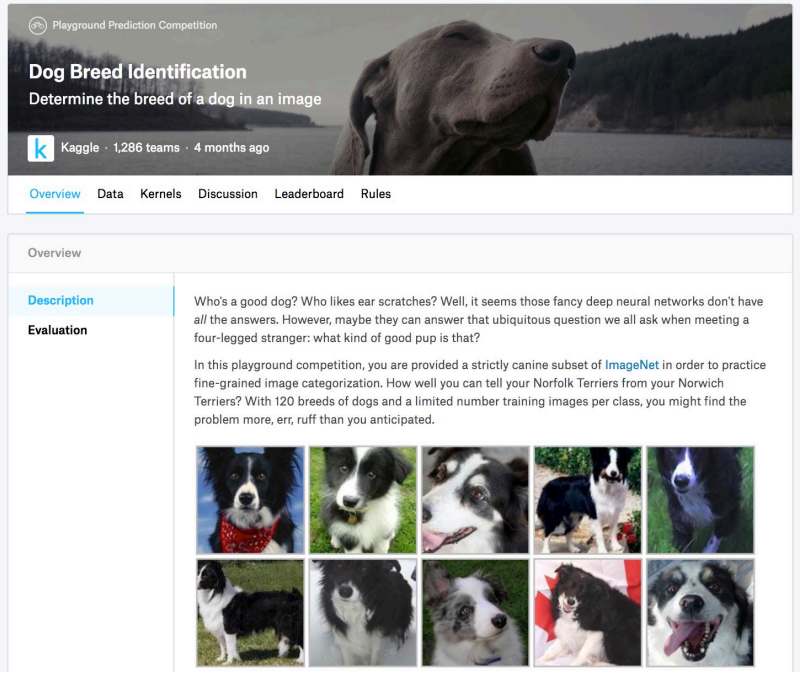


Figure 32.17: The dog breed identification competition website. The competition dataset can be obtained by clicking the "Data" tab.

```
import keras
import os
```

32.14.1 Obtaining and Organizing the Dataset

The competition dataset is divided into a training set and a test set, which contain 10222 and 10357 JPEG images of three RGB (color) channels, respectively. Among the training dataset, there are 120 breeds of dogs such as Labradors, Poodles, Dachshunds, Samoyeds, Huskies, Chihuahuas, and Yorkshire Terriers.

32.14.1.1 Downloading the Dataset

After logging into Kaggle, you can click on the "Data" tab on the competition webpage shown in Figure 32.17 and download the dataset by clicking the "Download All" button. After unzipping the downloaded file in `../data`, you will find the entire dataset in the following paths:

- ../data/dog-breed-identification/labels.csv
- ../data/dog-breed-identification/sample_submission.csv
- ../data/dog-breed-identification/train
- ../data/dog-breed-identification/test

You may have noticed that the above structure is similar to that of the CIFAR-10 competition in Section 32.13, where folders `train/` and `test/` contain training and testing dog images, respectively, and `labels.csv` contains the labels for the training images. Similarly, to make it easier to get started, we provide a small sample of the dataset mentioned above: `train_valid_test_tiny.zip`. If you are going to use the full dataset for the Kaggle competition, you need to change the `demo` variable below to `False`.

```
d2l.DATA_HUB['dog_tiny'] = (d2l.DATA_URL + 'kaggle_dog_tiny.zip',
                            '0cb91d09b814ecdc07b50f31f8dcad3e81d6a86d')

# If you use the full dataset downloaded for the Kaggle competition, change
# the variable below to `False`
demo = True
if demo:
    data_dir = d2l.download_extract('dog_tiny')
else:
    data_dir = os.path.join('..', 'data', 'dog-breed-identification')
```

32.14.1.2 Organizing the Dataset

We can organize the dataset similarly to what we did in Section 32.13, namely splitting out a validation set from the original training set, and moving images into subfolders grouped by labels.

The `reorg_dog_data` function below reads the training data labels, splits out the validation set, and organizes the training set.

```
def reorg_dog_data(data_dir, valid_ratio):
    labels = d2l.read_csv_labels(os.path.join(data_dir, 'labels.csv'))
    d2l.reorg_train_valid(data_dir, labels, valid_ratio)
    d2l.reorg_test(data_dir)

batch_size = 32 if demo else 128
valid_ratio = 0.1
reorg_dog_data(data_dir, valid_ratio)
```

32.14.2 Image Augmentation

Recall that this dog breed dataset is a subset of the ImageNet dataset, whose images are larger than those of the CIFAR-10 dataset in Section 32.13. The following lists a few image augmentation operations that might be useful for relatively larger images.

```
def transform_train_fn(image, label):
    """Training augmentation: random crop, flip, color jitter, normalize."""
    image = tf.cast(image, tf.float32)
    # Random resized crop to 224x224
    image = tf.image.resize(image, [256, 256])
    image = tf.image.random_crop(image, size=[224, 224, 3])
    image = tf.image.random_flip_left_right(image)
    image = tf.image.random_brightness(image, max_delta=0.4 * 255)
    image = tf.image.random_contrast(image, lower=0.6, upper=1.4)
    image = tf.image.random_saturation(image, lower=0.6, upper=1.4)
    image = tf.clip_by_value(image, 0.0, 255.0)
    return tf.keras.applications.resnet50.preprocess_input(image), label
```

During prediction, we only use image preprocessing operations without randomness.

```
def transform_test_fn(image, label):
    """Test preprocessing: resize, center crop, normalize."""
    image = tf.cast(image, tf.float32)
    image = tf.image.resize(image, [256, 256])
    # Center crop to 224x224
    image = tf.image.resize_with_crop_or_pad(image, 224, 224)
    return tf.keras.applications.resnet50.preprocess_input(image), label
```

32.14.3 Reading the Dataset

As in Section 32.13, we can read the organized dataset consisting of raw image files.

```
def _load_image_folder_tf(folder_path):
    """Load images from a class-subfolder directory into a tf.data.Dataset."""
    ds = keras.utils.image_dataset_from_directory(
        folder_path, label_mode='int', image_size=(256, 256),
        batch_size=None, shuffle=False)
    return ds
```

```
train_ds = _load_image_folder_tf(
    os.path.join(data_dir, 'train_valid_test', 'train'))
train_valid_ds = _load_image_folder_tf(
    os.path.join(data_dir, 'train_valid_test', 'train_valid'))
valid_ds = _load_image_folder_tf(
    os.path.join(data_dir, 'train_valid_test', 'valid'))
test_ds = _load_image_folder_tf(
    os.path.join(data_dir, 'train_valid_test', 'test'))
```

```

```

Below we create data iterator instances the same way as in Section 32.13.

```
train_iter = (train_ds.map(transform_train_fn, num_parallel_calls=tf.data.AUTOTUNE)
              .shuffle(10000).batch(batch_size, drop_remainder=True)
              .prefetch(tf.data.AUTOTUNE))
train_valid_iter = (train_valid_ds.map(transform_train_fn,
                    num_parallel_calls=tf.data.AUTOTUNE)
                    .shuffle(10000).batch(batch_size, drop_remainder=True)
                    .prefetch(tf.data.AUTOTUNE))
valid_iter = (valid_ds.map(transform_test_fn, num_parallel_calls=tf.data.AUTOTUNE)
              .batch(batch_size, drop_remainder=True)
              .prefetch(tf.data.AUTOTUNE))
test_iter = (test_ds.map(transform_test_fn, num_parallel_calls=tf.data.AUTOTUNE)
             .batch(batch_size, drop_remainder=False)
             .prefetch(tf.data.AUTOTUNE))
```

32.14.4 Fine-Tuning a Pretrained Model

Again, the dataset for this competition is a subset of the ImageNet dataset. Therefore, we can use the approach discussed in Section 32.2 to select a model pretrained on the full ImageNet dataset and use it to extract image features to be fed into a custom small-scale output network. High-level APIs of deep learning frameworks provide a wide range of models pretrained on the ImageNet dataset. Here, we choose a pretrained ResNet-34 model, where we simply reuse the input of this model's output layer (i.e., the extracted features). Then we can replace the original output layer with a small custom output network that can be trained, such as stacking two fully connected layers. Different from the experiment in Section 32.2, the following does not retrain the pretrained model used for feature extraction. This reduces training time and memory for storing gradients.

The TensorFlow code uses a pretrained ResNet-50, whose pooled features have 2048 dimensions.

Recall that we standardized images using the means and standard deviations of the three RGB channels for the full ImageNet dataset. In fact, this is also consistent with the standardization operation by the pretrained model on ImageNet.

```
# Frozen ImageNet ResNet-50 feature extractor plus a small trainable 120-way
# head. We keep them as SEPARATE models (not one Keras `Model`) so the frozen
# backbone can run OUTSIDE the GradientTape and in micro-batches: a batch-32
# ResNet-50 forward at 224x224 otherwise reserves ~8.6 GiB (its activations are
# held for the head's backprop). Micro-batching caps the peak activation
# working set.
BACKBONE_MICROBATCH = 16

def get_net():
    # Remove the ImageNet output layer and keep the 2048 pooled features
    backbone = keras.applications.ResNet50(
        weights='imagenet', include_top=False, pooling='avg',
        input_shape=(224, 224, 3))
    backbone.trainable = False
    head = keras.Sequential([keras.layers.Input(shape=(2048,)),
                             keras.layers.Dense(256, activation='relu'),
                             keras.layers.Dense(120)])
    return backbone, head

def backbone_features(backbone, X):
    """Run the frozen backbone in micro-batches. The concatenated result is
    identical to a single forward pass, but only one micro-batch's activations
    are live at a time, so the peak footprint stays small."""
    outs = [backbone(X[i:i + BACKBONE_MICROBATCH], training=False)
            for i in range(0, X.shape[0], BACKBONE_MICROBATCH)]
    return tf.concat(outs, axis=0)
```

Before calculating the loss, we first obtain the input of the pretrained model's output layer, i.e., the extracted feature. Then we use this feature as input for our small custom output network to calculate the loss.

```
loss = keras.losses.SparseCategoricalCrossentropy(
    from_logits=True, reduction='none')

def evaluate_loss(data_iter, backbone, head):
    l_sum, n = 0.0, 0
    for features, labels in data_iter:
        logits = head(backbone_features(backbone, features), training=False)
        l = loss(labels, logits)
        l_sum += float(tf.reduce_sum(l))
        n += len(labels)
    return l_sum / n
```

32.14.5 Defining the Training Function

We will select the model and tune hyperparameters according to the model's performance on the validation set. The model training function `train` only iterates parameters of the small custom output network.

```
def train(backbone, head, train_iter, valid_iter, num_epochs, lr, wd,
          lr_period, lr_decay):
    # Only train the custom head; the backbone is frozen (see get_net()) and is
    # run outside the tape.
    # Keras's `ExponentialDecay.decay_steps` counts *gradient-update
    # steps*, not epochs. Scale by `num_batches` so the LR decays every
    # `lr_period` *epochs*.
    num_batches = sum(1 for _ in train_iter)
    lr_schedule = keras.optimizers.schedules.ExponentialDecay(
        initial_learning_rate=lr,
        decay_steps=lr_period * num_batches,
        decay_rate=lr_decay,
        staircase=True)
    optimizer = keras.optimizers.SGD(learning_rate=lr_schedule, momentum=0.9,
                                     weight_decay=wd)
    timer = d2l.Timer()
    legend = ['train loss']
    if valid_iter is not None:
        legend.append('valid loss')
    animator = d2l.Animator(xlabel='epoch', xlim=[1, num_epochs],
                            legend=legend)
    for epoch in range(num_epochs):
        metric = d2l.Accumulator(2)
        for i, (features, labels) in enumerate(train_iter):
            timer.start()
            # Frozen backbone forward runs outside the tape (its activations are
            # freed immediately); only the small head is taped for backprop.
            feats = backbone_features(backbone, features)
            with tf.GradientTape() as tape:
                logits = head(feats, training=True)
                l = loss(labels, logits)
            grads = tape.gradient(l, head.trainable_variables)
            optimizer.apply_gradients(zip(grads, head.trainable_variables))
            metric.add(float(tf.reduce_sum(l)), len(labels))
            timer.stop()
            if (i + 1) % (num_batches // 5) == 0 or i == num_batches - 1:
                animator.add(epoch + (i + 1) / num_batches,
                             (metric[0] / metric[1], None))
        measures = f'train loss {metric[0] / metric[1]:.3f}'
        if valid_iter is not None:
            valid_loss = evaluate_loss(valid_iter, backbone, head)
            animator.add(epoch + 1, (None, valid_loss))
    if valid_iter is not None:
        measures += f', valid loss {valid_loss:.3f}'
    print(measures + f'\n{metric[1] * num_epochs / timer.sum():.1f}'
          f' examples/sec')
    return head
```

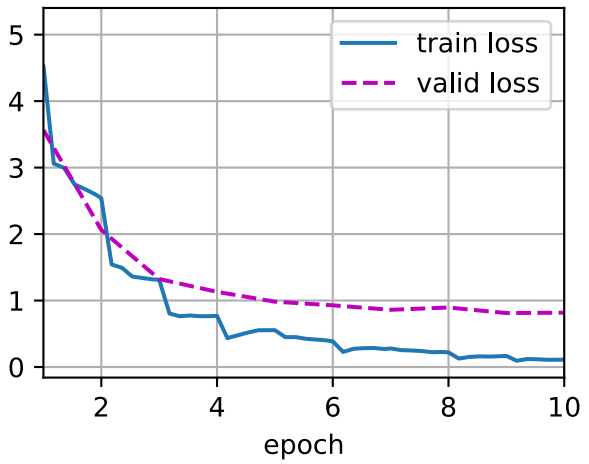
32.14.6 Training and Validating the Model

Now we can train and validate the model. The following hyperparameters are all tunable. For example, the number of epochs can be increased. Because `lr_period` and `lr_decay` are set to 2 and 0.9, respectively, the learning rate of the optimization algorithm will be multiplied

by 0.9 after every 2 epochs.

```
num_epochs, lr, wd = 10, 3e-4, 1e-4
lr_period, lr_decay = 2, 0.9
backbone, head = get_net()
head = train(backbone, head, train_iter, valid_iter, num_epochs, lr, wd,
             lr_period, lr_decay)
```

```
train loss 0.112, valid loss 0.817
95.0 examples/sec
```



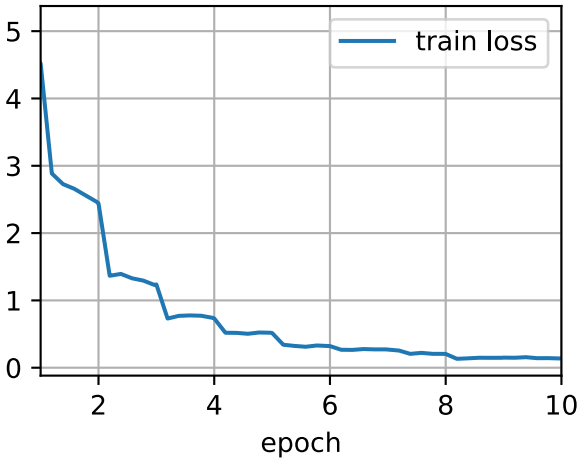
32.14.7 Classifying the Testing Set and Submitting Results on Kaggle

Similar to the final step in Section 32.13, in the end all the labeled data (including the validation set) are used for training the model and classifying the testing set. We will use the trained custom output network for classification.

```
backbone, head = get_net()
head = train(backbone, head, train_valid_iter, None, num_epochs, lr, wd,
             lr_period, lr_decay)
preds = []
for data, label in test_iter:
    logits = head(backbone_features(backbone, data), training=False)
    output = tf.nn.softmax(logits, axis=-1)
    preds.extend(output.numpy())
# Get class names from the train_valid dataset directory
class_names = sorted(os.listdir(
    os.path.join(data_dir, 'train_valid_test', 'train_valid')))
ids = sorted(os.listdir(
    os.path.join(data_dir, 'train_valid_test', 'test', 'unknown')))
with open('submission.csv', 'w') as f:
    f.write('id,' + ','.join(class_names) + '\n')
    for i, output in zip(ids, preds):
        f.write(i.split('.')[0] + ',' + ','.join(
```

```
            [str(num) for num in output]) + '\n')
```

```
train loss 0.138
103.3 examples/sec
```



The above code will generate a `submission.csv` file to be submitted to Kaggle in the same way described in Section 4.7.

32.14.8 Summary

- Images in the ImageNet dataset are larger (with varying dimensions) than CIFAR-10 images. We may modify image augmentation operations for tasks on a different dataset.
- To classify a subset of the ImageNet dataset, we can leverage pre-trained models on the full ImageNet dataset to extract features and only train a custom small-scale output network. This will lead to less computational time and memory cost.

32.14.9 Exercises

1. The competition scores a submission by the average cross-entropy of the predicted probabilities of the true breeds, so the code submits softmax outputs and reports the validation loss rather than the accuracy.
    1. Compute the score of a submission that assigns probability $1/120$ to every breed.
    2. A submission puts probability 1 on its predicted breed and 0 on all others, and the scorer clips every probability to the interval $[10^{-15}, 1 - 10^{-15}]$. Compute its score when 10% of its predictions are wrong, and compare it with the uniform submission.
    3. Divide the logits of the trained output network by a temperature $T > 0$, and choose T by minimizing the validation loss over a grid of values. Report the best T and the validation loss before and after the change, and explain why the validation accuracy does not change.
2. When using the full Kaggle competition dataset, what results can you achieve when you increase `batch_size` (batch size) and `num_epochs` (number of epochs) while setting some other hyperparameters as `lr = 0.01`, `lr_period = 10`, and `lr_decay = 0.1`?

3. Do you get better results if you use a deeper pretrained model? How do you tune hyperparameters? Can you further improve the results?
4. The output network takes the pooled features that enter the pretrained model's output layer. Feed it instead the 1000 ImageNet class scores that this layer produces, and compare the validation loss after the same 10 epochs on the full dataset. Explain the result using the fact that the 1000 ImageNet classes include more than a hundred dog breeds.
5. The pretrained network is frozen, so the features of the training images could be computed once and cached, which rules out random augmentation. Count the forward passes through the pretrained network over 10 epochs of the section's training, with and without a cache. Implement training on cached features of the training images under the test transform (resize and center crop), and compare the time per epoch and the validation loss on the full dataset with those of the section's training. State whether augmentation still lowers the validation loss when only the output network is trained.

Mathematics for Deep Learning

Throughout the main chapters of this book, we introduce mathematical tools *just in time*—stating each result alongside its geometric, statistical, or physical intuition so that you can build and train working models without losing momentum. Yet anyone who wants to move beyond applying existing recipes to diagnosing subtle training failures, reading frontier research papers critically, or inventing new methods eventually needs to look inside the mathematical engine. Why does the learning rate of gradient descent have a hard ceiling set by the largest eigenvalue of the Hessian? Why does minimizing cross-entropy estimate the true conditional distribution, and why does the Jensen–Shannon divergence saturate when two distributions fail to overlap? How does adding Gaussian noise to an image day by day define a reverse-time differential equation that turns pure noise back into a photograph?

This six-chapter appendix answers those questions in full. It is designed to serve two complementary purposes:

- **A companion reference for the main text.** Whenever a chapter in *Basics* or *Advanced* uses a mathematical theorem or identity and focuses on its practical consequences, it points to the corresponding section here for the complete derivation, proof, and boundary conditions. If you are already comfortable with a topic, you can skip its chapter here and dip in only when a cross-reference piques your curiosity.
- **A self-contained textbook for a course on the mathematics of deep learning.** Read from start to finish, these six chapters form a coherent, modern mathematical curriculum tailored specifically to deep learning—developing each subject from first principles as far as modern machine learning actually uses it, without getting bogged down in pathology for its own sake.

Just like the rest of the book, every section in this appendix pairs its mathematical derivations with runnable code and computational experiments (implemented in PyTorch, JAX, TensorFlow, and MXNet), turning abstract theorems into concrete numerical phenomena that you can inspect, plot, and test for yourself:

- **Linear Algebra (Chapter 33).** Deep networks represent data and parameters as vectors, matrices, and tensors, and every layer transforms the geometry of space. Beginning with lengths, angles, inner products, projections, and vector/matrix norms, this chapter treats matrices as active linear transformations that rotate, stretch, and collapse subspaces. We then develop the spectral decompositions that govern high-dimensional dynamics: *eigendecomposition* (showing how repeated matrix multiplication in recurrences or optimization is controlled by eigenvalues), *spectra in practice* (from Gershgorin circles and condition numbers to random matrix theory and the Marchenko–Pastur law), and the *singular value decomposition* (SVD), Moore–Penrose

pseudoinverse, and Eckart–Young low-rank approximation that underlie parameter-efficient fine-tuning (LoRA) and spectral normalization.

- **Calculus (Chapter 34).** Training a neural network with billions of parameters rests entirely on our ability to compute how a scalar loss changes when every parameter is perturbed simultaneously. Starting from single-variable derivatives, Taylor series, and numerical differentiation pitfalls, we move to multivariable gradients, directional derivatives, Jacobian matrices, and Hessian curvature. We then trace the multivariate chain rule through computation graphs to demystify *automatic differentiation*—contrasting forward-mode and reverse-mode (*backpropagation*) accumulation and showing why reverse-mode computes the exact gradient with respect to millions of parameters at the cost of a single forward pass.
- **Optimization (Chapter 35).** This chapter supplies the formal proofs behind the empirical phenomena observed in Chapter 9. We establish the geometry of convex sets and convex functions (Jensen's inequality, first- and second-order convexity characterizations), prove how L-smoothness and μ-strong convexity govern the convergence rate and step-size stability of gradient descent via the condition number $\kappa = L/\mu$, analyze momentum and Newton/quasi-Newton preconditioning on ill-conditioned quadratic models, and develop constrained optimization via Lagrange multipliers, Karush–Kuhn–Tucker (KKT) optimality conditions, and Lagrangian duality.
- **Probability and Statistics (Chapter 36).** Machine learning reasons under uncertainty at every stage, from noisy data generation and stochastic minibatch sampling to out-of-sample generalization. We build from probability spaces, conditional distributions, Bayes' rule, expectations, and key parametric families (Bernoulli, categorical, Gaussian, Laplace, exponential) to the classical *concentration inequalities* (Markov, Chebyshev, Hoeffding) that bound rare deviations of empirical averages. We then develop statistical inference and learning theory: maximum likelihood estimation (MLE), Fisher information, the Cramér–Rao lower bound, Bayesian *maximum a posteriori* (MAP) estimation, sufficient statistics, hypothesis testing, confidence intervals, and the theoretical foundations of *generalization* (empirical risk minimization, uniform convergence, Rademacher complexity, VC dimension, and the bias–variance trade-off).
- **Information Theory (Chapter 37).** Nearly every classification, language-modeling, and generative objective in deep learning descends from information theory. Starting from Claude Shannon's axioms of self-information and entropy, we show how *cross-entropy* and *Kullback–Leibler (KL) divergence* measure the coding inefficiency of using an approximate model distribution Q in place of the true data distribution P, and extend these concepts to continuous random variables via differential entropy and the maximum-entropy principle. We then broaden the lens to compare probability distributions when KL divergence fails: f-divergences, the variational dual representations behind GANs, and *Wasserstein optimal transport* distances that respect the underlying geometry of the sample space. The chapter closes with *mutual information*, the data processing inequality, the variational information bottleneck, and the InfoNCE lower bound that drives modern contrastive representation learning.
- **Dynamics, Flows, and Diffusion (Chapter 38).** Many of the most powerful ideas in modern deep learning—from continuous normalizing flows and state space models to denoising diffusion and flow matching—are most naturally understood in continuous time. This final chapter builds the dynamical toolkit from the ground up: systems of ordinary differential equations (ODEs), vector fields, phase portraits, linear stability, numerical integrators (Euler, Runge–Kutta, and symplectic leapfrog), and *Neural ODEs* trained via the continuous adjoint sensitivity method. We then track how

a velocity field transports an entire probability density via the *continuity equation* and Hutchinson's trace estimator, before introducing randomness: Brownian motion, *Itô stochastic differential equations* (SDEs), Itô's lemma, the Ornstein–Uhlenbeck process, the *Fokker–Planck equation*, and Anderson's reverse-time SDE and the *probability-flow ODE*, which reveal how learning the score function $\nabla_{\mathbf{x}} \log p_t(\mathbf{x})$ allows a neural network to turn pure Gaussian noise into samples from any target distribution.

Chapter 33

Linear Algebra

Every neural network in this book is built out of matrix products: a linear layer multiplies its input by a weight matrix, attention multiplies queries by keys, and a recurrent network multiplies its hidden state by the same matrix at every step. In Section 1.3, we computed these products without asking what a matrix actually *does* to the vectors it acts on. This optional chapter takes up that geometric question, proofs included; nothing in the main text depends on it, yet seeing the geometry behind matrix products changes how you read almost every model in the book.

Consider a 784-pixel Fashion-MNIST image mapped to 256 features. How similar are two images, how much information does the layer discard, and what happens if we apply the same linear map fifty times in a row? Because we cannot draw in 784 dimensions, our answers come from algebra that carries plane geometry into any dimension.

A complicated matrix becomes transparent once viewed along the right directions. Around 1810, Gauss fitted the orbit of the asteroid Pallas to more observations than unknowns via least squares, a problem our first section solves and our last revisits. In orthonormal axes, lengths and angles reduce to dot products; along eigenvectors, a square matrix scales each direction by a single scalar; and in a pair of singular bases, *any* matrix decomposes into independent stretches. These ideas explain why attention divides scores by $\sqrt{d}$ (Section 10.2), when recurrent gradients explode (Section 8.5), and what a low-rank adapter can represent.

The chapter moves in two stages. First, we apply a matrix once: Section 33.1 extends lengths, angles, and orthogonal projections (giving the closest point in a subspace), while Section 33.2 tracks which directions collapse to zero and when a map is invertible. Next, we choose coordinates tailored to the matrix: eigenvectors and the spectral theorem for symmetric matrices (Section 33.3), non-normal behavior that eigenvalues alone miss (Section 33.4), and singular vectors with optimal low-rank truncation for any shape (Section 33.5). Two small matrices keep us honest throughout: $\mathbf{A} = \left(\begin{smallmatrix} 1 & 2 \\ -1 & 3 \end{smallmatrix}\right)$, with complex eigenvalues, and the shear $\mathbf{T} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$, whose eigenvectors fail to span the plane.

On a first reading, feel free to skim n-dimensional determinants and the discussions of Gershgorin discs, PageRank, and pseudospectra in Section 33.4. Numerical eigensolvers and linear solvers are surveyed in Section 33.6.

33.1 Vectors, Angles, and Projections

Throughout the Basics chapters, we represented every input as a vector: an image became a list of pixel values, and a word became an embedding. At heart, machine learning models perform three geometric operations on these vectors. They *compare* them, as when we measure whether two embeddings are similar; they *fit* them, as when we seek the combination of features that best matches a set of targets; and they *separate* them, as when a classifier decides which side of a boundary an input falls on. In the two-dimensional plane, each of these operations is a familiar picture of lengths, angles, and shadows. Real inputs, however, live in spaces of hundreds or thousands of dimensions that nobody can draw. Do those geometric pictures still mean anything there?

Telling t-shirts from trousers offers a concrete test. Each 28×28 Fashion-MNIST image (Section 3.2) is a list of 784 pixel intensities, so it is a point in $\mathbb{R}^{784}$. Consider the simplest rule imaginable: compute the average t-shirt and the average pair of trousers, and assign each new image to whichever average lies closer. In the plane, "closer" is something we can check by eye; in $\mathbb{R}^{784}$, it becomes a calculation requiring a single dot product per image. On the $2{,}000$ test images from these two classes, this rule is right about 92% of the time. The fact that such a simple rule works so well tells us that the two clouds of points sit well apart, and that geometric notions like distance remain meaningful even where we cannot see them.

What carries the geometry of the plane into arbitrary dimensions is the dot product. Lengths are square roots of dot products, the shadow of one vector onto another is a ratio of dot products, and the angle between two vectors is defined directly from them. We develop this geometry in three stages. First, we study a pair of vectors: projection onto a line, the angle between them, and the Cauchy–Schwarz inequality, which Section 1.3 proved algebraically and which we prove again here from a right triangle. Second, we introduce the language of subspaces (span, independence, basis, and dimension) that the rest of the chapter relies on, and we solve least squares as a projection, with the QR factorization as our computational tool. Third, we take these ideas to high-dimensional images, asking how similar unrelated vectors are in $\mathbb{R}^d$ and reading a linear classifier as a hyperplane.

Three results stand out above the rest: the residual of a projection is orthogonal to the line or subspace we project onto, which is what makes the projection the closest point; Cauchy–Schwarz, which ensures that angles remain well defined in any dimension; and the typical scale $1/\sqrt{d}$ of the cosine between random directions in $\mathbb{R}^d$. Aside from loading the dataset, all code in this section is plain NumPy and runs identically across frameworks.

33.1.1 Vectors and Their Geometry

33.1.1.1 Points and Directions

We can picture a vector in two complementary ways. Viewed as a *point*, $\mathbf{v} = (3, 2)$ marks the location 3 units to the right of the *origin* and 2 units up. This viewpoint turns an entire dataset into a cloud of points, turning a classification task such as separating t-shirts from trousers into a geometric problem of separating two clouds. Viewed as a *direction* (or displacement), the same vector instructs us to move 3 steps right and 2 steps up. Because a displacement can start anywhere, all of the parallel arrows in Figure 33.1 represent the same vector.

The direction viewpoint makes vector addition immediate: follow the first arrow, then fol-

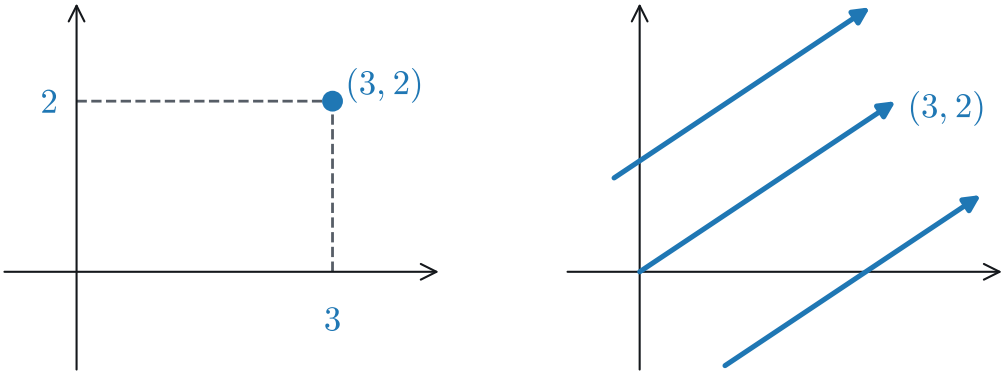


Figure 33.1: Two ways to read a vector: as a *point* with coordinates (x, y) (left), or as a *direction*, an arrow that can start anywhere, so every arrow shown represents the same vector $(3, 2)$ (right).

low the second from its tip, as shown in Figure 33.2.

Subtraction works the same way. Because $\mathbf{u} = \mathbf{v} + (\mathbf{u} - \mathbf{v})$, the difference $\mathbf{u} - \mathbf{v}$ is simply the displacement arrow that carries us from the point $\mathbf{v}$ to the point $\mathbf{u}$.

Everything else in this section grows out of a single operation, the *dot product* introduced in Section 1.3. Given two vectors $\mathbf{u}, \mathbf{v} \in \mathbb{R}^d$, it multiplies their corresponding entries and sums the results:

$$\mathbf{u}^\top \mathbf{v} = \sum_{i=1}^{d} u_i v_i. \tag{33.1}$$

Since the dot product is symmetric, $\mathbf{u}^\top \mathbf{v} = \mathbf{v}^\top \mathbf{u}$, we often write it as $\mathbf{u} \cdot \mathbf{v}$: using the dot when we picture two arrows and the transpose when the product sits inside a matrix expression. For $\mathbf{u} = (1, 3)$ and $\mathbf{v} = (2, 1)$, we have $\mathbf{u} \cdot \mathbf{v} = 2 + 3 = 5$, and the squared length of $\mathbf{u}$ is $\mathbf{u} \cdot \mathbf{u} = 1 + 9 = 10$.

33.1.1.2 Projection onto a Line

How much of a vector $\mathbf{v}$ points along another vector $\mathbf{w}$? Equivalently, which scalar multiple $t\mathbf{w}$ comes closest to $\mathbf{v}$? This is the simplest fitting problem in linear algebra: we approximate $\mathbf{v}$ using a single direction and seek the best coefficient t.

Let us test this on our pair $\mathbf{v} = (1, 3)$ and $\mathbf{w} = (2, 1)$ by trying a few values of t. At $t = 1$, the error $\mathbf{v} - t\mathbf{w} = (-1, 2)$ has squared length 5. At $t = 0.5$, the error is $(0, 2.5)$ with squared length 6.25; at $t = 1.5$, it is $(-2, 1.5)$, again with squared length 6.25. The minimum occurs at $t = 1$, giving the closest point $(2, 1)$. We call the remaining error the *residual*. Here the residual is $\mathbf{r} = (-1, 2)$, and notice its dot product with $\mathbf{w}$: $\mathbf{r} \cdot \mathbf{w} = -2 + 2 = 0$. The shortest error meets the line at a right angle. Even better, the squared lengths satisfy a right-triangle relation: $\|\mathbf{v}\|^2 = 10$, the closest point has squared length 5, the residual has squared length 5, and $10 = 5 + 5$.

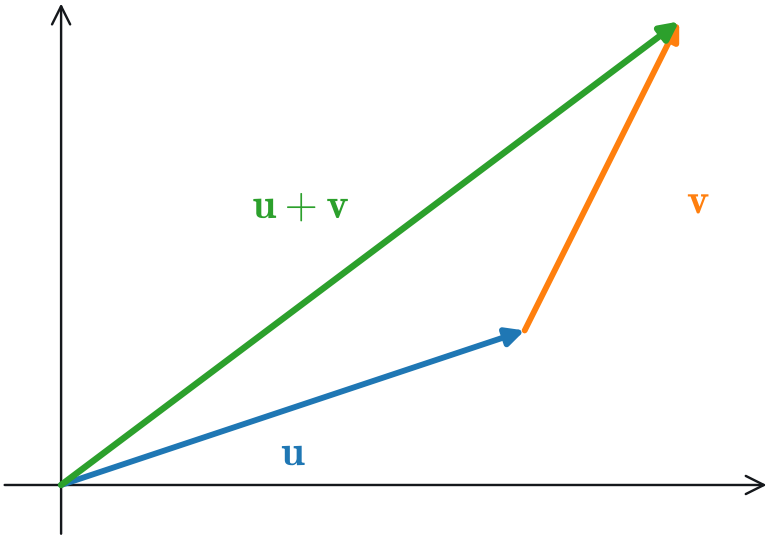

Figure 33.2: Vector addition visualized tip to tail: follow the first arrow, then follow the second from where the first ends.

This pattern holds in every dimension.

Proposition (orthogonal projection). *Let* $\mathbf{w} \neq \mathbf{0}$*. The multiple of* $\mathbf{w}$ *closest to* $\mathbf{v}$ *is*

$$\operatorname{proj}_{\mathbf{w}} \mathbf{v} = \frac{\mathbf{v} \cdot \mathbf{w}}{\mathbf{w} \cdot \mathbf{w}} \, \mathbf{w}, \tag{33.2}$$

and the residual $\mathbf{r} = \mathbf{v} - \operatorname{proj}_{\mathbf{w}} \mathbf{v}$ *satisfies* $\mathbf{r} \cdot \mathbf{w} = 0$*.*

Proof. We minimize the squared error as a function of t. Expanding the dot product of $\mathbf{v} - t\mathbf{w}$ with itself yields a quadratic in t,

$$q(t) = \|\mathbf{v} - t\mathbf{w}\|^2 = \|\mathbf{w}\|^2 \, t^2 - 2 \, (\mathbf{v} \cdot \mathbf{w}) \, t + \|\mathbf{v}\|^2.$$

Because its leading coefficient $\|\mathbf{w}\|^2$ is positive, $q(t)$ has a unique minimum where its derivative $q'(t) = 2\|\mathbf{w}\|^2 t - 2\,\mathbf{v} \cdot \mathbf{w}$ vanishes, namely at $t^\star = (\mathbf{v} \cdot \mathbf{w})/(\mathbf{w} \cdot \mathbf{w})$. Substituting $t^\star$ gives Equation 33.2. Checking the residual, we find $\mathbf{r} \cdot \mathbf{w} = \mathbf{v} \cdot \mathbf{w} - t^\star \, \mathbf{w} \cdot \mathbf{w} = 0$. ∎

For our example, $q(t) = 5t^2 - 10t + 10$, which reaches its minimum value of 5 at $t^\star = 5/5 = 1$, confirming our trial values. We call $\operatorname{proj}_{\mathbf{w}} \mathbf{v}$ the *projection*, or *shadow*, of $\mathbf{v}$ onto $\mathbf{w}$. The projection captures the part of $\mathbf{v}$ aligned with $\mathbf{w}$, while the residual captures the part at right angles to it. Notice why we required $\mathbf{w} \neq \mathbf{0}$: the zero vector defines no direction, and setting $\mathbf{w} = \mathbf{0}$ would divide by zero.

That right angle is the reason squared lengths add cleanly. Two vectors $\mathbf{a}$ and $\mathbf{b}$ are *orthogonal* whenever $\mathbf{a} \cdot \mathbf{b} = 0$. Expanding the squared length of their sum then gives *Pythagoras' theorem*,

$$\|\mathbf{a}+\mathbf{b}\|^2 = \|\mathbf{a}\|^2 + 2\,\mathbf{a}\cdot\mathbf{b} + \|\mathbf{b}\|^2 = \|\mathbf{a}\|^2 + \|\mathbf{b}\|^2. \tag{33.3}$$

In any dimension, orthogonal components add in squared length with no cross term. Applying this to the decomposition $\mathbf{v} = \operatorname{proj}_{\mathbf{w}}\mathbf{v} + \mathbf{r}$ gives $\|\mathbf{v}\|^2 = \|\operatorname{proj}_{\mathbf{w}}\mathbf{v}\|^2 + \|\mathbf{r}\|^2$, which is $10 = 5 + 5$ in our example.

We will also need the length of the shadow together with a sign indicating whether it points in the same direction as $\mathbf{w}$ or opposite to it. Multiplying the coefficient $t^\star$ by $\|\mathbf{w}\|$ gives this *signed length*:

$$\frac{\mathbf{v}\cdot\mathbf{w}}{\|\mathbf{w}\|}. \tag{33.4}$$

In our example it equals $5/\sqrt{5} = \sqrt{5}$, the length of $(2,1)$. This signed length will reappear at the end of the section as the signed distance from a point to a hyperplane. Figure 33.3 illustrates the entire geometry.

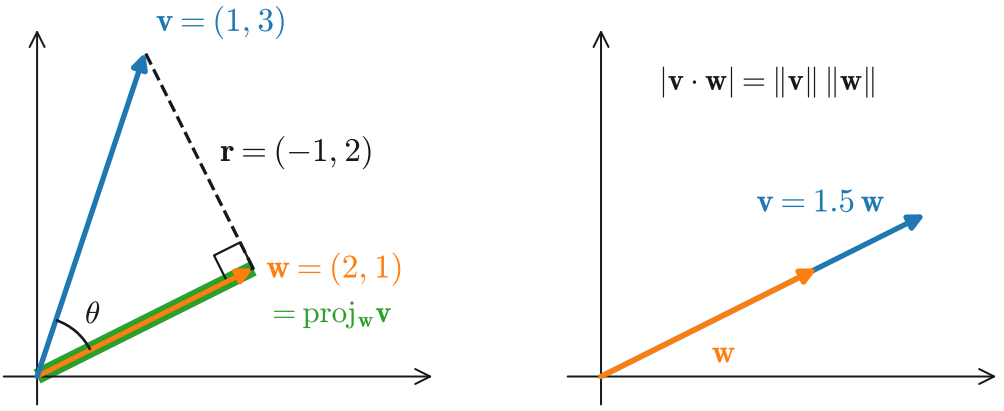

Figure 33.3: (a) The projection (shadow) of $\mathbf{v} = (1,3)$ onto $\mathbf{w} = (2,1)$ is $(2,1)$; the residual $(-1,2)$ meets $\mathbf{w}$ at a right angle, so $\|\mathbf{v}\|^2 = 10 = 5+5$. (b) The Cauchy–Schwarz equality case: $\mathbf{v}$ is collinear with $\mathbf{w}$ and the residual vanishes.

33.1.1.3 Cauchy–Schwarz and the Angle

In 784 dimensions there is no protractor. Can "the angle between two images" still mean anything? Surprisingly, the answer comes from a much simpler question: can the shadow of a vector ever be longer than the vector itself? Panel (a) of Figure 33.3 says no, because the shadow is a leg of a right triangle whose hypotenuse is $\mathbf{v}$. Pythagoras' theorem turns that picture into a proof that works in every dimension.

Proposition (Cauchy–Schwarz). *For all vectors* $\mathbf{v}, \mathbf{w}$*,*

$$|\mathbf{v}\cdot\mathbf{w}| \le \|\mathbf{v}\|\,\|\mathbf{w}\|, \tag{33.5}$$

with equality if and only if $\mathbf{v}$ *and* $\mathbf{w}$ *are collinear (one is a scalar multiple of the other).*

Proof. If $\mathbf{w} = \mathbf{0}$, both sides vanish and the vectors are collinear. Otherwise, split $\mathbf{v}$ into its projection onto $\mathbf{w}$ and its orthogonal residual $\mathbf{r}$. By Pythagoras' theorem Equation 33.3,

$$\|\mathbf{v}\|^2 = \|\operatorname{proj}_{\mathbf{w}} \mathbf{v}\|^2 + \|\mathbf{r}\|^2 \geq \|\operatorname{proj}_{\mathbf{w}} \mathbf{v}\|^2 = \frac{(\mathbf{v}\cdot\mathbf{w})^2}{\|\mathbf{w}\|^2}.$$

Multiplying both sides by $\|\mathbf{w}\|^2$ and taking square roots yields the inequality. Equality holds precisely when $\mathbf{r} = \mathbf{0}$, meaning $\mathbf{v} = t^\star\mathbf{w}$. Conversely, if $\mathbf{v} = t\mathbf{w}$, then $|\mathbf{v}\cdot\mathbf{w}| = |t|\,\|\mathbf{w}\|^2 = \|\mathbf{v}\|\,\|\mathbf{w}\|$. ■

In plain terms, a vector's shadow is never longer than the vector itself, and matches its length only when nothing is left over in the residual. Where Section 1.3 proved Cauchy–Schwarz algebraically, here it falls straight out of panel (a) of Figure 33.3, with panel (b) showing the equality case.

Now we can define angles in any dimension. In the plane, the law of cosines gives $\mathbf{v}\cdot\mathbf{w} = \|\mathbf{v}\|\|\mathbf{w}\|\cos\theta$ (Section 1.3). In $\mathbb{R}^d$ we have no physical triangle to measure, so we turn this identity into a definition. For nonzero vectors $\mathbf{v}, \mathbf{w} \in \mathbb{R}^d$, the *angle* between them is

$$\theta = \arccos\left(\frac{\mathbf{v}\cdot\mathbf{w}}{\|\mathbf{v}\|\|\mathbf{w}\|}\right) \in [0, \pi]. \tag{33.6}$$

Because arccos is defined only on $[-1, 1]$, this formula makes sense only if the ratio lies inside that interval, and Cauchy–Schwarz guarantees that it always does. Thus the angle is well defined in every dimension, and the planar dot-product formula now holds everywhere as an immediate consequence:

$$\mathbf{v}\cdot\mathbf{w} = \|\mathbf{v}\|\|\mathbf{w}\|\cos\theta. \tag{33.7}$$

The two equality cases of Cauchy–Schwarz correspond to $\theta = 0$ (vectors pointing in the same direction) and $\theta = \pi$ (vectors pointing in opposite directions).

A natural objection arises: does this algebraic definition agree with the angle a protractor would actually measure? It does. Any two vectors lie inside a single plane (or a line, if they are collinear), and inside that plane ordinary geometry applies. Projection gives us rectangular coordinates for that plane: set $\mathbf{q}_1 = \mathbf{w}/\|\mathbf{w}\|$ and, provided $\mathbf{r} \neq \mathbf{0}$, set $\mathbf{q}_2 = \mathbf{r}/\|\mathbf{r}\|$. These two vectors have unit length and are orthogonal, so dot products of their combinations behave just like dot products in $\mathbb{R}^2$. In this coordinate system, $\mathbf{w} = (\|\mathbf{w}\|, 0)$ and $\mathbf{v} = (\mathbf{v}\cdot\mathbf{w}/\|\mathbf{w}\|,\ \|\mathbf{r}\|)$. The angle a protractor measures between these two planar arrows has cosine $(\mathbf{v}\cdot\mathbf{w}/\|\mathbf{w}\|)/\|\mathbf{v}\|$, matching Equation 33.6. For our worked pair $\mathbf{v} = (1, 3)$ and $\mathbf{w} = (2, 1)$, we get $\cos\theta = 5/(\sqrt{10}\sqrt{5}) = 1/\sqrt{2}$, so $\theta = 45^\circ$.

For nonzero vectors, orthogonality means $\theta = \pi/2$. Defining orthogonality via $\mathbf{v}\cdot\mathbf{w} = 0$ has the minor convenience of including the zero vector as well: it is orthogonal to every vector, even though no angle is defined for it.

Turning Equation 33.6 into code takes only two lines, with one practical safeguard worth noticing. Let us test it on our worked pair and on a deliberately tricky collinear pair, $\mathbf{v} = (10^8 + 1, 3, 7)$ and $3\mathbf{v}$, whose true cosine is 1 and whose true angle is 0. For the collinear pair, we also print the raw cosine minus 1 and the unclipped `arccos`.

```
def angle(v, w):
    cos = v @ w / (np.linalg.norm(v) * np.linalg.norm(w))
    return np.arccos(np.clip(cos, -1, 1))  # roundoff can push |cos| past 1

v = np.array([1e8 + 1, 3, 7])
cos = v @ (3 * v) / (np.linalg.norm(v) * np.linalg.norm(3 * v))
with np.errstate(invalid='ignore'):        # silence the warning for nan
    print(angle(np.array([1., 3]), np.array([2., 1])), cos - 1,
          np.arccos(cos), angle(v, 3 * v))
```

```
0.7853981633974484 2.220446049250313e-16 nan 0.0
```

The first number is $0.785 = \pi/4$, matching the 45° angle of our worked pair. The remaining three values show why `np.clip` is essential. In exact arithmetic, Cauchy–Schwarz keeps the ratio inside $[-1, 1]$. In floating-point arithmetic, rounding can nudge it past the boundary by one unit in the last place: here the collinear pair yields $1 + 2.2 \times 10^{-16}$, causing `np.arccos` to return `nan`. Clipping to $[-1, 1]$ restores the right answer, 0.

Cauchy–Schwarz also shows that the length of a sum never exceeds the sum of the lengths. Expanding $\|\mathbf{v}+\mathbf{w}\|^2$ and bounding the cross term $2\,\mathbf{v}\cdot\mathbf{w}$ by $2\,\|\mathbf{v}\|\|\mathbf{w}\|$ via Equation 33.5 yields the *triangle inequality*, $\|\mathbf{v}+\mathbf{w}\| \le \|\mathbf{v}\| + \|\mathbf{w}\|$, just as in Section 1.3.

33.1.2 Subspaces and Least Squares

33.1.2.1 Span, Bases, and Subspaces

Suppose we measure a quantity three times, at $t = 0, 1, 2$, and want to fit the best straight line $C + Dt$ to our data. Stack the measurements into a vector $\mathbf{y} \in \mathbb{R}^3$, collect the times in $\mathbf{t} = (0, 1, 2)$, and let $\mathbf{1} = (1, 1, 1)$. Evaluating the line at the three times produces the vector $C\mathbf{1} + D\mathbf{t}$. Finding the best line therefore means finding the vector of the form $C\mathbf{1} + D\mathbf{t}$ that lies closest to $\mathbf{y}$. As C and D vary over all real numbers, these candidate vectors sweep out a plane through the origin in $\mathbb{R}^3$. Projection onto a line handled a single direction; to handle planes and their higher-dimensional counterparts, we need a small set of standard terms. Readers already comfortable with span, bases, and subspaces can skip straight to the next subsection, where we finish the line fit.

A weighted sum $a_1\mathbf{v}_1 + \cdots + a_k\mathbf{v}_k$ is called a *linear combination* of $\mathbf{v}_1, \dots, \mathbf{v}_k$. The collection of all such combinations is their *span*,

$$\operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_k) = \{a_1\mathbf{v}_1 + \cdots + a_k\mathbf{v}_k : a_1, \dots, a_k \in \mathbb{R}\}.$$

In $\mathbb{R}^2$ (Figure 33.4), the span of a single nonzero vector is the line through the origin along its direction, while the span of two vectors not lying on a common line through the origin is the entire plane. In our line-fitting problem, the set of all candidate fits is $\operatorname{span}(\mathbf{1}, \mathbf{t})$.

Notice that a span is always closed under addition and scalar multiplication: adding two linear combinations, or scaling one by a real number, produces another linear combination. Any nonempty set of vectors with these two closure properties is called a *subspace*. Every subspace must contain the zero vector $\mathbf{0}$ (just multiply any element by 0), which means a line or plane that misses the origin is not a subspace. In $\mathbb{R}^2$, the only subspaces are the origin alone, the lines through the origin, and $\mathbb{R}^2$ itself; in $\mathbb{R}^3$, planes through the origin join the list.

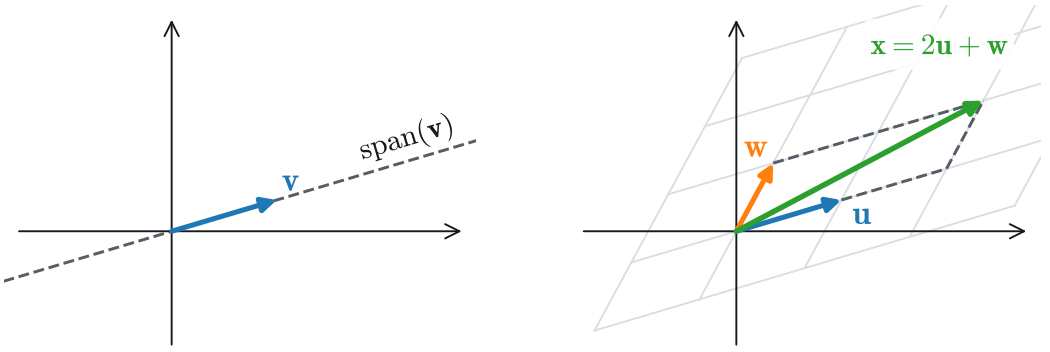

Figure 33.4: Left: the span of a single nonzero vector $\mathbf{v}$ is the set of all its scalar multiples, forming a line through the origin and thus a one-dimensional subspace. Right: two vectors not on a common line through the origin span the whole plane; the dashed parallelogram resolves $\mathbf{x}$ as $2\mathbf{u} + \mathbf{w}$, with unique coordinates because $\mathbf{u}$ and $\mathbf{w}$ are linearly independent.

A list of vectors that spans a subspace can contain redundancies. Whenever one vector already lies in the span of the others, we can drop it without shrinking the span. A list of vectors is *linearly independent* when no such redundancy exists, meaning that the only linear combination $a_1\mathbf{v}_1 + \cdots + a_k\mathbf{v}_k$ equal to $\mathbf{0}$ is the trivial one with every $a_i = 0$. Our vectors $\mathbf{1}$ and $\mathbf{t}$ are linearly independent: $a_1\mathbf{1} + a_2\mathbf{t} = (a_1,\, a_1 + a_2,\, a_1 + 2a_2)$ vanishes only when $a_1 = a_2 = 0$.

A *basis* of a subspace is a linearly independent list of vectors that spans it. The familiar vectors $\mathbf{e}_1 = (1, 0)$ and $\mathbf{e}_2 = (0, 1)$ form the *standard basis* of $\mathbb{R}^2$, though the slanted pair in Figure 33.4 is an equally good basis. A fundamental theorem of linear algebra (which we use without proof) states that every basis of a given subspace has the same number of vectors; that shared count is the subspace's *dimension*. This gives a crisp meaning to the d in "d-dimensional space": $\mathbb{R}^d$ has dimension d because $\mathbf{e}_1, \ldots, \mathbf{e}_d$ is a basis. Likewise, our candidate line fits form a two-dimensional subspace of $\mathbb{R}^3$.

Linear independence is what gives every point in a subspace unique coordinates. If $\mathbf{v}_1, \ldots, \mathbf{v}_k$ is a basis of a subspace S, then every $\mathbf{x} \in S$ can be written as $\mathbf{x} = a_1\mathbf{v}_1 + \cdots + a_k\mathbf{v}_k$ in only one way. At least one representation exists because the basis spans S. If two representations existed with coefficients a_i and b_i, subtracting them would give $\sum_i (a_i - b_i)\,\mathbf{v}_i = \mathbf{0}$, and independence forces $a_i = b_i$ for every i.

Once we fix a basis, a k-dimensional subspace behaves just like $\mathbb{R}^k$: each point is uniquely named by its coefficient tuple $(a_1, \ldots, a_k)$. For our line fit, those coordinates are simply the intercept C and the slope D.

33.1.2.2 Projection onto a Subspace

Let us return to the line fit with concrete measurements $\mathbf{y} = (6, 0, 0)$. We want the point $C\mathbf{1} + D\mathbf{t}$ in the plane $\operatorname{span}(\mathbf{1}, \mathbf{t})$ closest to $\mathbf{y}$. When we projected onto a single line, the closest point left a residual orthogonal to that line. Projecting onto a plane should leave a residual orthogonal to the entire plane, and therefore orthogonal to both $\mathbf{1}$ and $\mathbf{t}$ (a fact we prove in a moment). Setting both dot products to zero gives two linear equations in two unknowns:

$$\mathbf{1} \cdot (\mathbf{y} - C\mathbf{1} - D\mathbf{t}) = 6 - 3C - 3D = 0,$$
$$\mathbf{t} \cdot (\mathbf{y} - C\mathbf{1} - D\mathbf{t}) = 0 - 3C - 5D = 0.$$

Subtracting the first equation from the second yields $2D = -6$, so $D = -3$ and $C = 5$. The best-fitting line is $5 - 3t$. Its predicted values at $t = 0, 1, 2$ are $(5, 2, -1)$, leaving the residual $\mathbf{r} = \mathbf{y} - (5, 2, -1) = (1, -2, 1)$. Both orthogonality checks hold: $\mathbf{r} \cdot \mathbf{1} = 1 - 2 + 1 = 0$ and $\mathbf{r} \cdot \mathbf{t} = 0 - 2 + 2 = 0$. Pythagoras' theorem again splits the squared length of $\mathbf{y}$ cleanly: $36 = 30 + 6$. By comparison, projecting $\mathbf{y}$ onto $\mathbf{1}$ alone yields the constant fit $\mathbf{y} \cdot \mathbf{1} / \mathbf{1} \cdot \mathbf{1} = 2$ (the sample mean), whose residual $(4, -2, -2)$ has squared length 24. Allowing a slope along $\mathbf{t}$ reduces the squared error from 24 down to 6. Figure 33.5 shows this projection in $\mathbb{R}^3$.

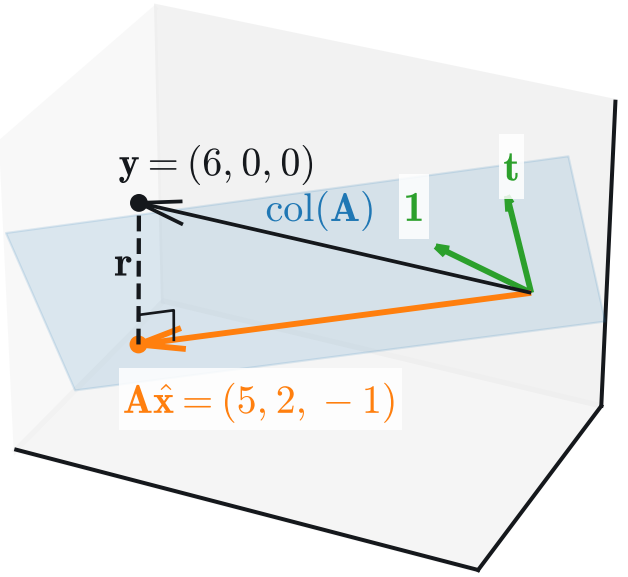

Figure 33.5: Least squares as projection: the measurements $\mathbf{y} = (6, 0, 0)$ lie outside the plane of candidate lines $C\mathbf{1} + D\mathbf{t}$; the closest point in the plane is $(5, 2, -1)$ (the line $5 - 3t$), and the residual $(1, -2, 1)$ is perpendicular to both $\mathbf{1}$ and $\mathbf{t}$.

To state and prove the general result cleanly, it helps to choose a basis whose vectors are mutually orthogonal and have unit length. A basis $\mathbf{q}_1, \dots, \mathbf{q}_k$ of a subspace $S \subseteq \mathbb{R}^n$ is *orthonormal* when every vector satisfies $\|\mathbf{q}_i\| = 1$ and distinct vectors satisfy $\mathbf{q}_i \cdot \mathbf{q}_j = 0$. Every finite spanning list admits such a basis: Section 33.1.2.3 constructs one using nothing more than projection onto a line. If we place these basis vectors as the columns of an $n \times k$ matrix $\mathbf{Q}$, orthonormality takes the compact form $\mathbf{Q}^\top \mathbf{Q} = \mathbf{I}_k$, because entry (i, j) of $\mathbf{Q}^\top \mathbf{Q}$ is $\mathbf{q}_i \cdot \mathbf{q}_j$. Throughout this chapter, we reserve the letter $\mathbf{Q}$ for a matrix with orthonormal columns. The following proposition is the workhorse result that the rest of the chapter draws on most.

Proposition (projection onto a subspace). *Let* $\mathbf{Q}$ *have orthonormal columns spanning* S*, and set* $\mathbf{P} = \mathbf{Q}\mathbf{Q}^\top$*. Then for every* $\mathbf{x} \in \mathbb{R}^n$*:* (i) $\mathbf{P}\mathbf{x} \in S$*, and the residual* $\mathbf{x} - \mathbf{P}\mathbf{x}$ *is orthogonal to every vector of* S*;* (ii) $\mathbf{P}\mathbf{x}$ *is the unique closest point of* S *to* $\mathbf{x}$*;* (iii) $\mathbf{P}^2 = \mathbf{P}$ *and* $\mathbf{P}^\top = \mathbf{P}$*.*

Proof. For (i), $\mathbf{P}\mathbf{x} = \mathbf{Q}(\mathbf{Q}^\top\mathbf{x})$ is a linear combination of the columns of $\mathbf{Q}$, so it lies in S. Multiplying the residual on the left by $\mathbf{Q}^\top$ gives

$$\mathbf{Q}^\top(\mathbf{x} - \mathbf{P}\mathbf{x}) = \mathbf{Q}^\top\mathbf{x} - (\mathbf{Q}^\top\mathbf{Q})\,\mathbf{Q}^\top\mathbf{x} = \mathbf{0},$$

so the residual is orthogonal to every column $\mathbf{q}_i$, and therefore to every linear combination of them. For (ii), take any $\mathbf{s} \in S$ and write $\mathbf{x} - \mathbf{s} = (\mathbf{x} - \mathbf{P}\mathbf{x}) + (\mathbf{P}\mathbf{x} - \mathbf{s})$. Since $\mathbf{P}\mathbf{x} - \mathbf{s}$ lies in S while $\mathbf{x} - \mathbf{P}\mathbf{x}$ is orthogonal to S, Pythagoras' theorem Equation 33.3 gives

$$\|\mathbf{x} - \mathbf{s}\|^2 = \|\mathbf{x} - \mathbf{P}\mathbf{x}\|^2 + \|\mathbf{P}\mathbf{x} - \mathbf{s}\|^2 \geq \|\mathbf{x} - \mathbf{P}\mathbf{x}\|^2,$$

with equality only when $\mathbf{s} = \mathbf{P}\mathbf{x}$. For (iii), $\mathbf{P}^2 = \mathbf{Q}(\mathbf{Q}^\top\mathbf{Q})\mathbf{Q}^\top = \mathbf{Q}\mathbf{Q}^\top = \mathbf{P}$, and $\mathbf{P}^\top = (\mathbf{Q}^\top)^\top\mathbf{Q}^\top = \mathbf{P}$. ■

Conversely, the orthogonality condition in (i) uniquely identifies the closest point. If some $\mathbf{s} \in S$ leaves a residual $\mathbf{x} - \mathbf{s}$ orthogonal to S, then the difference $\mathbf{P}\mathbf{x} - \mathbf{s} = (\mathbf{x} - \mathbf{s}) - (\mathbf{x} - \mathbf{P}\mathbf{x})$ both lies in S and is orthogonal to S, hence orthogonal to itself, which forces $\mathbf{s} = \mathbf{P}\mathbf{x}$. That is why solving the two orthogonality equations in our line fit was guaranteed to produce the closest point.

Each half of property (iii) has a clear geometric meaning. The identity $\mathbf{P}^2 = \mathbf{P}$ says that projecting a second time changes nothing, since the first projection already landed in S. Symmetry, $\mathbf{P}^\top = \mathbf{P}$, is what makes the projection *orthogonal*. A matrix satisfying $\mathbf{P}^2 = \mathbf{P}$ without symmetry is an *oblique* projector: it maps vectors into its column space along a slanted direction and generally misses the closest point (3). In the one-dimensional case $k = 1$, taking the single unit column $\mathbf{q} = \mathbf{w}/\|\mathbf{w}\|$ reduces $\mathbf{P} = \mathbf{q}\mathbf{q}^\top$ directly to our earlier line projection Equation 33.2.

Our line fit is one example of *least squares*, the optimization problem at the heart of linear regression. Let $\mathbf{A}$ be a data matrix whose rows are examples and whose columns are features, and let $\mathbf{y}$ be the vector of targets. Least squares seeks the coefficient vector $\mathbf{x}$ that minimizes the squared error:

$$\min_{\mathbf{x}} \|\mathbf{A}\mathbf{x} - \mathbf{y}\|^2. \tag{33.8}$$

As $\mathbf{x}$ varies over all coefficient vectors, $\mathbf{A}\mathbf{x}$ traces out the span of the columns of $\mathbf{A}$, known as its *column space* $\mathrm{col}(\mathbf{A})$. Least squares therefore asks for the point in $\mathrm{col}(\mathbf{A})$ closest to $\mathbf{y}$. By our projection proposition, that point is the one whose residual $\mathbf{y} - \mathbf{A}\hat{\mathbf{x}}$ is orthogonal to every column of $\mathbf{A}$. Writing this orthogonality condition as $\mathbf{A}^\top(\mathbf{y} - \mathbf{A}\hat{\mathbf{x}}) = \mathbf{0}$ produces the *normal equations*,

$$\mathbf{A}^\top\mathbf{A}\,\hat{\mathbf{x}} = \mathbf{A}^\top\mathbf{y}. \tag{33.9}$$

These are the matrix form of the 2×2 system we solved by hand: for the line fit, $\mathbf{A} = [\mathbf{1}\ \mathbf{t}]$ gives $\mathbf{A}^\top\mathbf{A} = \left(\begin{smallmatrix} 3 & 3 \\ 3 & 5 \end{smallmatrix}\right)$ and $\mathbf{A}^\top\mathbf{y} = (6, 0)$. Whenever the columns of $\mathbf{A}$ are linearly independent, $\mathbf{A}^\top\mathbf{A}$ is invertible and the optimal coefficients $\hat{\mathbf{x}}$ are unique. Even when the columns are

dependent, the fitted vector $\mathbf{A}\hat{\mathbf{x}}$ remains unique because it is still the closest point in $\mathrm{col}(\mathbf{A})$, though more than one coefficient vector $\hat{\mathbf{x}}$ can produce it.

In code, we therefore have two ways to compute the fit $5 - 3t$: solve the normal equations directly, or project using $\mathbf{P} = \mathbf{Q}\mathbf{Q}^\top$. To obtain $\mathbf{Q}$, we call `np.linalg.qr`, which builds an orthonormal basis for the column space of a matrix with independent columns (we will construct one by hand in the next subsection).

```
A = np.array([[1., 0], [1, 1], [1, 2]])     # columns 1 and t
y = np.array([6., 0, 0])
x_hat = np.linalg.solve(A.T @ A, A.T @ y)   # normal equations
Q, R = np.linalg.qr(A)                      # orthonormal basis of col(A)
P = Q @ Q.T
r = y - P @ y
print(x_hat.round(6), (P @ y).round(6), r.round(6))
print(np.linalg.norm(P @ P - P), np.linalg.norm(Q.T @ r))
```

```
[ 5. -3.] [ 5.  2. -1.] [ 1. -2.  1.]
1.962615573354719e-16 0.0
```

Both routes recover our hand calculation: the coefficients $C = 5$ and $D = -3$, the projected values $(5, 2, -1)$, and the residual $(1, -2, 1)$. The two check norms on the second line vanish up to floating-point roundoff, confirming $\mathbf{P}^2 = \mathbf{P}$ and $\mathbf{Q}^\top \mathbf{r} = \mathbf{0}$.

On a tiny, well-behaved problem like this, the two methods agree completely. When the columns of $\mathbf{A}$ are nearly dependent, however, forming $\mathbf{A}^\top \mathbf{A}$ squares the problem's condition number, its sensitivity to rounding errors (as we will show in Section 33.5.3.2). For that reason, production least-squares solvers avoid the normal equations and work with an orthonormal basis of the column space instead.

33.1.2.3 Gram–Schmidt and QR

How do we actually build an orthonormal basis? By repeated projection. Given two linearly independent vectors, keep the direction of the first and subtract from the second its shadow along the first. By our projection proposition, whatever remains is orthogonal to the first vector.

Let us carry this out on $\mathbf{a}_1 = (3, 4)$ and $\mathbf{a}_2 = (1, 0)$. Normalizing $\mathbf{a}_1$ gives $\mathbf{q}_1 = \mathbf{a}_1/5 = (0.6, 0.8)$. The shadow of $\mathbf{a}_2$ onto $\mathbf{q}_1$ is $(\mathbf{q}_1 \cdot \mathbf{a}_2)\,\mathbf{q}_1 = 0.6\,(0.6, 0.8) = (0.36, 0.48)$. Subtracting it leaves $(1, 0) - (0.36, 0.48) = (0.64, -0.48)$, a vector of length 0.8 that is indeed orthogonal to $\mathbf{q}_1$ ($0.384 - 0.384 = 0$). Normalizing this remainder gives $\mathbf{q}_2 = (0.8, -0.6)$. Reading the steps in reverse writes each original vector in terms of the new orthonormal basis:

$$\mathbf{a}_1 = 5\,\mathbf{q}_1, \qquad \mathbf{a}_2 = 0.6\,\mathbf{q}_1 + 0.8\,\mathbf{q}_2.$$

In matrix notation, this is $\mathbf{A} = \mathbf{Q}\mathbf{R}$, where $\mathbf{A} = [\mathbf{a}_1\ \mathbf{a}_2]$, $\mathbf{Q} = [\mathbf{q}_1\ \mathbf{q}_2]$, and $\mathbf{R} = \left(\begin{smallmatrix} 5 & 0.6 \\ 0 & 0.8 \end{smallmatrix}\right)$ collects the dot products $\mathbf{q}_i \cdot \mathbf{a}_j$. Notice why $\mathbf{R}$ is upper triangular: by construction, each $\mathbf{a}_j$ depends only on $\mathbf{q}_1, \dots, \mathbf{q}_j$.

Extending this idea to any linearly independent list $\mathbf{a}_1, \dots, \mathbf{a}_k$ gives the *Gram–Schmidt process*. We process the vectors in order: for each $\mathbf{a}_j$, subtract its projections Equation 33.2 onto

the unit vectors $\mathbf{q}_1, \ldots, \mathbf{q}_{j-1}$ already constructed, and normalize the remainder to obtain $\mathbf{q}_j$. The result is both an orthonormal basis for $\operatorname{span}(\mathbf{a}_1, \ldots, \mathbf{a}_k)$ and the *QR factorization* $\mathbf{A} = \mathbf{QR}$, where $\mathbf{Q}$ has orthonormal columns and $\mathbf{R}$ is upper triangular with positive diagonal entries. Linear independence is essential for the factorization, because a vector that already lies in the span of its predecessors leaves a zero remainder that cannot be normalized. If we only want an orthonormal basis for the span, we can simply skip any vector with a zero remainder and continue. Every finite spanning list therefore yields an orthonormal basis, justifying the existence claim we relied on earlier.

Numerical libraries compute the QR factorization using a different algorithm based on reflections, which behaves much better in floating-point arithmetic. Its output matches Gram–Schmidt only up to signs: negating a column of $\mathbf{Q}$ together with the corresponding row of $\mathbf{R}$ leaves the product $\mathbf{QR}$ untouched. When $\mathbf{A}$ has independent columns, those sign flips are the only ambiguity. Let us compare our two-step Gram–Schmidt calculation against `np.linalg.qr` and verify that they produce the same columns up to sign.

```
a1, a2 = np.array([3., 4]), np.array([1., 0])
q1 = a1 / np.linalg.norm(a1)
v = a2 - (q1 @ a2) * q1                    # remove the shadow on q1
q2 = v / np.linalg.norm(v)
Q_qr, R_qr = np.linalg.qr(np.stack([a1, a2], axis=1))
print(np.stack([q1, q2], axis=1).round(6))
print(Q_qr.round(6))
print(R_qr.round(6))
```

```
[[ 0.6  0.8]
 [ 0.8 -0.6]]
[[-0.6 -0.8]
 [-0.8  0.6]]
[[-5.  -0.6]
 [ 0.  -0.8]]
```

Gram–Schmidt produces $(0.6, 0.8)$ and $(0.8, -0.6)$, while `np.linalg.qr` returns the negatives of both columns along with diagonal entries -5 and -0.8 in $\mathbf{R}$: the same basis and, up to sign, the same dot products 5, 0.6, and 0.8 we found by hand. In floating point, the order in which we perform the subtractions also matters. On nearly dependent columns, the formulation above, known as *classical* Gram–Schmidt, gradually loses orthogonality (5).

33.1.3 Similarity in High Dimensions

Up to this point, every result came with a picture in $\mathbb{R}^2$ or $\mathbb{R}^3$. Now we move to spaces where no picture is possible, asking how similar two real images are and what similarity we should expect between unrelated vectors by pure chance. We load the Fashion-MNIST dataset (Section 3.2) through `d2l.FashionMNIST` as NumPy arrays, flattening each image into a 784-pixel row scaled to $[0, 1]$.

```
data = d2l.FashionMNIST()
(X_train, y_train), (X_test, y_test) = data.train, data.val
X_train = X_train.reshape(-1, 784) / 255
X_test = X_test.reshape(-1, 784) / 255
X_train.shape, X_test.shape
```

```
((60000, 784), (10000, 784))
```

Each of these $70{,}000$ images is now a point in $\mathbb{R}^{784}$.

33.1.3.1 Cosine Similarity

The ratio inside Equation 33.6 is the *cosine similarity* (Section 1.3),

$$\cos\theta = \frac{\mathbf{v}\cdot\mathbf{w}}{\|\mathbf{v}\|\,\|\mathbf{w}\|} \;\in\; [-1,1]. \tag{33.10}$$

Cosine similarity compares directions while ignoring lengths: an image and a copy of it dimmed to 10% brightness sit far apart in Euclidean distance, yet their cosine similarity is still 1.

That scale invariance makes cosine similarity the standard metric for nearest-neighbor retrieval over embeddings and for contrastive learning objectives such as SimCLR (Chen et al. 2020), which align the directions of embeddings produced from two views of the same image. The attention layer of the original transformer makes a different choice: it uses the *unnormalized* dot product scaled by $1/\sqrt{d}$ (for reasons we derive shortly), so vector lengths remain informative there. Many later models normalize queries and keys first (Section 11.1.2.5), which turns the score back into a scaled cosine.

33.1.3.2 Near-Orthogonality of Random Directions

Suppose we pick two unrelated images or two unrelated embeddings. What cosine similarity should we expect between them purely by chance? Without a baseline, we cannot judge whether an observed cosine is meaningfully large. The cleanest baseline is a direction chosen uniformly at random on the unit sphere, with no preference for any region of space.

Proposition (near-orthogonality). *Fix a unit vector $\mathbf{u}\in\mathbb{R}^d$ and let $\mathbf{v}$ be drawn uniformly from the unit sphere in $\mathbb{R}^d$. Then $\cos\theta = \mathbf{u}\cdot\mathbf{v}$ satisfies*

$$\mathbb{E}[\cos\theta] = 0, \qquad \mathrm{Var}(\cos\theta) = \frac{1}{d}, \qquad \Pr(|\cos\theta| \ge \varepsilon) \le \frac{1}{d\,\varepsilon^2} \quad \text{for every } \varepsilon > 0.$$

Proof. Because the uniform distribution on the sphere is invariant under rotations, we may rotate coordinates so that $\mathbf{u} = \mathbf{e}_1$; then $\cos\theta = v_1$. The distribution is also unchanged by sign reversal $\mathbf{v}\mapsto -\mathbf{v}$, so $\mathbb{E}[v_1] = 0$. By symmetry, every coordinate has the same second moment $\mathbb{E}[v_i^2]$. Since $\sum_{i=1}^{d} v_i^2 = \|\mathbf{v}\|^2 = 1$, taking expectations yields $d\,\mathbb{E}[v_1^2] = \mathbb{E}\big[\sum_{i=1}^{d} v_i^2\big] = 1$, and therefore $\mathrm{Var}(\cos\theta) = \mathbb{E}[v_1^2] = 1/d$. The tail bound follows immediately from Chebyshev's inequality, $\Pr(|X-\mathbb{E}[X]|\ge\varepsilon)\le \mathrm{Var}(X)/\varepsilon^2$ (Section 1.6). ■

The typical cosine between two random directions is therefore of order $1/\sqrt{d}$. In $d = 784$, the standard deviation is $1/28 \approx 0.036$, meaning two random directions in image space are almost always within a few degrees of orthogonal. Chebyshev's inequality bounds the probability of seeing $|\cos\theta| \ge 0.1$ by $1/(784\cdot 0.01) \approx 0.13$, whereas the true probability is under 0.01. Chebyshev is loose because it uses only the variance; sharper exponential bounds appear in Section 36.9.

Low dimensions look completely different (Figure 33.6). In the plane ($d = 2$), the angle between a fixed direction and a random one is uniform on $[0, \pi]$, so landing within 0.1 radians of orthogonal is just as likely as landing within 0.1 radians of collinear (about 6% each). Yet the *cosine* piles up near ± 1, because $\cos\theta$ flattens out near $\theta = 0$ and $\theta = \pi$: the probability that $|\cos\theta| > 0.9$ is about 0.29, compared with only 0.06 for $|\cos\theta| < 0.1$. In $d = 3$, the cosine is uniform on $[-1, 1]$, a classical result known to Archimedes. Starting at $d = 4$, the density peaks at 0; by $d = 10$ it forms a bell of width $1/\sqrt{10} \approx 0.32$, and by $d = 1000$ it has narrowed into a sharp spike of width roughly 0.03.

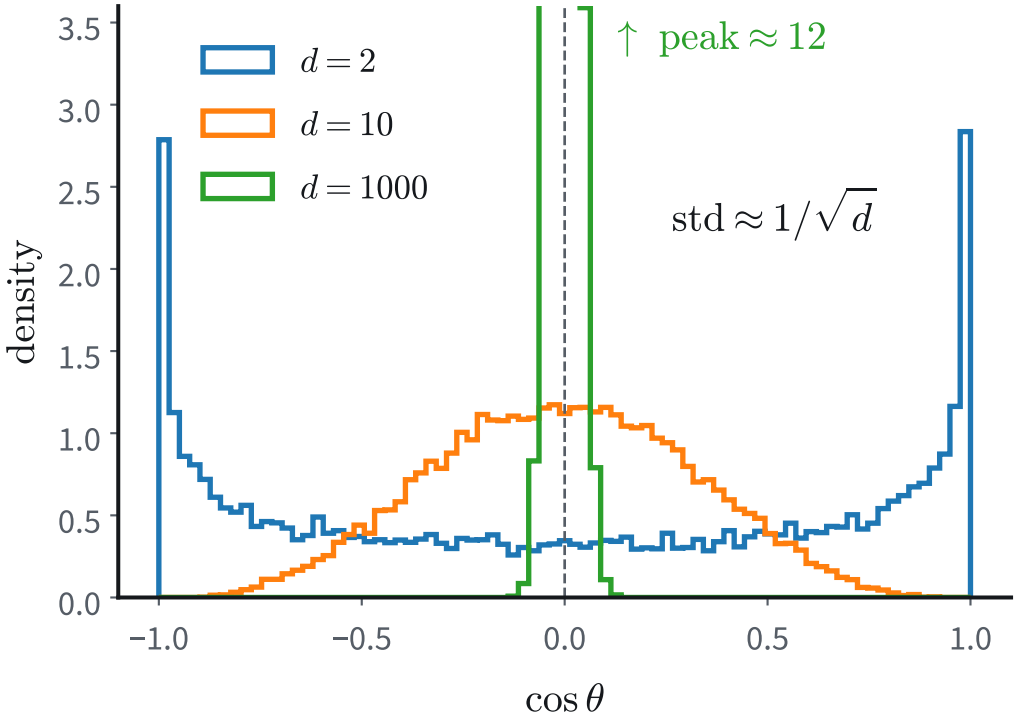

Figure 33.6: Histograms of the cosine between independent random unit vectors in dimensions $d = 2$, 10, and 1000. In $d = 2$, the cosine piles up near ± 1 even though the angle is uniform. By $d = 10$ it forms a bell around 0, and by $d = 1000$ it concentrates into a narrow spike of width $\approx 1/\sqrt{d}$, matching the proposition.

Let us check this isotropic baseline in $d = 784$ by simulation. Because a standard Gaussian vector's distribution is rotationally invariant, normalizing it produces a uniformly random unit vector. In the same cell, we also estimate a variance we will need for attention in a moment: the variance of $\mathbf{q} \cdot \mathbf{k}$ for independent standard normal vectors in 64 dimensions.

```
rng = np.random.default_rng()
d = 784
U = rng.standard_normal((10000, d))
U /= np.linalg.norm(U, axis=1, keepdims=True)
V = rng.standard_normal((10000, d))
V /= np.linalg.norm(V, axis=1, keepdims=True)
```

```
q, k = rng.standard_normal((10000, 64)), rng.standard_normal((10000, 64))
np.std((U * V).sum(axis=1)), 1 / np.sqrt(d), np.var((q * k).sum(axis=1))
```

```
(np.float64(0.0355854614613905),
 np.float64(0.03571428571428571),
 np.float64(64.6268729188249))
```

The empirical standard deviation matches $1/\sqrt{784} \approx 0.036$, and the variance of the unnormalized dot product is close to 64, the dimension.

Real data, however, rarely look isotropic. Do two unrelated Fashion-MNIST images behave like nearly orthogonal vectors? Let us sample $5{,}000$ random pairs of test images and measure their cosines, first on the raw pixels and then after subtracting the mean training image.

```
def cosines(A, B):
    """Cosine similarity between corresponding rows of A and B."""
    return (A * B).sum(axis=1) / (np.linalg.norm(A, axis=1)
                                  * np.linalg.norm(B, axis=1))

i, j = rng.integers(0, len(X_test), (2, 5000))
mean_image = X_train.mean(axis=0)
raw = cosines(X_test[i], X_test[j])
centered = cosines(X_test[i] - mean_image, X_test[j] - mean_image)
raw.mean(), raw.std(), centered.mean(), centered.std()
```

```
(np.float64(0.5922613828635285),
 np.float64(0.1811030008009743),
 np.float64(0.00941396698447776),
 np.float64(0.33995555537225597))
```

Not even close. Raw images have an average cosine around 0.6 with a standard deviation of roughly 0.18, nowhere near 0 ± 0.036. The reason is simple: pixel intensities are nonnegative, so every image lives in the same positive orthant of $\mathbb{R}^{784}$, making negative dot products impossible. Subtracting the mean image centers the cosines at 0, yet their standard deviation, about 0.34, is still nearly ten times the isotropic value. By our proposition, a spread of 0.34 corresponds to random directions in only eight or nine dimensions ($1/0.34^2$ lies between 8 and 9). Judged by their cosines, the centered images behave like a cloud living in fewer than ten dimensions rather than 784, an early glimpse of the low-rank structure we will study in Section 33.5. Practically, this means a cosine counts as large only when it stands out above the spread of unrelated pairs from the *same* dataset; training an embedding model is what pushes related pairs above that background.

33.1.3.3 The Scale of Attention Scores

Dot-product attention (Section 10.2) scores a query $\mathbf{q} \in \mathbb{R}^d$ against keys $\mathbf{k}_1, \mathbf{k}_2, \ldots$ using $\mathbf{q} \cdot \mathbf{k}_j / \sqrt{d}$ and passes those scores through a softmax (Vaswani et al. 2017). A brief variance calculation explains where the $\sqrt{d}$ comes from. Suppose all $2d$ entries of $\mathbf{q}$ and $\mathbf{k}$ are mutually independent with mean 0 and variance 1. Each product $q_i k_i$ then has mean 0 and variance $\mathbb{E}[q_i^2]\,\mathbb{E}[k_i^2] = 1$, and distinct terms are uncorrelated because $\mathbb{E}[(q_i k_i)(q_j k_j)] = \mathbb{E}[q_i]\,\mathbb{E}[k_i]\,\mathbb{E}[q_j]\,\mathbb{E}[k_j] = 0$ for $i \neq j$. The variances of the d terms therefore add:

$$\mathrm{Var}(\mathbf{q}\cdot\mathbf{k}) = \sum_{i=1}^{d} \mathrm{Var}(q_i k_i) = d.$$

Thus the raw dot products have standard deviation $\sqrt{d}$, which grows with the head dimension; dividing by $\sqrt{d}$ restores unit variance. Without that scaling, the softmax saturates into near-one-hot weights. For $d = 64$, raw scores have standard deviation 8, and two scores separated by 8 receive softmax weights 0.9997 and 0.0003; dividing by $\sqrt{d} = 8$ brings the weights back to a healthy 0.73 and 0.27. Geometry gives the exact same scaling: each vector has length roughly $\sqrt{d}$, while the cosine between unrelated directions is roughly $1/\sqrt{d}$, so their dot product has typical magnitude $\sqrt{d}\cdot\sqrt{d}\cdot(1/\sqrt{d}) = \sqrt{d}$.

Near-orthogonality does not, however, make unrelated keys harmless when there are many of them. Although any single unrelated cosine has scale $1/\sqrt{d}$, the *largest* cosine among n independent keys grows, to leading order, like $\sqrt{2\ln n/d}$. In a large retrieval index, that worst-case background match is several times larger than $1/\sqrt{d}$, so a relevant key must clear a much higher bar, which is what training arranges (1 puts concrete numbers on this effect).

33.1.4 Hyperplanes and Decision Boundaries

A linear classifier asks two geometric questions about an input $\mathbf{x}$: which side of a decision boundary does it fall on, and how far is it from that boundary? Throughout this section, we write the boundary as $\mathbf{w}\cdot\mathbf{x} + b = 0$.

33.1.4.1 Hyperplanes and Signed Distance

In the plane, this equation defines a straight line, and a quick example shows the roles of $\mathbf{w}$ and b. Take $\mathbf{w} = (2, 1)$ and $b = -1$. The points satisfying $2x + y - 1 = 0$ form the line $y = 1 - 2x$. Every point $\mathbf{x}$ on this line satisfies $\mathbf{w}\cdot\mathbf{x} = -b$, so its shadow onto $\mathbf{w}$ has the same signed length Equation 33.4:

$$\frac{\mathbf{w}\cdot\mathbf{x}}{\|\mathbf{w}\|} = \frac{-b}{\|\mathbf{w}\|} = \frac{1}{\sqrt{5}}.$$

Geometrically, the line runs perpendicular to $\mathbf{w}$ and crosses it at signed position $-b/\|\mathbf{w}\|$, at distance $|b|/\|\mathbf{w}\| = 1/\sqrt{5} \approx 0.45$ from the origin.

Nothing changes in higher dimensions. A *hyperplane* in $\mathbb{R}^d$ is a set $\{\mathbf{x} : \mathbf{w}\cdot\mathbf{x} + b = 0\}$ with $\mathbf{w} \neq \mathbf{0}$; we call $\mathbf{w}$ its *normal* vector and b its *offset*. It is simply a shifted copy of the subspace $\mathbf{w}\cdot\mathbf{x} = 0$, which has dimension $d - 1$ (Section 33.2.2.2): a line in $\mathbb{R}^2$, a plane in $\mathbb{R}^3$, and a 783-dimensional flat sheet inside image space. The hyperplane partitions $\mathbb{R}^d$ into two *half-spaces*, $\mathbf{w}\cdot\mathbf{x} + b > 0$ and $\mathbf{w}\cdot\mathbf{x} + b < 0$. Adjusting b translates the hyperplane parallel to itself along $\mathbf{w}$ without tilting it.

How far is an arbitrary point $\mathbf{x}$ from the hyperplane? Pick any point $\mathbf{x}_0$ lying on the hyperplane, so $\mathbf{w}\cdot\mathbf{x}_0 = -b$. The distance from $\mathbf{x}$ to the hyperplane is the signed length of the shadow of the displacement $\mathbf{x} - \mathbf{x}_0$ onto the normal $\mathbf{w}$, giving the *signed distance*

$$\frac{\mathbf{w}\cdot(\mathbf{x}-\mathbf{x}_0)}{\|\mathbf{w}\|} = \frac{\mathbf{w}\cdot\mathbf{x}+b}{\|\mathbf{w}\|}. \tag{33.11}$$

Notice that $\mathbf{x}_0$ drops out completely: the signed distance depends only on $\mathbf{x}$, $\mathbf{w}$, and b. It is positive on the side $\mathbf{w}$ points toward, negative on the opposite side, and zero on the hyperplane itself. In our planar example, the origin sits at signed distance $-1/\sqrt{5}$, while the point $(1,1)$ has score $\mathbf{w}\cdot\mathbf{x}+b = 2$, placing it at signed distance $+2/\sqrt{5} \approx 0.89$ on the positive side; its closest point on the line is $(1,1) - (2/5)(2,1) = (0.2, 0.6)$. The point $(0,1)$ scores 0 and lies directly on the line (Figure 33.7).

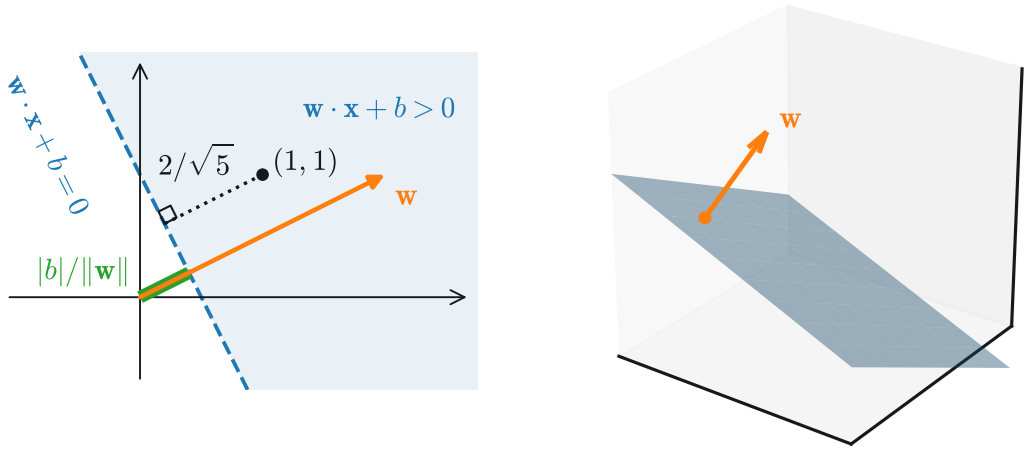

Figure 33.7: The hyperplane $\mathbf{w}\cdot\mathbf{x}+b=0$ with normal $\mathbf{w}$. Left: for $\mathbf{w}=(2,1)$ and $b=-1$, the hyperplane is the line $2x+y=1$ at distance $1/\sqrt{5}$ from the origin; the point $(1,1)$ lies at signed distance $2/\sqrt{5}$ on the side $\mathbf{w}$ points toward, and the shaded half-plane is $\mathbf{w}\cdot\mathbf{x}+b>0$. Right: in three dimensions the same equation defines a plane.

For a labeled example $(\mathbf{x}, y)$ with $y \in \{-1, +1\}$, we also want to know whether it falls on the *correct* side. Multiplying the signed distance by the label defines the *margin*, $y\,(\mathbf{w}\cdot\mathbf{x}+b)/\|\mathbf{w}\|$, which is positive when the classification is right and grows larger the deeper the point sits inside its own half-space. Rescaling $(\mathbf{w}, b) \to (c\mathbf{w}, cb)$ for any $c>0$ leaves both the hyperplane and the margin unchanged, while multiplying the raw score $\mathbf{w}\cdot\mathbf{x}+b$ by c. Any learning objective that maximizes the raw score must therefore constrain the scale of $\mathbf{w}$.

33.1.4.2 The Nearest-Mean Classifier

Which hyperplane should we pick to separate two classes? The simplest rule requires no iterative training at all: assign $\mathbf{x}$ to the class whose mean lies closer. Remarkably, this rule is itself a single hyperplane. Let $\bar{\mathbf{x}}_0$ and $\bar{\mathbf{x}}_1$ denote the two class means. Expanding both squared distances, the quadratic term $\|\mathbf{x}\|^2$ cancels on both sides:

$$\begin{aligned}\|\mathbf{x}-\bar{\mathbf{x}}_1\|^2 < \|\mathbf{x}-\bar{\mathbf{x}}_0\|^2 &\iff -2\,\mathbf{x}\cdot\bar{\mathbf{x}}_1 + \|\bar{\mathbf{x}}_1\|^2 < -2\,\mathbf{x}\cdot\bar{\mathbf{x}}_0 + \|\bar{\mathbf{x}}_0\|^2 \\ &\iff (\bar{\mathbf{x}}_1-\bar{\mathbf{x}}_0)\cdot\mathbf{x} - \tfrac{1}{2}\big(\|\bar{\mathbf{x}}_1\|^2 - \|\bar{\mathbf{x}}_0\|^2\big) > 0.\end{aligned}$$

Using the identity $\|\mathbf{a}\|^2 - \|\mathbf{c}\|^2 = (\mathbf{a}-\mathbf{c})\cdot(\mathbf{a}+\mathbf{c})$, the final inequality becomes $\mathbf{w}\cdot\mathbf{x}+b>0$ with

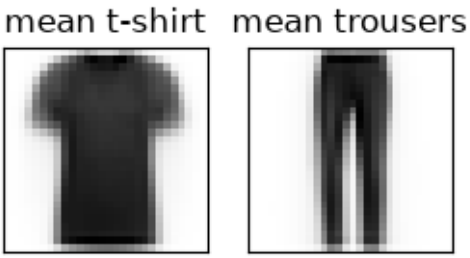
$$\mathbf{w} = \bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_0, \qquad b = -\mathbf{w}\cdot\tfrac{1}{2}\left(\bar{\mathbf{x}}_0 + \bar{\mathbf{x}}_1\right).$$

So "nearest mean" is just the perpendicular bisector hyperplane: its normal points from one mean to the other, and it cuts directly through their midpoint. There is no threshold to tune by hand, and the rule is invariant to uniform pixel rescaling: multiplying every pixel by $c>0$ sends $\mathbf{w}\to c\mathbf{w}$ and $b\to c^2 b$, scaling every score by c^2 without changing a single prediction (2 extends this invariance to rotations and translations, and constructs a per-pixel rescaling that *does* change predictions).

Before testing this classifier on t-shirts and trousers, let us inspect the two class means and compute the angle between them.

```
X0, X1 = X_train[y_train == 0], X_train[y_train == 1]    # t-shirts, trousers
mean_0, mean_1 = X0.mean(axis=0), X1.mean(axis=0)
d2l.show_images([mean_0.reshape(28, 28), mean_1.reshape(28, 28)], 1, 2,
                titles=['mean t-shirt', 'mean trousers'], cmap='Greys')
np.degrees(angle(mean_0, mean_1))
```

```
np.float64(33.20917997376519)
```



Both mean images are blurry yet immediately recognizable. They sit only about 33° apart (a cosine of 0.84), far from orthogonal, because both garments occupy the bright center of the frame. Seeing the two means so close in angle might make us pessimistic, but the nearest-mean classifier does not require orthogonal means; it relies only on their *difference*. Let us evaluate it on all $2{,}000$ test images of t-shirts and trousers.

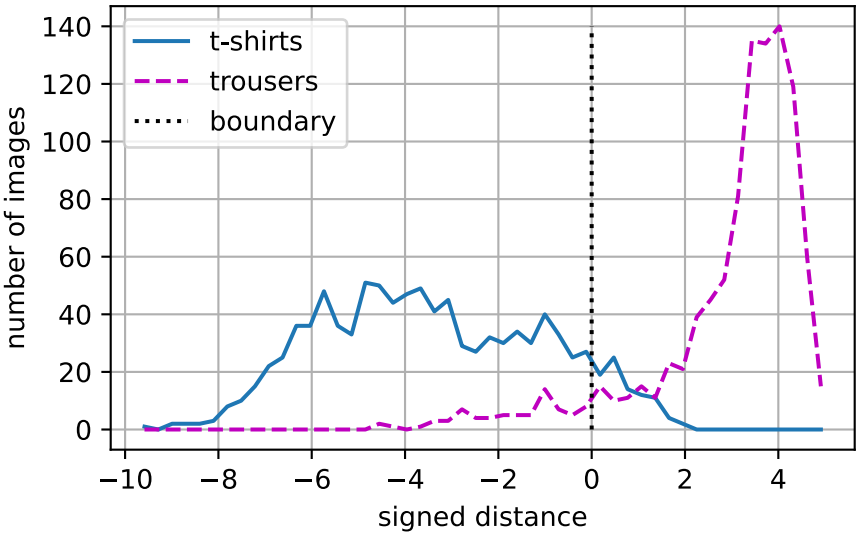
```
w = mean_1 - mean_0
b = -w @ (mean_0 + mean_1) / 2
mask = (y_test == 0) | (y_test == 1)
X2, y2 = X_test[mask], y_test[mask]
predictions = X2 @ w + b > 0                              # True: trousers
np.mean(predictions == (y2 == 1))
```

```
np.float64(0.9155)
```

The rule classifies about 92% of the test images correctly, putting only 169 of the $2{,}000$ on the wrong side. All we did was average each class and check which side of one hyperplane each test image falls on.

To understand where the remaining errors come from, we compress every test image to a single number, its signed distance Equation 33.11 to the boundary, and plot the histogram for each class.

```
dist = (X2 @ w + b) / np.linalg.norm(w)         # signed distance to boundary
bins = np.linspace(dist.min(), dist.max(), 51)
counts = [np.histogram(dist[y2 == c], bins)[0] for c in (0, 1)]
top = max(counts[0].max(), counts[1].max())
d2l.plot([bins[:-1]] * 2 + [[0, 0]], counts + [[0, top]], 'signed distance',
         'number of images', fmts=('-', 'm--', 'k:'),
         legend=['t-shirts', 'trousers', 'boundary'], figsize=(5, 3))
```



The two classes form distinct modes whose tails cross the boundary. T-shirts form a broad hump centered around -4, while trousers form a sharper peak near $+4$ with a long tail stretching toward zero. On average, each class sits near the signed distance of its training mean, $\mp\|\mathbf{w}\|/2 \approx \mp 3.2$. Let us quantify this picture by computing each class's standard deviation along $\mathbf{w}$ and counting how many examples land on the wrong side.

```
(dist[y2 == 0].std(), dist[y2 == 1].std(),
 int((dist[y2 == 0] > 0).sum()), int((dist[y2 == 1] < 0).sum()))
```

```
(np.float64(2.356225995048113), np.float64(1.6627004538100882), 101, 68)
```

Along $\mathbf{w}$, t-shirts have a standard deviation of about 2.4 and trousers about 1.7, with 101 t-shirts and 68 trousers misclassified. Because each class center lies less than two standard deviations from the boundary, an error rate of several percent is entirely expected. Notice the built-in limitation of the midpoint rule: it looks only at the two class means and has no way to account for the size or shape of either cloud. What happens when we apply it to harder pairs that look much more alike, such as t-shirts versus shirts or pullovers versus coats?

```
# t-shirt/trouser, t-shirt/shirt, pullover/coat
for a, c in [(0, 1), (0, 6), (2, 4)]:
    m_a = X_train[y_train == a].mean(axis=0)
    m_c = X_train[y_train == c].mean(axis=0)
    w_ac, b_ac = m_c - m_a, -(m_c - m_a) @ (m_a + m_c) / 2
    pair = (y_test == a) | (y_test == c)
    acc = np.mean((X_test[pair] @ w_ac + b_ac > 0) == (y_test[pair] == c))
    dist_ac = (X_test[pair] @ w_ac + b_ac) / np.linalg.norm(w_ac)
    sd_a, sd_c = (dist_ac[y_test[pair] == k].std() for k in (a, c))
    names = data.text_labels([a, c])
    print(f'{names[0]:>8} vs {names[1]:<9}accuracy {acc:.3f}   '
          f'||w||/2 {np.linalg.norm(w_ac) / 2:.2f}   '
          f'std along w {sd_a:.2f}, {sd_c:.2f}')
```

```
 T-shirt vs trouser  accuracy 0.915   ||w||/2 3.23   std along w 2.36, 1.66
 T-shirt vs shirt    accuracy 0.786   ||w||/2 1.86   std along w 1.77, 2.38
pullover vs coat     accuracy 0.716   ||w||/2 1.24   std along w 1.88, 2.09
```

Accuracy drops sharply: t-shirts versus shirts falls to about 79%, and pullovers versus coats falls to about 72%. The remaining columns explain why. Each training mean sits at distance $\|\mathbf{w}\|/2$ from the boundary, and what governs overlap is that distance measured in units of each class's standard deviation along $\mathbf{w}$. For t-shirts and trousers, the gap is 1.4 to 1.9 standard deviations. For the two harder pairs, it shrinks to just 0.6 to 1.0 standard deviations, so a boundary placed at the midpoint slices straight through the bulk of both classes. The cure is to tilt $\mathbf{w}$ away from directions along which the classes vary widely, which is the idea behind Fisher's linear discriminant (4). Softmax regression goes a step further by learning both the tilt and the offset directly from data, while a deep network transforms the inputs themselves into a representation where the classes become nearly separable by a single hyperplane.

33.1.4.3 Layers as Stacked Hyperplanes

A linear neural network layer runs many hyperplane tests in parallel. Entry i of the matrix-vector product $\mathbf{Ax}$ is the dot product of row i of $\mathbf{A}$ with $\mathbf{x}$, a score $\mathbf{a}_i \cdot \mathbf{x}$ against the normal $\mathbf{a}_i$, and adding a bias vector turns each entry into a hyperplane score. For instance, the ten-class softmax layer of Section 3.1 on Fashion-MNIST stores ten normals $\mathbf{w}_1, \ldots, \mathbf{w}_{10}$ and ten offsets. Because it predicts the class with the highest score, the decision boundary separating classes i and j is the hyperplane $(\mathbf{w}_i - \mathbf{w}_j) \cdot \mathbf{x} + (b_i - b_j) = 0$ where their two scores tie.

To see this concretely, take our chapter's running matrix $\mathbf{A} = \left(\begin{smallmatrix} 1 & 2 \\ -1 & 3 \end{smallmatrix}\right)$ and the input $\mathbf{x} = (2, -1)$. Row one yields $1 \cdot 2 + 2 \cdot (-1) = 0$, meaning $\mathbf{x}$ lies directly on the hyperplane through the origin with normal $(1, 2)$. Row two yields $-2 - 3 = -5$, placing $\mathbf{x}$ on the negative side of the hyperplane with normal $(-1, 3)$ at signed distance $-5/\sqrt{10} \approx -1.58$. Stacking both results gives $\mathbf{Ax} = (0, -5)$.

Viewing $\mathbf{Ax}$ row by row reveals a linear layer as a stack of hyperplane tests, yet it leaves two essential questions unanswered: which inputs does the transformation collapse to zero, and when can its action be inverted? Reading the very same product column by column answers both questions in Section 33.2.

33.1.5 Summary

The dot product extends lengths, angles, and projections from the plane to any dimension using the exact same formulas. Projecting onto a line or subspace produces the unique closest point, characterized by a residual orthogonal to the target space; from this single geometric fact follow the Cauchy–Schwarz inequality (which makes high-dimensional angles well defined) and the normal equations of least squares. The Gram–Schmidt process converts any spanning list into an orthonormal basis, yielding the $\mathbf{Q}$ factor of the QR factorization. While random directions in $\mathbb{R}^d$ are nearly orthogonal with typical cosines of order $1/\sqrt{d}$, real image datasets are far from isotropic, so an observed cosine is meaningful only relative to unrelated pairs from the same distribution. Finally, the nearest-mean classifier defines a single hyperplane bisecting the two class means: it reaches about 92% accuracy on t-shirts versus trousers, but drops to 72%–79% on visually similar pairs where class spread along the boundary normal matters.

33.1.6 Exercises

1. code **Cosines between random vectors.**
    1. Sample $1{,}000$ pairs of independent random unit vectors in $d = 10{,}000$ dimensions by normalizing standard Gaussian vectors, and compute the cosine of each pair. Compare the empirical standard deviation with the prediction $1/\sqrt{d} = 0.01$ from the near-orthogonality proposition, and report the largest $|\cos\theta|$ observed.
    2. A retrieval system compares one query against n keys and returns the key with the largest cosine. Model the query and keys as independent random unit vectors in $d = 256$ dimensions. Compute the maximum of the n cosines for $n = 10$, 10^3, and 10^5, and compare it with $\sqrt{2\ln n/d}$, the leading-order estimate for the maximum of n independent Gaussian draws of variance $1/d$. How large a cosine does an unrelated key achieve as the top match among 10^5 keys? How should a threshold for declaring two embeddings related scale with n and d?
2. **Nearest means and invariance.** The nearest-mean rule assigns $\mathbf{x}$ to class 1 when $\mathbf{w}\cdot\mathbf{x}+b>0$, where $\mathbf{w}=\bar{\mathbf{x}}_1-\bar{\mathbf{x}}_0$ and $b=-\mathbf{w}\cdot\frac{1}{2}(\bar{\mathbf{x}}_0+\bar{\mathbf{x}}_1)$.
    1. Suppose every training and test image undergoes the same transformation $\mathbf{x}\mapsto c\mathbf{Q}\mathbf{x}+\mathbf{z}$, where $c>0$, $\mathbf{Q}$ is square with $\mathbf{Q}^\top\mathbf{Q}=\mathbf{I}$, and $\mathbf{z}$ is a fixed vector, and we recompute the class means and b. Show that no prediction changes, and connect this to the rescaling $\mathbf{w}\to c\mathbf{w}$, $b\to c^2 b$ discussed in the text.
    2. Standardizing each pixel to unit variance replaces $\mathbf{x}$ by $\mathbf{D}\mathbf{x}$ for a positive diagonal matrix $\mathbf{D}$. Construct two class means and a test point in $\mathbb{R}^2$ whose predicted class flips under such a $\mathbf{D}$.
    3. With q classes under the nearest-mean rule, show that the region assigned to class i is the intersection of the $q-1$ half-spaces $(\bar{\mathbf{x}}_i-\bar{\mathbf{x}}_j)\cdot\mathbf{x}+b_{ij}>0$ for $j\neq i$, and find b_{ij}. Compare this with the pairwise boundaries $(\mathbf{w}_i-\mathbf{w}_j)\cdot\mathbf{x}+(b_i-b_j)=0$ of a softmax layer: which choice of weights and biases makes a softmax layer reproduce the nearest-mean classifier?
3. **Orthogonal and oblique projectors.**
    1. Let $\mathbf{P}$ satisfy $\mathbf{P}^2=\mathbf{P}$ and $\mathbf{P}^\top=\mathbf{P}$. Show that for every $\mathbf{x}$, $\mathbf{P}\mathbf{x}$ lies in the column space of $\mathbf{P}$ and $\mathbf{x}-\mathbf{P}\mathbf{x}$ is orthogonal to it. Deduce via Pythagoras' theorem that $\mathbf{P}\mathbf{x}$

is the closest point in the column space, without invoking an orthonormal basis.

2. The matrix $\mathbf{P}_{\mathrm{o}} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 0 \end{smallmatrix}\right)$ satisfies $\mathbf{P}_{\mathrm{o}}^2 = \mathbf{P}_{\mathrm{o}}$ but is not symmetric. For $\mathbf{x} = (1, 1)$, compute $\mathbf{P}_{\mathrm{o}}\mathbf{x}$ and the orthogonal projection of $\mathbf{x}$ onto the same column space (the first coordinate axis), along with the distance of each from $\mathbf{x}$. Along what direction does $\mathbf{P}_{\mathrm{o}}$ project points?
3. Show that any matrix $\mathbf{P}$ with $\mathbf{P}^2 = \mathbf{P}$ decomposes every $\mathbf{x}$ as $\mathbf{P}\mathbf{x} + (\mathbf{x} - \mathbf{P}\mathbf{x})$, with the first term in the column space of $\mathbf{P}$ and the second in its null space $\{\mathbf{z} : \mathbf{P}\mathbf{z} = \mathbf{0}\}$. Show that these two subspaces are orthogonal if and only if $\mathbf{P}^{\top} = \mathbf{P}$.

4. code **Tilting the boundary.** ● The mean-difference normal $\Delta = \bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_0$ ignores how the images in each class spread around their mean. Let $\mathbf{C}$ be the average of the two within-class covariance matrices on the training set. Fisher's linear discriminant (Fisher 1936) selects the normal $\mathbf{w}$ maximizing

$$J(\mathbf{w}) = \frac{(\mathbf{w} \cdot \Delta)^2}{\mathbf{w}^{\top} \mathbf{C} \mathbf{w}},$$

the squared separation between the projected class means divided by the within-class variance of the projections. When $\mathbf{C}$ is positive definite ($\mathbf{v}^{\top}\mathbf{C}\mathbf{v} > 0$ for all $\mathbf{v} \neq \mathbf{0}$), its inverse $\mathbf{C}^{-1}$ exists and the maximizer is $\mathbf{w} \propto \mathbf{C}^{-1}\Delta$. (This problem uses the matrix inverse from Section 33.2.2.3, positive definiteness from Section 33.3.2.2, and the condition number from Section 33.5.3.2.)

1. Show that $J(c\mathbf{w}) = J(\mathbf{w})$ for every $c \neq 0$. When $\mathbf{C} = s^2\mathbf{I}$, apply Cauchy–Schwarz to show that Δ maximizes J.
2. Using the arrays `X0` and `X1` of t-shirts and trousers from the text, compute $\mathbf{C}$ and let $\bar{s}^2 = \operatorname{tr}(\mathbf{C})/784$ be the average pixel variance. For these images, $\mathbf{C}$ has a condition number of about 10^9 because some border pixels are nearly constant. For $\gamma \in \{10^{-4}, 10^{-2}, 1, 10^2, 10^4\}$, form the regularized normal $\mathbf{w}_\gamma = (\mathbf{C} + \gamma \bar{s}^2 \mathbf{I})^{-1}\Delta$, place the boundary at the midpoint of the two means, and evaluate both training and test accuracy. Next, hold out $1{,}000$ training images per class, recompute $\mathbf{C}$ and the class means on the remaining images, select γ by validation accuracy on the held-out set, and replot the signed-distance histogram using that $\mathbf{w}_\gamma$.
3. Why does $\mathbf{w}_\gamma$ align with Δ as $\gamma \to \infty$? Why scale the regularizer by $\bar{s}^2$ instead of adding a fixed multiple of $\mathbf{I}$?

5. code **Gram–Schmidt in floating point.** ● The Gram–Schmidt process can be executed in two algebraically equivalent orders. Classical Gram–Schmidt (CGS) computes $\mathbf{q}_j$ by normalizing $\mathbf{a}_j - \sum_{i<j} (\mathbf{q}_i \cdot \mathbf{a}_j)\,\mathbf{q}_i$, as in our two-vector example. Modified Gram–Schmidt (MGS) initializes $\mathbf{v} = \mathbf{a}_j$, updates $\mathbf{v} \leftarrow \mathbf{v} - (\mathbf{q}_i \cdot \mathbf{v})\,\mathbf{q}_i$ sequentially for $i = 1, \dots, j-1$, and then normalizes $\mathbf{v}$.

1. Show that CGS and MGS produce identical vectors in exact arithmetic.
2. Implement both algorithms and run them on the Hilbert matrices $\mathbf{H}_n$ with entries $1/(i + j - 1)$ for $n = 4, 6, 8, 10, 12$, whose columns are nearly linearly dependent. Plot the Frobenius norm $\|\mathbf{Q}^{\top}\mathbf{Q} - \mathbf{I}\|_F$ against n for CGS, MGS, and `np.linalg.qr`. For each method, at what n does $\mathbf{P} = \mathbf{Q}\mathbf{Q}^{\top}$ fail to act as a projector, as measured by $\|\mathbf{P}^2 - \mathbf{P}\|_F$?
3. Apply the CGS subtraction step twice to each column, running the second pass on the vector left by the first. How close to orthonormal are the resulting columns

compared with a single pass of CGS and with MGS? Explain the improvement by comparing the size of the components along $\mathbf{q}_1, \dots, \mathbf{q}_{j-1}$ entering the first pass versus those entering the second.

6. [extended] **Packing nearly orthogonal directions.** ●● Although $\mathbb{R}^d$ accommodates at most d mutually orthogonal directions, it can pack vastly more directions whose pairwise cosines stay small. Elhage et al. (2022) use this geometry to explain how a layer of width d can represent more than d features in *superposition* as nearly orthogonal directions. Their features are *sparse*: each activates on only a small fraction of inputs, so only a few need to be read out at once. Let $\mathbf{u}_1, \dots, \mathbf{u}_n$ be unit vectors in $\mathbb{R}^d$, stacked as the rows of $\mathbf{U} \in \mathbb{R}^{n \times d}$, and let $\mu = \max_{i \neq j} |\mathbf{u}_i \cdot \mathbf{u}_j|$ denote their worst pairwise interference.

   1. Expand $\sum_{i,j} (\mathbf{u}_i \cdot \mathbf{u}_j)^2$ in coordinates and show that it equals $\sum_{k,l} \left(\sum_i u_{ik} u_{il}\right)^2$, the sum of squared entries of the $d \times d$ matrix $\mathbf{U}^\top \mathbf{U}$. Bound this sum below using its d diagonal terms together with Cauchy–Schwarz in the form $\sum_{k=1}^{d} a_k^2 \geq \left(\sum_k a_k\right)^2 / d$, noting that $\sum_k (\mathbf{U}^\top \mathbf{U})_{kk} = n$. Bound the original sum above by $n + n(n-1)\mu^2$ to derive the *Welch bound* (Welch 1974):

$$\mu^2 \geq \frac{n - d}{d\,(n-1)}.$$

      Evaluate this bound for $d = 32$ with $n = 64$ and $n = 512$.

   2. A union bound over all pairs shows that independent random directions keep $\mu \leq \varepsilon$ for n on the order of $e^{d\varepsilon^2/4}$ (Section 36.9). For $d = 32$ and $n \in \{64, 128, 256, 512\}$, compute μ for random unit vectors and compare it against the Welch bound.

   3. Reduce μ directly by optimization: minimize $\sum_{i \neq j} (\mathbf{u}_i \cdot \mathbf{u}_j)^p$ for an even power such as $p = 10$ via gradient steps on $\mathbf{U}$, renormalizing every row after each step. For $d \in \{16, 32, 48, 64\}$ and $n \in \{d, 2d, 4d, 8d, 16d\}$, plot μ against n for random vectors, optimized vectors, and the Welch bound.

   4. Use these curves to estimate, for each d, the largest n for which optimized directions keep $\mu \leq 0.2$. How does this capacity grow with d compared with the random-direction rate $e^{d\varepsilon^2/4}$? How would your conclusions change if some features were more important than others, or if many features activated simultaneously?

33.2 Matrices as Linear Maps

In Section 33.1 we read a matrix–vector product $\mathbf{Ax}$ one row at a time: entry i is the dot product of row i with $\mathbf{x}$, a single hyperplane test. That row view tells us what a matrix computes for one input vector, but it hides what the matrix does to the entire input space at once. In particular, it does not tell us whether the map preserves information or throws it away, and whether its effect can ever be undone.

This question comes up as soon as a neural network layer is narrower than its input. A fully connected layer mapping the 784 pixels of a Fashion-MNIST image to 256 hidden features is

a 256×784 matrix. Because its output holds fewer numbers than its input, it must collapse space: by a count we will make precise shortly, at least $784 - 256 = 528$ independent input directions are sent to zero, so distinct images can produce identical features before any nonlinearity even sees them.

Even a square matrix can lose information. Consider the running matrix of this chapter, $\mathbf{A} = \left(\begin{smallmatrix} 1 & 2 \\ -1 & 3 \end{smallmatrix}\right)$. It sends $(2, -1)$ to $(0, -5)$, and there is another matrix that sends $(0, -5)$ right back to $(2, -1)$. In fact, that second matrix undoes $\mathbf{A}$ on every input, so $\mathbf{A}$ loses nothing. Contrast this with $\mathbf{B} = \left(\begin{smallmatrix} 2 & 1 \\ 4 & 2 \end{smallmatrix}\right)$, which sends both $(1, 1)$ and $(0, 3)$ to $(3, 6)$. Given only the output $(3, 6)$, we have no way to tell which input produced it, so no matrix can reverse $\mathbf{B}$.

Whether a linear map can be undone determines whether a layer discards information, whether a linear system has a unique solution, and how a probability density rescales under a change of variables (Section 36.2.3.1). To answer this question cleanly, we shift from rows to columns. Column j of a matrix is simply where it sends the j-th coordinate axis, and those images alone fix the entire map. Counting how many columns are linearly independent tells us how many input dimensions survive the map, while measuring the signed volume of the transformed unit cube gives a single number that detects whether any dimension was lost. We develop both ideas first in two dimensions, where every statement is a picture, and then extend them to n dimensions.

Three results organize the section: the balance between surviving and collapsed dimensions, the exact conditions under which a square matrix has an inverse, and the rule for how volume scaling behaves when two maps are composed. The general n-dimensional construction of the determinant (Section 33.2.3.2) is the most technical part and can be skimmed on a first reading.

```
import numpy as np
```

33.2.1 Linear Maps

33.2.1.1 Columns as Images of the Axes

A matrix acts on infinitely many input vectors, yet it is stored as a finite table of numbers. How can just four numbers fix the output for every vector in the plane? Take a 2×2 matrix $\mathbf{A}$ with entries p, q, r, s and apply it to $\mathbf{x} = (x, y)$. Collecting the terms that multiply x and those that multiply y gives

$$\mathbf{A}\mathbf{x} = \begin{bmatrix} p & q \\ r & s \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} px + qy \\ rx + sy \end{bmatrix} = x \begin{bmatrix} p \\ r \end{bmatrix} + y \begin{bmatrix} q \\ s \end{bmatrix} = x\,\mathbf{A}\mathbf{e}_1 + y\,\mathbf{A}\mathbf{e}_2.$$

Thus $\mathbf{A}\mathbf{x}$ is simply a weighted sum of the two columns of $\mathbf{A}$, using the coordinates of $\mathbf{x}$ as weights. Because $\mathbf{A}\mathbf{e}_1 = (p, r)$ and $\mathbf{A}\mathbf{e}_2 = (q, s)$, the columns are the images of the standard basis vectors $\mathbf{e}_1 = (1, 0)$ and $\mathbf{e}_2 = (0, 1)$. Once we know where those two axes land, the image of every other vector in the plane is completely determined.

For our running matrix ($p = 1$, $q = 2$, $r = -1$, $s = 3$), the two axes go to $\mathbf{A}\mathbf{e}_1 = (1, -1)$ and $\mathbf{A}\mathbf{e}_2 = (2, 3)$. Since the input $\mathbf{v} = (2, -1)$ is $2\mathbf{e}_1 - \mathbf{e}_2$, its image is the exact same combination of the columns:

$$\mathbf{A}\mathbf{v} = 2\,(1, -1) - (2, 3) = (0, -5).$$

Checking by rows confirms the result: $(1,2)\cdot(2,-1) = 0$ and $(-1,3)\cdot(2,-1) = -5$. Both views compute the same product, but the column view lets us see what $\mathbf{A}$ does to the entire plane at once. Figure 33.8 illustrates this geometry: the unit square spanned by $\mathbf{e}_1$ and $\mathbf{e}_2$ is carried to the parallelogram spanned by the two columns, and the grid point $\mathbf{v}$ lands on the corresponding point $\mathbf{Av}$ of the transformed grid.

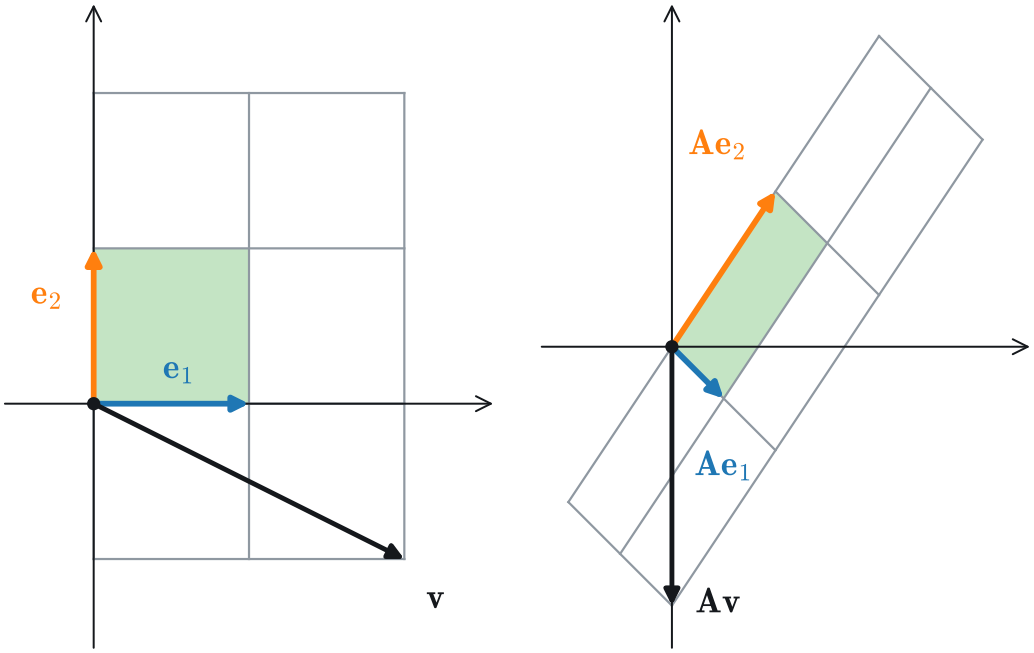


Figure 33.8: The running matrix $\mathbf{A} = \left(\begin{smallmatrix} 1 & 2 \\ -1 & 3 \end{smallmatrix}\right)$ acting on the plane. (a) The input grid, shaded unit square, basis vectors, and input $\mathbf{v} = (2,-1)$. (b) Its image: $\mathbf{e}_1$ goes to $(1,-1)$, $\mathbf{e}_2$ to $(2,3)$, and $\mathbf{v}$ to $(0,-5)$. Lines remain lines, the origin stays fixed, and equally spaced points stay equally spaced. The shaded square maps to the shaded parallelogram, whose area leads to the determinant. Panel (b) is drawn at one-third the scale of (a).

The same column picture holds in any dimension. An $m \times n$ matrix maps vectors in $\mathbb{R}^n$ to vectors in $\mathbb{R}^m$, and it is *linear*:

$$\mathbf{A}(\alpha\mathbf{x} + \beta\mathbf{y}) = \alpha\,\mathbf{Ax} + \beta\,\mathbf{Ay} \quad \text{for all } \mathbf{x},\mathbf{y} \in \mathbb{R}^n \text{ and } \alpha,\beta \in \mathbb{R}.$$

In words, the image of a weighted sum is the same weighted sum of the images. Writing any input as $\mathbf{x} = \sum_j x_j \mathbf{e}_j$ gives $\mathbf{Ax} = \sum_j x_j\,\mathbf{Ae}_j$, where multiplying by $\mathbf{e}_j$ picks out column j. Conversely, every map $f : \mathbb{R}^n \to \mathbb{R}^m$ that satisfies this linearity rule can be written as a matrix whose j-th column is $f(\mathbf{e}_j)$, because $f(\mathbf{x}) = f(\sum_j x_j \mathbf{e}_j) = \sum_j x_j f(\mathbf{e}_j)$. Linear maps from $\mathbb{R}^n$ to $\mathbb{R}^m$ and $m \times n$ matrices are therefore two ways of describing the same object.

Linearity is also what keeps the grid in Figure 33.8 looking like a grid. Every line $\mathbf{p} + t\mathbf{u}$ maps to $\mathbf{Ap} + t\,\mathbf{Au}$, which is again a line (or a single point if $\mathbf{Au} = \mathbf{0}$), and the origin never moves: $\mathbf{A0} = \mathbf{0}$.

Nothing here requires the matrix to be square. A 2×3 matrix maps $\mathbb{R}^3$ into the span of its three columns in $\mathbb{R}^2$, filling the whole output plane as long as at least two columns are linearly independent. Going the other way, a 3×2 matrix maps the plane into $\mathbb{R}^3$, where its outputs form a plane through the origin, a line, or the origin alone, depending on its two columns. Every fully connected layer in a neural network is a rectangular map of this kind, followed by a bias shift and a nonlinearity.

To build visual intuition, Figure 33.9 displays six 2×2 matrices through their effect on the unit square. A 90° counter-clockwise rotation sends $\mathbf{e}_1$ to $\mathbf{e}_2$ and $\mathbf{e}_2$ to $-\mathbf{e}_1$, so its columns are $(0, 1)$ and $(-1, 0)$. A horizontal shear leaves $\mathbf{e}_1$ untouched and tilts $\mathbf{e}_2$ to $(1, 1)$, sliding every horizontal line sideways in proportion to its height. The last two panels are qualitatively different: they lose a dimension, flattening the entire square, and with it the entire plane, onto a single line.

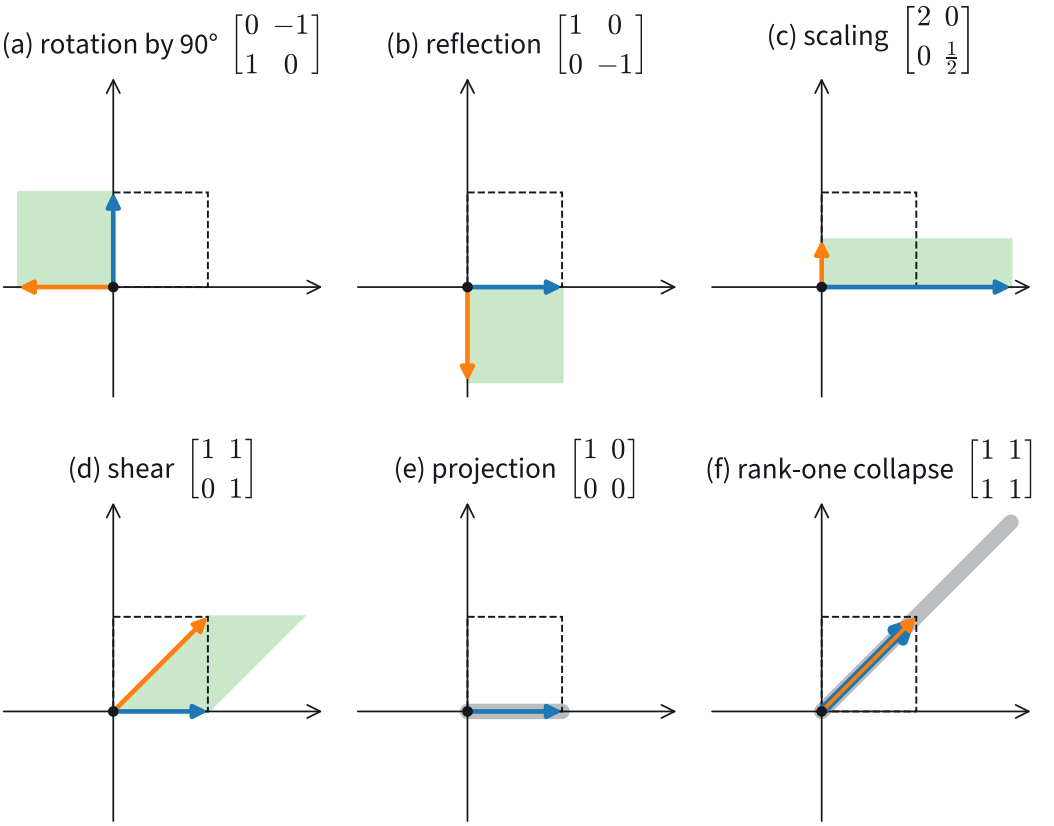

Figure 33.9: Six ways a 2×2 matrix can transform the unit square (dashed). In each panel, the arrows show the columns, which are the images of $\mathbf{e}_1$ (blue) and $\mathbf{e}_2$ (orange), and the shaded region is the image of the square. Panels (e) and (f) collapse the plane onto a line; in (f) both columns are $(1, 1)$.

One familiar operation is noticeably absent from this gallery: a translation $\mathbf{x} \mapsto \mathbf{x} + \mathbf{c}$ with $\mathbf{c} \neq \mathbf{0}$. Because it moves the origin, it is not linear. An affine layer $\mathbf{W}\mathbf{x} + \mathbf{b}$ in a neural network is therefore a linear map followed by a translation.

33.2.1.2 Composition

Two linear layers placed back to back, with no nonlinearity between them, collapse into a single linear map. Which matrix represents that combined map? Let us test this on two concrete maps from Figure 33.9: the 90° rotation $\mathbf{R}_{90}$ and the shear $\mathbf{T}$ (named for how it tilts the vertical axis),

$$\mathbf{R}_{90} = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}, \qquad \mathbf{T} = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}.$$

Both matrices will reappear throughout the chapter. Let us track where the standard basis vectors go under each ordering. If we shear first, $\mathbf{e}_1$ stays at $(1, 0)$ and the rotation sends it to $(0, 1)$; meanwhile $\mathbf{e}_2$ shears to $(1, 1)$ and rotates to $(-1, 1)$. Thus "shear, then rotate" has columns $(0, 1)$ and $(-1, 1)$. In the opposite order, rotating sends $\mathbf{e}_1$ to $(0, 1)$, which the shear moves to $(1, 1)$, and sends $\mathbf{e}_2$ to $(-1, 0)$, which the shear leaves unchanged. The two composites are therefore

$$\text{shear, then rotate: } \begin{bmatrix} 0 & -1 \\ 1 & 1 \end{bmatrix}, \qquad \text{rotate, then shear: } \begin{bmatrix} 1 & -1 \\ 1 & 0 \end{bmatrix}.$$

They are not the same map, as Figure 33.10 makes clear.

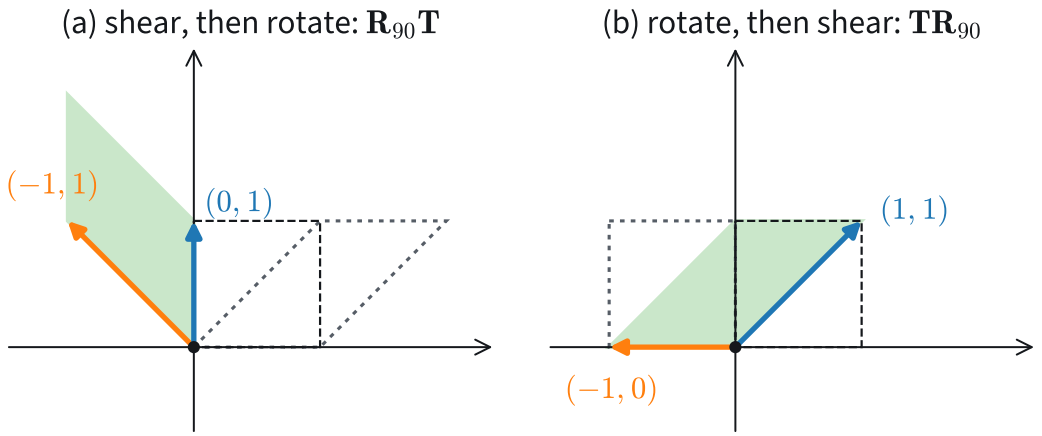

Figure 33.10: The order of composition matters. (a) Applying the shear $\mathbf{T}$ (dotted outline) followed by the rotation $\mathbf{R}_{90}$ produces $\mathbf{R}_{90}\mathbf{T}$. (b) Applying the rotation (dotted outline) followed by the shear produces $\mathbf{T}\mathbf{R}_{90}$. The labels show the final images of $\mathbf{e}_1$ (blue) and $\mathbf{e}_2$ (orange). Matrix products are always read from right to left.

Matrix multiplication is the algebraic rule that computes such composites. For any two matrices $\mathbf{A}$ and $\mathbf{B}$ whose dimensions match, apply $\mathbf{B}$ to $\mathbf{v}$, then $\mathbf{A}$ to the result, and inspect entry i:

$$\big(\mathbf{A}(\mathbf{B}\mathbf{v})\big)_i = \sum_j a_{ij}(\mathbf{B}\mathbf{v})_j = \sum_j \sum_k a_{ij} b_{jk} v_k = \sum_k \Big(\sum_j a_{ij} b_{jk}\Big) v_k = \big((\mathbf{A}\mathbf{B})\mathbf{v}\big)_i. \quad (33.12)$$

Applying the two maps in sequence is identical to applying the single matrix $\mathbf{AB}$, whose (i, k) entry is the dot product of row i of $\mathbf{A}$ with column k of $\mathbf{B}$. Notice the order: the product $\mathbf{AB}$ means "apply $\mathbf{B}$ first, then $\mathbf{A}$," read from right to left just like function composition $f(g(x))$. Setting $\mathbf{v} = \mathbf{e}_j$ in Equation 33.12 also gives a useful column rule: column j of $\mathbf{AB}$ is $\mathbf{A}\mathbf{b}_j$, the image under $\mathbf{A}$ of column j of $\mathbf{B}$. We will lean on this fact when we study the determinant.

Seeing multiplication as composition explains its seemingly odd definition. The row-times-column formula is not an arbitrary convention; it is simply what composing two linear maps produces. It also makes the algebraic properties immediate. Matrix multiplication is associative, $(\mathbf{AB})\mathbf{C} = \mathbf{A}(\mathbf{BC})$, because function composition is associative: both sides apply $\mathbf{C}$, then $\mathbf{B}$, then $\mathbf{A}$. And it is not commutative in general, because performing two geometric operations in opposite orders usually leads to different results. In NumPy, matrix multiplication uses the `@` operator. Let us check that it reproduces both composites of the rotation and the shear (stored as `R90` and `S` below).

```
R90 = np.array([[0.0, -1.0], [1.0, 0.0]])  # rotation by 90 degrees
S = np.array([[1.0, 1.0], [0.0, 1.0]])     # shear
print(R90 @ S)
print(S @ R90)
```

```
[[ 0. -1.]
 [ 1.  1.]]
[[ 1. -1.]
 [ 1.  0.]]
```

Of course, some pairs of matrices do commute. Two rotations in the plane commute, since rotating by ϕ and then by ψ yields a rotation by $\phi + \psi$ in either order. Two diagonal matrices commute as well, since each scales the coordinate axes independently. Exercise 3 characterizes every 2×2 matrix that commutes with $\mathbf{R}_{90}$.

33.2.1.3 Orthogonal Matrices

Some linear maps move space rigidly, leaving every length and every angle untouched. Which matrices have this property? Consider a counter-clockwise rotation by an angle ϕ in the plane. It sends $\mathbf{e}_1$ to $(\cos\phi, \sin\phi)$ and $\mathbf{e}_2$ to $(-\sin\phi, \cos\phi)$, so its matrix is

$$\mathbf{R}_\phi = \begin{bmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{bmatrix}.$$

Its columns have unit length, $\sqrt{\cos^2\phi + \sin^2\phi} = 1$, and zero dot product, $-\cos\phi\sin\phi + \sin\phi\cos\phi = 0$. They are orthonormal, a condition we wrote in Section 33.1 as $\mathbf{R}_\phi^\top \mathbf{R}_\phi = \mathbf{I}$. Setting $\phi = 90^\circ$ recovers $\mathbf{R}_{90}$, which sends $(3, 2)$ to $(-2, 3)$; both vectors have length $\sqrt{13}$. The reflection $\mathrm{diag}(1, -1)$ across the x-axis has orthonormal columns as well.

In any dimension, a square matrix $\mathbf{Q}$ is called *orthogonal* when its columns are orthonormal, that is,

$$\mathbf{Q}^\top \mathbf{Q} = \mathbf{I}.$$

Two subtleties in this definition are worth flagging. First, columns that are merely perpendicular are not enough: $\mathrm{diag}(1, 10)$ has perpendicular columns of lengths 1 and 10, yet it bends the 90° angle between $(1, 1)$ and $(1, -1)$ into $\arccos(-99/101) \approx 169^\circ$ (1). Second, the name "orthogonal" is reserved for square matrices. A tall $n \times k$ matrix with $k < n$ orthonormal columns still preserves lengths, but it embeds $\mathbb{R}^k$ into a larger space $\mathbb{R}^n$ and therefore has no two-sided inverse (Section 33.2.2.3).

An orthogonal map preserves every dot product:

$$(\mathbf{Q}\mathbf{x}) \cdot (\mathbf{Q}\mathbf{y}) = (\mathbf{Q}\mathbf{x})^\top (\mathbf{Q}\mathbf{y}) = \mathbf{x}^\top \mathbf{Q}^\top \mathbf{Q}\, \mathbf{y} = \mathbf{x}^\top \mathbf{y} = \mathbf{x} \cdot \mathbf{y}.$$

Setting $\mathbf{y} = \mathbf{x}$ gives $\|\mathbf{Q}\mathbf{x}\| = \|\mathbf{x}\|$, so lengths are unchanged; and because angles depend only on dot products and lengths, angles are unchanged as well. If you rotate an entire set of embedding vectors by the same orthogonal matrix, every pairwise cosine similarity stays identical.

The defining equation $\mathbf{Q}^\top \mathbf{Q} = \mathbf{I}$ says that applying $\mathbf{Q}^\top$ *after* $\mathbf{Q}$ undoes it. For a square matrix $\mathbf{Q}$, it turns out that $\mathbf{Q}^\top$ also undoes $\mathbf{Q}$ when applied *before* it, $\mathbf{Q}\mathbf{Q}^\top = \mathbf{I}$, meaning the rows of $\mathbf{Q}$ are orthonormal too and $\mathbf{Q}^{-1} = \mathbf{Q}^\top$. This is not obvious from the definition alone; it follows from a general theorem on square matrices that we prove in Section 33.2.2.3.

In two dimensions, rotations and reflections are the only orthogonal matrices. The first column must be a unit vector $(\cos\phi, \sin\phi)$, which leaves only two unit vectors perpendicular to it for the second column: $\pm(-\sin\phi, \cos\phi)$. The plus sign gives the rotation $\mathbf{R}_\phi$. The minus sign gives $\mathbf{R}_\phi\, \mathrm{diag}(1, -1)$, a reflection across the x-axis followed by a rotation, which is itself a reflection across a line through the origin. Later, the sign of the determinant will separate rotations from reflections at a glance (Section 33.2.3.3).

33.2.1.4 Tensors and Einstein Summation

In a transformer, self-attention compares every query with every key, across every attention head and every sequence in a batch. Labeling the batch by b, the head by h, the query position by i, the key position by t, and the feature dimension within a head by j, the attention scores are

$$s_{bhit} = \sum_j q_{bhij}\, k_{bhtj},$$

where q_{bhij} and k_{bhtj} are entries of the four-axis query and key tensors (Section 1.1). Each score is a dot product along the feature axis j, evaluated for every combination of the other four indices. Standard matrix notation has no clean way to write this four-index contraction; calling it "a batched matrix multiplication with a transpose on the last two axes" obscures which axis is actually being summed.

Step back, and notice that every product we have met so far follows the exact same pattern. The dot product, the matrix–vector product, the matrix product, and the *trace* $\mathrm{tr}(\mathbf{A})$ (the sum of the diagonal entries of a square matrix) all read

$$\mathbf{v} \cdot \mathbf{w} = \sum_i v_i w_i, \qquad (\mathbf{A}\mathbf{v})_i = \sum_j a_{ij} v_j, \qquad (\mathbf{A}\mathbf{B})_{ik} = \sum_j a_{ij} b_{jk}, \qquad \mathrm{tr}(\mathbf{A}) = \sum_i a_{ii}.$$

The trace is new here and will return in Section 33.3 as the sum of a matrix's eigenvalues. Each of these four formulas multiplies entries together and sums over an index that appears twice. *Einstein notation* turns that pattern into a convention: drop the summation sign and automatically sum over every repeated index. Under this rule, $\mathbf{v} \cdot \mathbf{w} = v_i w_i$ and $(\mathbf{AB})_{ik} = a_{ij} b_{jk}$.

The attention scores reveal where the classical convention falls short: the batch and head indices b and h appear in both factors, yet we want to keep them rather than sum them out. Numerical libraries solve this in `einsum` by having you name the kept indices explicitly. You pass a string listing the input indices, an arrow `->`, and the output indices; any index omitted from the right-hand side is summed over. Let us express our four basic products this way and check them on our running matrices.

```
A = np.array([[1.0, 2.0], [-1.0, 3.0]])    # the running matrix
v = np.array([2.0, -1.0])
(np.einsum('i,i->', v, v),         # dot product: v.v
 np.einsum('ij,j->i', A, v),       # matrix-vector product: Av
 np.einsum('ij,jk->ik', R90, S),   # matrix product: R90 S
 np.einsum('ii->', A))             # trace: tr(A)
```

```
(np.float64(5.0),
 array([ 0., -5.]),
 array([[ 0., -1.],
        [ 1.,  1.]]),
 np.float64(4.0))
```

Every output matches our hand calculations from earlier, including $\operatorname{tr} \mathbf{A} = 1 + 3 = 4$. The attention scores take just one line in the same notation. Below, we compute them with `einsum`, verify that they agree with a batched matrix product against the transposed keys, and count the total number of multiply–adds.

```
rng = np.random.default_rng()
queries = rng.standard_normal((2, 3, 4, 8))   # (batch, heads, queries, width)
keys = rng.standard_normal((2, 3, 5, 8))      # (batch, heads, keys, width)
scores = np.einsum('bhij,bhtj->bhit', queries, keys)
(scores.shape, np.allclose(scores, queries @ keys.swapaxes(-1, -2)),
 scores.size * queries.shape[-1])             # multiply-adds
```

```
((2, 3, 4, 5), True, 960)
```

The output has shape $(2, 3, 4, 5)$, giving one 4×5 score table per sequence and head. Both expressions agree, and the contraction takes $2 \cdot 3 \cdot 4 \cdot 5 \cdot 8 = 960$ multiply–adds, which is simply the product of the sizes of all five indices.

Beyond code, index notation yields effortless one-line proofs. For any $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{B} \in \mathbb{R}^{n \times m}$, both $\mathbf{AB}$ and $\mathbf{BA}$ are square, and their traces satisfy

$$\operatorname{tr}(\mathbf{AB}) = a_{ij} b_{ji} = b_{ji} a_{ij} = \operatorname{tr}(\mathbf{BA}). \tag{33.13}$$

The middle step merely swaps two scalar numbers while leaving the indices alone. Surprisingly, the trace of a product does not depend on the order of the two factors, even when

$\mathbf{AB} \neq \mathbf{BA}$ and even when the two products do not have the same dimensions. One immediate consequence will matter when we study eigenvalues: if $\mathbf{V}$ has an inverse $\mathbf{V}^{-1}$ (Section 33.2.2.3), then $\operatorname{tr}(\mathbf{VAV}^{-1}) = \operatorname{tr}(\mathbf{AV}^{-1}\mathbf{V}) = \operatorname{tr}(\mathbf{A})$. Because $\mathbf{VAV}^{-1}$ represents the same linear map $\mathbf{A}$ written in a different coordinate system, the trace is an intrinsic property of the map rather than an artifact of the coordinates we chose. The determinant will turn out to share this invariance (Section 33.2.3.3).

One practical warning: when an `einsum` expression combines three or more tensors, the string specifies the mathematical result but not the order in which pairwise contractions are carried out, and that order can make a huge difference in speed. For $n \times n$ matrices, computing $(\mathbf{AB})\mathbf{v}$ takes roughly n^3 multiply–adds, whereas computing $\mathbf{A}(\mathbf{Bv})$ takes only $2n^2$.

33.2.2 Rank and Invertibility

33.2.2.1 Column Space and Null Space

Which outputs can a matrix actually produce, and which inputs does it erase? To see both at once, examine our singular example

$$\mathbf{B} = \begin{bmatrix} 2 & 1 \\ 4 & 2 \end{bmatrix}.$$

Its columns are $\mathbf{b}_1 = (2, 4)$ and $\mathbf{b}_2 = (1, 2)$, so one is simply twice the other: $\mathbf{b}_1 = 2\mathbf{b}_2$. Because every output of $\mathbf{B}$ is a weighted sum of its columns, every output collapses to a scalar multiple of $\mathbf{b}_2$:

$$a_1\mathbf{b}_1 + a_2\mathbf{b}_2 = (2a_1 + a_2)\,\mathbf{b}_2.$$

Thus $\mathbf{B}$ sends the entire two-dimensional plane onto the single line $y = 2x$ through $(1, 2)$. Inevitably, distinct inputs collide on that line: both $(1, 1)$ and $(0, 3)$ land on $(3, 6)$. By linearity, their difference $(1, -2)$ must map to the difference of their outputs, $\mathbf{B}(1, -2) = \mathbf{0}$. The row view gives a second way to see why: both rows of $\mathbf{B}$, $(2, 1)$ and $(4, 2)$, are perpendicular to $(1, -2)$, so both hyperplane tests return zero. Figure 33.11 shows both lines side by side.

This example illustrates two fundamental subspaces attached to every $m \times n$ matrix $\mathbf{A}$. The *column space*, written $\operatorname{col}\mathbf{A}$, is the span of the columns of $\mathbf{A}$. Since $\mathbf{Ax}$ is a weighted combination of the columns with weights $x_1, \dots, x_n$, the column space is precisely the set of all reachable outputs. The *null space*, also called the *kernel* and written $\ker\mathbf{A}$, is the set of all inputs that $\mathbf{A}$ sends to zero:

$$\ker\mathbf{A} = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{Ax} = \mathbf{0}\}.$$

It is a subspace of $\mathbb{R}^n$: if $\mathbf{Ax} = \mathbf{Ay} = \mathbf{0}$, then $\mathbf{A}(\alpha\mathbf{x} + \beta\mathbf{y}) = \alpha\mathbf{Ax} + \beta\mathbf{Ay} = \mathbf{0}$. For $\mathbf{B}$, the column space is the line $y = 2x$ in the output plane, and the null space is the line through $(1, -2)$ in the input plane. (That both live in $\mathbb{R}^2$ is just an accident of $\mathbf{B}$ being square; in general, $\ker\mathbf{A} \subseteq \mathbb{R}^n$ and $\operatorname{col}\mathbf{A} \subseteq \mathbb{R}^m$.)

Three general facts carry straight over from this example:

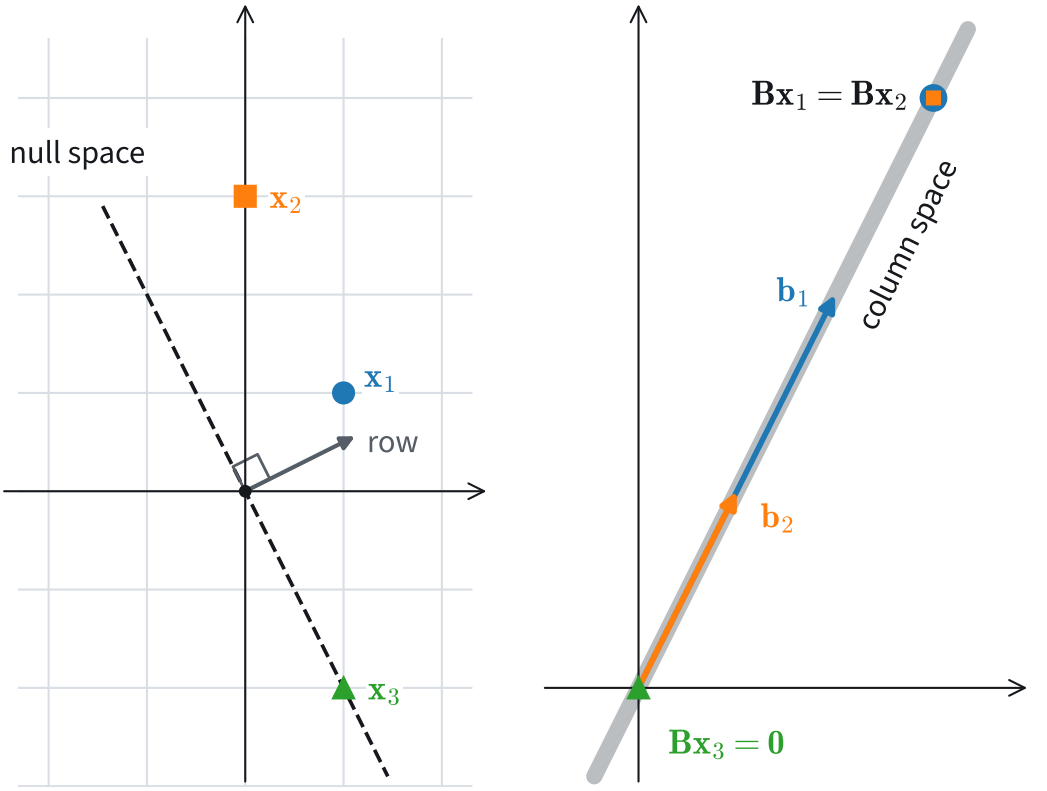

Figure 33.11: The matrix $\mathbf{B} = \left(\begin{smallmatrix} 2 & 1 \\ 4 & 2 \end{smallmatrix}\right)$ collapsing the plane. (a) In the input plane, the dashed null-space line through $(1, -2)$ is perpendicular to the row direction $(2, 1)$; three inputs are marked: $\mathbf{x}_1 = (1, 1)$, $\mathbf{x}_2 = (0, 3)$, and $\mathbf{x}_3 = (1, -2)$ on the null-space line. (b) In the output plane (same scale), every output lands on the column space, the line $y = 2x$ spanned by $\mathbf{b}_1$ and $\mathbf{b}_2$; both $\mathbf{x}_1$ and $\mathbf{x}_2$ map to $(3, 6)$, while $\mathbf{x}_3$ collapses to the origin. Because distinct inputs share the same image, no inverse can exist.

1. *The null space consists of all inputs perpendicular to every row.* In the row view, $(\mathbf{A}\mathbf{x})_i$ is the dot product of row i with $\mathbf{x}$, so all entries of $\mathbf{A}\mathbf{x}$ vanish if and only if $\mathbf{x}$ is orthogonal to every row.
2. *The columns are linearly dependent if and only if the null space contains a nonzero vector.* A nontrivial dependence $\sum_j x_j \mathbf{a}_j = \mathbf{0}$ among the columns $\mathbf{a}_j$ simply says $\mathbf{A}\mathbf{x} = \mathbf{0}$ for a nonzero vector $\mathbf{x}$, and reading the equation backwards gives the converse. For $\mathbf{B}$, the relation $\mathbf{b}_1 - 2\mathbf{b}_2 = \mathbf{0}$ yields the null vector $(1, -2)$.
3. *Two inputs produce the same output if and only if they differ by a null vector.* Indeed, $\mathbf{A}\mathbf{x} = \mathbf{A}\mathbf{y}$ is equivalent to $\mathbf{A}(\mathbf{x} - \mathbf{y}) = \mathbf{0}$. The set of all inputs that $\mathbf{B}$ maps to $(3, 6)$ is the shifted line $(1, 1) + t(1, -2)$, which passes through $(0, 3)$ at $t = -1$. Whenever $\ker \mathbf{A}$ contains a nonzero vector, distinct inputs collide and no inverse can exist.

33.2.2.2 Rank

How many input dimensions survive a linear map? The *rank* of a matrix is the dimension of its column space, or equivalently the maximum number of linearly independent columns:

$$\operatorname{rank} \mathbf{A} = \dim \operatorname{col} \mathbf{A}.$$

Our matrix $\mathbf{B}$ has rank 1: its two columns are dependent, and neither is zero. For a richer example, consider the 4×5 matrix

$$\mathbf{C} = \begin{bmatrix} 1 & 3 & 0 & -1 & 0 \\ -1 & 0 & 1 & 1 & -1 \\ 0 & 3 & 1 & 0 & -1 \\ 2 & 3 & -1 & -2 & 1 \end{bmatrix},$$

which has rank 2: its first two columns are linearly independent, yet every one of the $\binom{5}{3} = 10$ triples of columns is linearly dependent.

Remarkably, the number of dimensions that survive the map and the number of dimensions crushed to zero always add up to the dimension of the input space.

Proposition (rank–nullity). *For an $m \times n$ matrix $\mathbf{A}$,*

$$\operatorname{rank} \mathbf{A} + \dim \ker \mathbf{A} = n. \tag{33.14}$$

Proof. Pick a basis $\mathbf{w}_1, \dots, \mathbf{w}_k$ of $\ker \mathbf{A}$ and extend it to a basis $\mathbf{w}_1, \dots, \mathbf{w}_k, \mathbf{u}_1, \dots, \mathbf{u}_{n-k}$ of $\mathbb{R}^n$. (That any linearly independent list can be extended to a basis, and that all bases of a subspace have the same size, are standard facts we use without proof.) The images $\mathbf{A}\mathbf{u}_1, \dots, \mathbf{A}\mathbf{u}_{n-k}$ span $\operatorname{col} \mathbf{A}$, because any input $\mathbf{x} \in \mathbb{R}^n$ is a combination of the full basis and the $\mathbf{w}_j$ vanish under $\mathbf{A}$. They are also linearly independent: if $\sum_i c_i \mathbf{A}\mathbf{u}_i = \mathbf{0}$, then $\sum_i c_i \mathbf{u}_i$ lies in $\ker \mathbf{A}$ and can therefore be written as a combination of $\mathbf{w}_1, \dots, \mathbf{w}_k$. Within a basis, that is impossible unless every $c_i = 0$. Hence $\operatorname{col} \mathbf{A}$ has dimension $n - k$. $\blacksquare$

Figure 33.12 shows the basis that the proof builds. Each of its n vectors either vanishes under $\mathbf{A}$ or contributes one dimension to the column space, and no vector does both.

Let us check this conservation of dimensions on our examples. For $\mathbf{B}$ we get $1 + 1 = 2$. For the 256×784 Fashion-MNIST layer from the opening, the rank cannot exceed the 256 output coordinates, so the null space must have dimension at least $784 - 256 = 528$. For

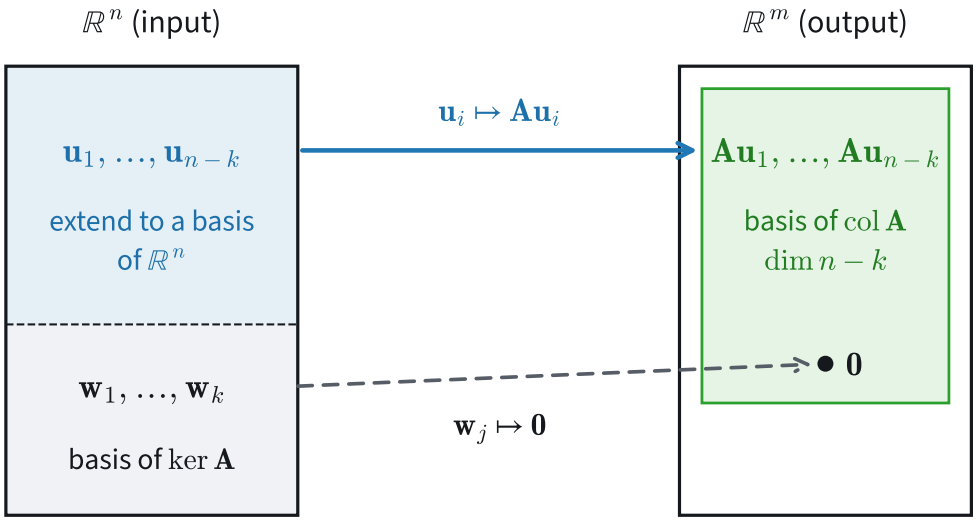

Figure 33.12: The basis in the proof of rank–nullity. The k vectors $\mathbf{w}_1, \dots, \mathbf{w}_k$ span $\ker \mathbf{A}$ and are sent to $\mathbf{0}$. The $n-k$ vectors $\mathbf{u}_1, \dots, \mathbf{u}_{n-k}$ complete them to a basis of $\mathbb{R}^n$, and their images form a basis of $\operatorname{col} \mathbf{A}$.

$\mathbf{C}$, the null space must have dimension $5 - 2 = 3$, meaning any three linearly independent null vectors form a basis of $\ker \mathbf{C}$. Below, we verify that $(3, -1, 3, 0, 0)$, $(1, 0, 0, 1, 0)$, and $(0, 0, 1, 0, 1)$ all map to zero under $\mathbf{C}$ and check the rank of the matrix `Z` holding them as columns.

```
B = np.array([[2.0, 1.0], [4.0, 2.0]])
C = np.array([[1, 3, 0, -1, 0], [-1, 0, 1, 1, -1],
              [0, 3, 1, 0, -1], [2, 3, -1, -2, 1]], dtype=float)
Z = np.array([[3, -1, 3, 0, 0], [1, 0, 0, 1, 0],
              [0, 0, 1, 0, 1]], dtype=float).T   # candidate null vectors
rank_C, rank_Z = np.linalg.matrix_rank(C), np.linalg.matrix_rank(Z)
np.linalg.matrix_rank(B), rank_C, np.abs(C @ Z).max(), rank_Z, rank_C + rank_Z
```

```
(np.int64(1), np.int64(2), np.float64(0.0), np.int64(3), np.int64(5))
```

The ranks of $\mathbf{B}$ and $\mathbf{C}$ come out to 1 and 2, the maximum entry of $|\mathbf{CZ}|$ is zero, and the three columns of `Z` have rank 3, confirming $2 + 3 = 5$.

What if we read a matrix by rows instead of columns? Its *row rank*, the maximum number of linearly independent rows, counts how many independent hyperplane tests the matrix performs. In $\mathbf{C}$, row 3 is row 1 plus row 2 and row 4 is row 1 minus row 2, so the row rank is 2, matching the column rank. That agreement is universal.

Proposition (row rank equals column rank). *For every matrix $\mathbf{A}$, the largest number of linearly independent rows equals the largest number of linearly independent columns.*

Proof. Let $r = \operatorname{rank} \mathbf{A}$, and place a basis of $\operatorname{col} \mathbf{A}$ into the columns of an $m \times r$ matrix $\mathbf{G}$. Since every column of $\mathbf{A}$ is a linear combination of the columns of $\mathbf{G}$, storing the coefficients

for column j of $\mathbf{A}$ in column j of an $r \times n$ matrix $\mathbf{H}$ gives the factorization

$$\mathbf{A} = \mathbf{G}\mathbf{H}. \tag{33.15}$$

Now read the same product by rows. Row i of $\mathbf{A}$ is $\sum_k g_{ik}\,(\text{row } k \text{ of } \mathbf{H})$, so every row of $\mathbf{A}$ lies in the span of the r rows of $\mathbf{H}$. Thus the row rank of $\mathbf{A}$ is at most r. Repeating the argument for $\mathbf{A}^\top$, whose columns are the rows of $\mathbf{A}$, shows that the column rank is at most the row rank, so the two must be equal. ■

The factorization $\mathbf{A} = \mathbf{G}\mathbf{H}$ is more than a proof device. It reveals that any rank-r matrix passes its input through a bottleneck of width r: $\mathbf{H}$ compresses $\mathbf{x} \in \mathbb{R}^n$ to r numbers, and $\mathbf{G}$ expands those r numbers back to $\mathbb{R}^m$. When r is much smaller than m and n, storing $\mathbf{G}$ and $\mathbf{H}$ requires only $r(m+n)$ parameters instead of mn, which is the core idea behind the low-rank updates of Section 33.5.4.1.

In practice, finding rank by testing subsets of columns would take exponentially long. By hand one uses Gaussian elimination (which this chapter does not cover). Numerical libraries like `np.linalg.matrix_rank` instead count how many *singular values* (Section 33.5) exceed a small tolerance. A tolerance is unavoidable because rank is not a continuous function of the matrix entries: a tiny perturbation can jump the rank from deficient to full (Section 33.2.3.6).

33.2.2.3 Inverses

Given an output $\mathbf{A}\mathbf{x}$, when can we reliably recover the input $\mathbf{x}$? An *inverse* of a square matrix $\mathbf{A}$ is a matrix $\mathbf{A}^{-1}$ that undoes $\mathbf{A}$ from both sides:

$$\mathbf{A}^{-1}\mathbf{A} = \mathbf{A}\mathbf{A}^{-1} = \mathbf{I},$$

so that $\mathbf{x} = \mathbf{A}^{-1}(\mathbf{A}\mathbf{x})$ for every input $\mathbf{x}$. For a 2×2 matrix with entries p, q, r, s satisfying $ps - qr \neq 0$, there is an explicit formula:

$$\mathbf{A}^{-1} = \frac{1}{ps - qr}\begin{bmatrix} s & -q \\ -r & p \end{bmatrix}. \tag{33.16}$$

A quick multiplication confirms it: multiplying $\left(\begin{smallmatrix} s & -q \\ -r & p \end{smallmatrix}\right)$ by $\mathbf{A}$ in either order yields $(ps - qr)\,\mathbf{I}$, and dividing by $ps - qr$ leaves $\mathbf{I}$. The condition $ps - qr \neq 0$ cannot be dropped. If $ps - qr = 0$, that product is the zero matrix; multiplying both sides by a hypothetical inverse $\mathbf{A}^{-1}$ would force $\left(\begin{smallmatrix} s & -q \\ -r & p \end{smallmatrix}\right) = \mathbf{0}$, and hence $\mathbf{A} = \mathbf{0}$, which plainly has no inverse. We will meet the quantity $ps - qr$ again as a signed area in Section 33.2.3.1. For our running matrix, $ps - qr = 3 + 2 = 5$, so

$$\mathbf{A}^{-1} = \frac{1}{5}\begin{bmatrix} 3 & -2 \\ 1 & 1 \end{bmatrix}, \qquad \mathbf{A}^{-1}(0, -5) = \tfrac{1}{5}\,(10, -5) = (2, -1).$$

Sure enough, $\mathbf{A}^{-1}$ reverses the worked example of Section 33.2.1.1.

Whenever an inverse exists, it is unique. Even better, any left inverse and any right inverse of the same matrix must coincide: if $\mathbf{L}\mathbf{A} = \mathbf{I}$ and $\mathbf{A}\mathbf{X} = \mathbf{I}$, then by associativity,

$$\mathbf{L} = \mathbf{L}(\mathbf{AX}) = (\mathbf{LA})\mathbf{X} = \mathbf{X}.$$

When does an inverse exist in general? For a square matrix, the answer requires only the null space and rank–nullity, and the rest of this chapter relies on it more than on any other result in this section.

Proposition (invertible matrices). *For an $n \times n$ matrix $\mathbf{A}$, the following are equivalent:* (i) $\mathbf{A}$ *is invertible;* (ii) *the columns of* $\mathbf{A}$ *are linearly independent;* (iii) $\ker \mathbf{A} = \{\mathbf{0}\}$*;* (iv) $\operatorname{rank} \mathbf{A} = n$.

Proof. Statements (ii) and (iii) are equivalent by fact 2 of Section 33.2.2.1, and (iii) and (iv) are equivalent by rank–nullity. If $\mathbf{A}$ is invertible and $\mathbf{Ax} = \mathbf{0}$, multiplying on the left by $\mathbf{A}^{-1}$ gives $\mathbf{x} = \mathbf{A}^{-1}\mathbf{Ax} = \mathbf{0}$, so (i) implies (iii).

The converse takes more work because we must actually construct the inverse. By (iv), the column space is an n-dimensional subspace of $\mathbb{R}^n$, which must be all of $\mathbb{R}^n$: appending any vector outside it to a basis of $\operatorname{col} \mathbf{A}$ would produce $n+1$ linearly independent vectors in $\mathbb{R}^n$, which is impossible. Thus every target vector in $\mathbb{R}^n$ is reached. By (iii) and fact 3, no two inputs map to the same output. We can therefore define column j of a matrix $\mathbf{X}$ to be the unique solution of $\mathbf{Ax} = \mathbf{e}_j$. By construction, $\mathbf{AX} = \mathbf{I}$. To see that $\mathbf{X}$ also works on the left, take any $\mathbf{x} \in \mathbb{R}^n$: since $\mathbf{A}(\mathbf{XAx}) = (\mathbf{AX})\mathbf{Ax} = \mathbf{Ax}$ and no two inputs collide, we must have $\mathbf{XAx} = \mathbf{x}$. Hence $\mathbf{XA} = \mathbf{I}$ as well, and $\mathbf{X} = \mathbf{A}^{-1}$. ∎

This immediately settles the claim left open in Section 33.2.1.3. For a square orthogonal matrix $\mathbf{Q}$ (satisfying $\mathbf{Q}^\top\mathbf{Q} = \mathbf{I}$), if $\mathbf{Qc} = \mathbf{0}$, then $\mathbf{c} = \mathbf{Q}^\top\mathbf{Qc} = \mathbf{0}$, so $\ker \mathbf{Q} = \{\mathbf{0}\}$. By the proposition, $\mathbf{Q}$ is invertible, its left inverse $\mathbf{Q}^\top$ must equal $\mathbf{Q}^{-1}$, and therefore $\mathbf{QQ}^\top = \mathbf{I}$.

A square matrix that has no inverse is called *singular*; $\mathbf{B}$ is our standard example. Rectangular matrices never have a two-sided inverse at all. The rank of an $m \times n$ matrix is at most $\min(m, n)$. When $m > n$, the column space has dimension at most $n < m$, so the map is not *onto*: some targets in $\mathbb{R}^m$ can never be hit. When $n > m$, rank–nullity forces a null space of dimension at least $n - m > 0$, so the map is not *one-to-one*: distinct inputs collide. Running a map backwards requires both properties, and the beauty of the proposition above is that for a square matrix, either one guarantees the other.

33.2.2.4 Solving Linear Systems in Practice

The matrix inverse is an indispensable tool for algebra and proofs, yet in numerical computation we almost never form it explicitly. When you need to solve $\mathbf{Ax} = \mathbf{b}$, use `np.linalg.solve(A, b)` rather than `np.linalg.inv(A) @ b`.

There are two main reasons: speed and accuracy. First, `solve` factors $\mathbf{A}$ once into triangular matrices (an *LU factorization*, costing about $n^3/3$ multiply–adds) and solves two fast triangular systems. Forming $\mathbf{A}^{-1}$ explicitly costs roughly n^3 multiply–adds, three times as much work, before you even multiply by $\mathbf{b}$. Second, `solve` is *backward stable*: its computed solution is the exact solution to a slightly perturbed system whose entries differ from $\mathbf{A}$ and $\mathbf{b}$ only at the level of floating-point rounding. Consequently, its residual $\|\mathbf{Ax} - \mathbf{b}\|$ stays on the order of machine precision times $\|\mathbf{A}\|\,\|\mathbf{x}\|$ (using the spectral norm of Section 1.3.4). Computing `inv(A) @ b` carries no such guarantee; its residual can be larger by a factor up to the *condition number* $\kappa(\mathbf{A})$, which measures how close $\mathbf{A}$ is to being singular (Section 33.5.3.2).

How close a matrix sits to singularity is a property of the problem itself, not of the algorithm. In double precision (roughly sixteen decimal digits), both methods can lose up to about $\log_{10} \kappa(\mathbf{A})$ digits of accuracy in the solution $\mathbf{x}$. That is a worst-case bound rather than an

exact prediction for any single right-hand side, so let us see how close a notorious example comes to it. The *Hilbert matrix*, with entries $h_{ij} = 1/(i + j - 1)$, is a classic test case of a nearly singular matrix. We take $\mathbf{x}_{\text{true}} = \mathbf{1}$, form $\mathbf{b} = \mathbf{H}\mathbf{1}$ for the 10×10 Hilbert matrix $\mathbf{H}$, and attempt to recover $\mathbf{x}$ both ways.

```
H = 1 / (np.arange(10)[:, None] + np.arange(10) + 1)   # Hilbert matrix
x_true = np.ones(10)
b = H @ x_true
for x in (np.linalg.solve(H, b), np.linalg.inv(H) @ b):
    print(f'residual {np.linalg.norm(H @ x - b):.1e}, '
          f'error {np.linalg.norm(x - x_true):.1e}')
np.linalg.cond(H)
```

```
residual 5.7e-16, error 2.7e-04
residual 4.8e-05, error 9.0e-03
```

```
np.float64(16024416987428.36)
```

The condition number is $\kappa(\mathbf{H}) \approx 1.6 \cdot 10^{13}$, warning us that up to thirteen digits can vanish. As promised, `solve` keeps its residual near machine precision, while `inv` suffers a residual roughly eleven orders of magnitude larger, right in line with the factor κ. Notice, however, that a tiny residual does not guarantee an accurate solution. Both routes lose twelve or more of the sixteen digits, approaching the worst-case bound, with `inv` still worse by more than an order of magnitude.

Sparse matrices add a third, decisive reason never to invert. A million-by-million matrix with only five million nonzero entries fits comfortably in memory, whereas its inverse is typically completely dense, requiring roughly 10^{12} entries.

33.2.3 The Determinant

33.2.3.1 Area of a Parallelogram

By what factor does a matrix scale areas? Look back at Figure 33.8: our running matrix $\mathbf{A}$ sends the unit square (edges $\mathbf{e}_1$ and $\mathbf{e}_2$, area 1) to the parallelogram with edges $\mathbf{a}_1 = (1, -1)$ and $\mathbf{a}_2 = (2, 3)$ and corners $(0, 0)$, $(1, -1)$, $(3, 2)$, and $(2, 3)$. That parallelogram sits snugly inside the bounding box $[0, 3] \times [-1, 3]$ of area 12. The unused portion of the box consists of four right triangles with legs 1 and 1, 2 and 3, 1 and 1, and 2 and 3, whose areas sum to $\frac{1}{2} + 3 + \frac{1}{2} + 3 = 7$. Subtracting leaves an area of $12 - 7 = 5$ (Figure 33.13, panel (a)). The matrix $\mathbf{A}$ multiplies the area of the unit square by 5.

Carving out triangles works for one picture, but every new arrangement of corners would need a new diagram. Base times height handles every case in one stroke. Let the parallelogram have edges $\mathbf{u} = (p, r)$ and $\mathbf{w} = (q, s)$, the two columns of a general 2×2 matrix. Its base has length $\|\mathbf{u}\|$. Rotating $\mathbf{u}$ counter-clockwise by 90° gives $\mathbf{R}_{90}\mathbf{u} = (-r, p)$, so

$$\mathbf{n} = \frac{(-r, p)}{\|\mathbf{u}\|}$$

is a unit vector perpendicular to the base. From Section 33.1, the signed component of $\mathbf{w}$ along a unit vector $\mathbf{n}$ is the dot product $\mathbf{w} \cdot \mathbf{n}$. Geometrically, this is the height of the

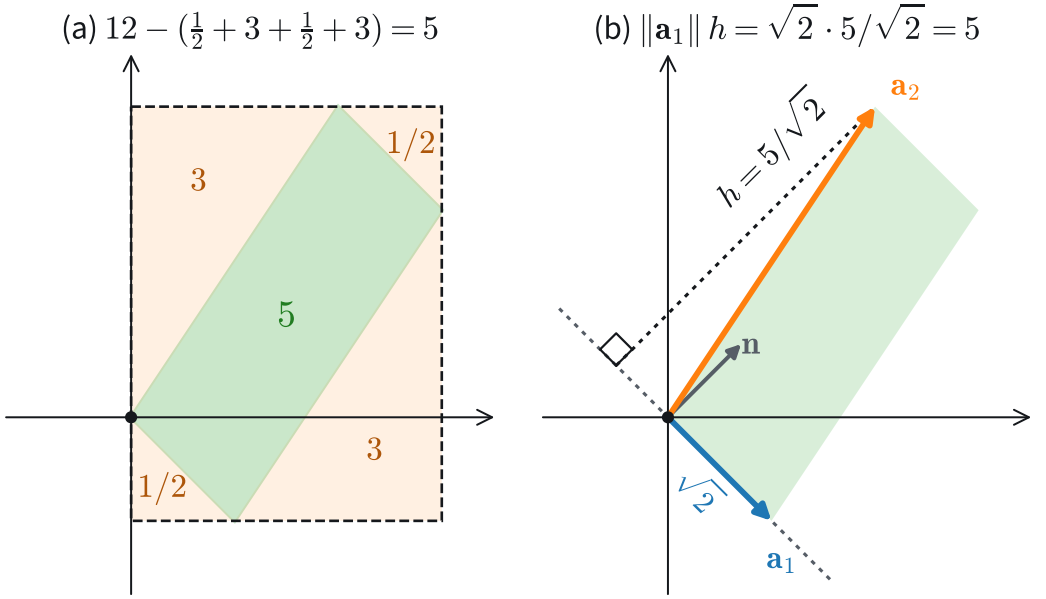

Figure 33.13: The image of the unit square under $\mathbf{A}$ has area 5. (a) Bounding-box method: the box $[0,3] \times [-1,3]$ of area 12 minus four right triangles of total area 7. (b) Base times height: the base $\mathbf{a}_1 = (1,-1)$ has length $\sqrt{2}$, the unit normal $\mathbf{n} = (1,1)/\sqrt{2}$ is perpendicular to it, and the height of $\mathbf{a}_2 = (2,3)$ above the base line is $\mathbf{a}_2 \cdot \mathbf{n} = 5/\sqrt{2}$.

parallelogram above its base, equipped with a sign: positive when $\mathbf{w}$ lies on the counter-clockwise side of $\mathbf{u}$, and negative when it lies on the clockwise side. Multiplying base by signed height gives

$$\|\mathbf{u}\|\,(\mathbf{w}\cdot\mathbf{n}) = \|\mathbf{u}\|\,\frac{-qr+ps}{\|\mathbf{u}\|} = ps - qr.$$

Conveniently, the lengths $\|\mathbf{u}\|$ cancel out, leaving a clean polynomial in the four matrix entries with no sign cases to split. For our running matrix, $\|\mathbf{u}\| = \sqrt{2}$, $\mathbf{n} = (1,1)/\sqrt{2}$, and $\mathbf{w}\cdot\mathbf{n} = 5/\sqrt{2}$, giving a signed area of 5 (panel (b)), positive because $\mathbf{a}_2$ lies counter-clockwise from $\mathbf{a}_1$.

We define the *determinant* of a 2×2 matrix to be this signed area of the image of the unit square:

$$\det \begin{bmatrix} p & q \\ r & s \end{bmatrix} = ps - qr. \tag{33.17}$$

Its magnitude $|\det \mathbf{A}|$ is the factor by which the map scales area, and its sign records whether the images of $\mathbf{e}_1$ and $\mathbf{e}_2$ preserve their counter-clockwise orientation. For $\mathbf{A}$, we get $1 \cdot 3 - 2 \cdot (-1) = 5$. Swapping the two columns of $\mathbf{A}$ produces $\left(\begin{smallmatrix} 2 & 1 \\ 3 & -1 \end{smallmatrix}\right)$, which spans the exact same parallelogram with its edges listed in the reverse order, and its determinant flips sign to

$-2 - 3 = -5$. For the singular matrix $\mathbf{B}$, we get $2 \cdot 2 - 1 \cdot 4 = 0$: the unit square flattens onto the line segment from $\mathbf{0}$ to $(3, 6)$, which has zero area.

Figure 33.14 contrasts all three regimes: a positive determinant preserves orientation, a negative determinant reverses it, and a zero determinant collapses the square.

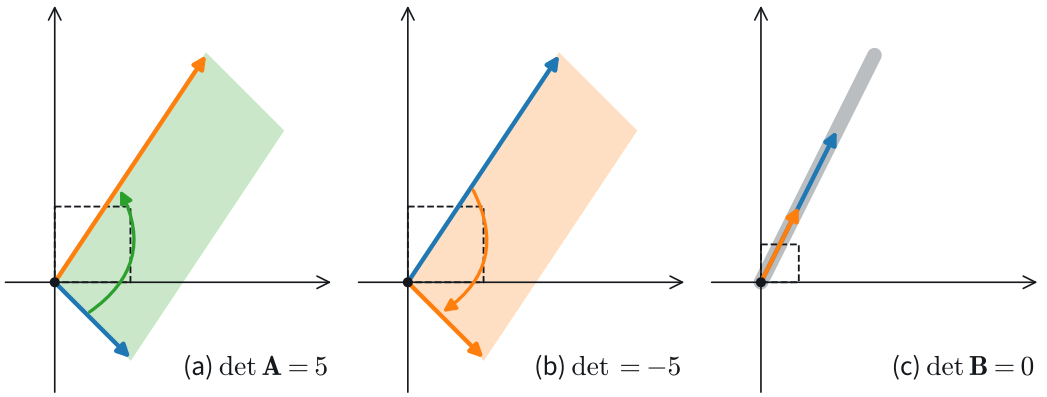

Figure 33.14: The determinant as signed area for our three 2×2 examples. The unit square (dashed) maps to the region spanned by the columns. (a) $\mathbf{A}$, with determinant 5: the columns keep their counter-clockwise order (curved arrow). (b) $\mathbf{A}$ with its columns swapped, determinant -5: the same parallelogram with reversed orientation. (c) $\mathbf{B}$, determinant 0: the square collapses onto a segment of the line $y = 2x$. Panel (c) is drawn at half the scale of (a) and (b).

Base times height gives us the plane. To move to n dimensions, we need the signed volume of an n-dimensional box.

33.2.3.2 The Determinant in General

How do we define the signed volume of the box spanned by n columns in $\mathbb{R}^n$? Rather than trying to compute high-dimensional volumes by chopping up shapes, we take a cleaner route: we write down the three geometric properties any signed volume must satisfy, and let those properties uniquely determine the formula. Viewed as a function of the columns $\mathbf{a}_1, \ldots, \mathbf{a}_n$ of an $n \times n$ matrix, the determinant is:

1. **Multilinear**: linear in each column separately while the other columns are held fixed. (Scaling one edge of a box scales its volume by the same factor; writing one edge as a sum splits the volume accordingly.)
2. **Alternating**: equal to zero whenever two columns are identical. (When two edges coincide, the box collapses into a lower-dimensional slab of zero volume.)
3. **Normalized**: $\det \mathbf{I} = 1$. (The unit cube has volume 1.)

Check that our 2×2 formula $ps - qr$ satisfies all three: it is linear in (p, r) and in (q, s), it vanishes whenever $(p, r) = (q, s)$, and it equals 1 on $\mathbf{I}$. Two powerful consequences follow immediately from these three axioms alone: a rule for swapping columns, and an explicit formula proving that at most one function can satisfy all three.

First, **swapping any two columns flips the sign of the determinant**. To see why, place $\mathbf{u}+\mathbf{w}$ in two column slots and expand using multilinearity:

$$\begin{aligned} 0 &= \det(\dots, \mathbf{u}+\mathbf{w}, \dots, \mathbf{u}+\mathbf{w}, \dots) \\ &= \det(\dots, \mathbf{u}, \dots, \mathbf{u}, \dots) + \det(\dots, \mathbf{u}, \dots, \mathbf{w}, \dots) \\ &\quad + \det(\dots, \mathbf{w}, \dots, \mathbf{u}, \dots) + \det(\dots, \mathbf{w}, \dots, \mathbf{w}, \dots). \end{aligned}$$

The left-hand side, the first term, and the last term all have two identical columns, so they vanish by the alternating property. What remains is

$$\det(\dots, \mathbf{u}, \dots, \mathbf{w}, \dots) = -\det(\dots, \mathbf{w}, \dots, \mathbf{u}, \dots).$$

Exchanging two edges of the box reverses its orientation, just as we saw in panel (b) of Figure 33.14.

Second, the three properties completely determine a formula. Expand each column in the standard basis as $\mathbf{a}_j = \sum_i a_{ij}\,\mathbf{e}_i$ and apply multilinearity column by column. This turns $\det \mathbf{A}$ into a large sum of terms $a_{i_1 1} a_{i_2 2} \cdots a_{i_n n}\,\det(\mathbf{e}_{i_1}, \dots, \mathbf{e}_{i_n})$, one for every choice of a row index i_j in each column j. Whenever two chosen row indices are equal, the term vanishes by the alternating property. When all n row indices are distinct, the list $\mathbf{e}_{i_1}, \dots, \mathbf{e}_{i_n}$ is just a reordering of the columns of $\mathbf{I}$, so repeated column swaps reduce $\det(\mathbf{e}_{i_1}, \dots, \mathbf{e}_{i_n})$ to ± 1.

In the 2×2 case, with columns $\mathbf{a}_1 = p\,\mathbf{e}_1 + r\,\mathbf{e}_2$ and $\mathbf{a}_2 = q\,\mathbf{e}_1 + s\,\mathbf{e}_2$, the expansion has four terms. The two with a repeated basis vector drop out, leaving

$$\det(\mathbf{a}_1, \mathbf{a}_2) = ps\,\det(\mathbf{e}_1, \mathbf{e}_2) + rq\,\det(\mathbf{e}_2, \mathbf{e}_1) = ps - qr,$$

recovering the signed area we derived by hand. In general, $\det \mathbf{A}$ is a signed sum over all ways of picking one entry from every row and every column. Writing $\sigma(j)$ for the row chosen in column j, we obtain the *permutation formula*:

$$\det \mathbf{A} = \sum_{\sigma} \operatorname{sgn}(\sigma)\, a_{\sigma(1)1}\, a_{\sigma(2)2} \cdots a_{\sigma(n)n}, \tag{33.18}$$

where σ ranges over all $n!$ permutations of $\{1, \dots, n\}$, and $\operatorname{sgn}(\sigma) = \det(\mathbf{e}_{\sigma(1)}, \dots, \mathbf{e}_{\sigma(n)})$ is $+1$ if σ requires an even number of swaps and -1 if it requires an odd number. Because any function satisfying the three axioms must equal this formula, there can be at most one determinant.

We do not prove existence in full here. The subtle point is that $\operatorname{sgn}(\sigma)$ is well defined (no permutation can be built from both an even and an odd number of swaps), a standard fact we take from (Horn and Johnson 2012). Once that parity fact is in hand, the formula satisfies all three axioms: each term contains one entry from each column (giving multilinearity), only the identity permutation survives for $\mathbf{I}$ (giving normalization), and the alternating property follows from the same parity argument (which we omit).

Notice that normalization entered only at the very end of the derivation. That observation gives us a sharper tool that we will use in the next subsection: if f is *any* multilinear and alternating function of the columns, the same swap rule and expansion apply, turning every factor $f(\mathbf{e}_{\sigma(1)}, \dots, \mathbf{e}_{\sigma(n)})$ into $\operatorname{sgn}(\sigma)\, f(\mathbf{I})$. Consequently,

$$f(\mathbf{A}) = f(\mathbf{I})\ \det \mathbf{A}.$$

In short, every multilinear alternating function of the columns is just a scalar multiple of the determinant.

For small hand calculations, grouping the terms of Equation 33.18 by the row picked in column 1 produces the *cofactor expansion*: each entry a_{i1} multiplies the determinant of the $(n-1)\times(n-1)$ submatrix formed by deleting row i and column 1, weighted by the alternating sign $(-1)^{i+1}$. For the 3×3 matrix

$$\mathbf{M} = \begin{bmatrix} 2 & 1 & 0 \\ 1 & 3 & 1 \\ 0 & 1 & 2 \end{bmatrix},$$

expanding along the first column gives

$$\begin{aligned} \det \mathbf{M} &= 2 \det \begin{bmatrix} 3 & 1 \\ 1 & 2 \end{bmatrix} - 1 \det \begin{bmatrix} 1 & 0 \\ 1 & 2 \end{bmatrix} + 0 \det \begin{bmatrix} 1 & 0 \\ 3 & 1 \end{bmatrix} \\ &= 2 \cdot 5 - 1 \cdot 2 + 0 = 8. \end{aligned} \tag{33.19}$$

Thus $\mathbf{M}$ maps the unit cube in $\mathbb{R}^3$ to a box of volume 8.

For a triangular matrix, the determinant simplifies dramatically: it is just the product of the diagonal entries. Of all the rules for computing determinants, this is the one to remember. Suppose $\mathbf{U}$ is upper triangular, so $u_{ij} = 0$ whenever $i > j$. In the permutation formula, a nonzero term must pick one entry from every column, all in distinct rows. From column 1, the only nonzero entry sits in row 1. From column 2, row 1 is already taken and rows $3, \dots, n$ are zero, forcing us to pick row 2. Continuing across the columns, only the diagonal permutation survives, and it requires zero swaps, so

$$\det \mathbf{U} = u_{11} u_{22} \cdots u_{nn}.$$

Running the same argument backwards from column n covers lower triangular matrices. Better still, it extends to blocks. Consider a *block upper triangular* matrix $\left(\begin{smallmatrix} \mathbf{D}_1 & * \\ \mathbf{0} & \mathbf{D}_2 \end{smallmatrix}\right)$ whose square diagonal blocks $\mathbf{D}_1$ and $\mathbf{D}_2$ need not be triangular themselves. Any nonzero permutation term must pick its entries in the columns of $\mathbf{D}_1$ from the rows of $\mathbf{D}_1$, because everything underneath is zero. That consumes all rows of $\mathbf{D}_1$, forcing the remaining columns to pick from the rows of $\mathbf{D}_2$; the off-diagonal block $*$ never contributes at all. Every surviving permutation splits into a pair of independent permutations on the two blocks, their signs multiply, and the sum factors cleanly:

$$\det \begin{bmatrix} \mathbf{D}_1 & * \\ \mathbf{0} & \mathbf{D}_2 \end{bmatrix} = \det \mathbf{D}_1\ \det \mathbf{D}_2.$$

Figure 33.15 marks the entries that survive in each case.

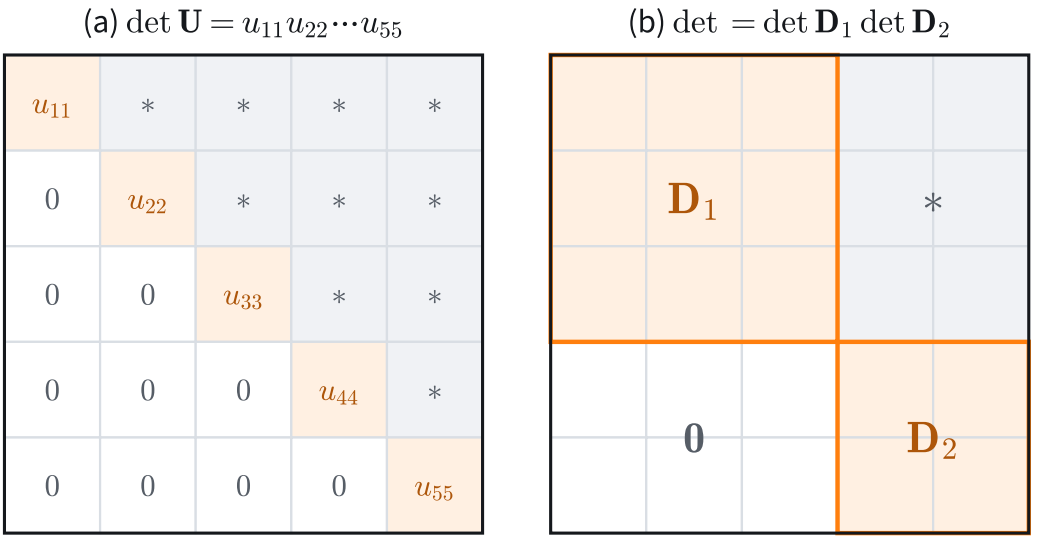

Figure 33.15: Entries that enter the determinant. (a) In an upper triangular matrix, the zeros below the diagonal rule out every permutation except the diagonal one, so the determinant is the product of the diagonal entries. (b) In a block upper triangular matrix, the zero block confines every surviving permutation to the diagonal blocks $\mathbf{D}_1$ and $\mathbf{D}_2$. The entries marked $*$ never enter.

These two rules are essential in modern machine learning, not just in hand calculations. A normalizing flow transforms a simple random variable through an invertible neural network and must evaluate the log-determinant of the network's Jacobian at every step, because a change of variables divides the probability density by the local volume scaling factor (Section 36.2.3.1). Flows are therefore designed so that each layer has a triangular or block-triangular Jacobian: the log-determinant then reduces to a sum of n scalar logarithms, avoiding the roughly $n^3/3$ multiply–adds required for a general matrix.

Another useful symmetry is that transposing leaves the determinant unchanged: $\det \mathbf{A}^\top = \det \mathbf{A}$. In the permutation formula for $\mathbf{A}^\top$, each term is $\operatorname{sgn}(\sigma) \prod_j a_{j\sigma(j)}$. Setting $j = \sigma^{-1}(i)$ rewrites the product as $\prod_i a_{\sigma^{-1}(i)\,i}$, which is the term for $\mathbf{A}$ corresponding to the inverse permutation σ^{-1}. Since undoing a sequence of swaps takes the exact same number of swaps, $\operatorname{sgn}(\sigma^{-1}) = \operatorname{sgn}(\sigma)$. The two sums therefore contain the exact same terms, which means every statement about columns of a determinant applies equally well to rows.

With $n!$ terms, the permutation formula is strictly a theoretical tool and is never used numerically beyond tiny matrices. Libraries compute determinants by factoring the matrix into triangular factors (as in `solve`) and multiplying their diagonal entries, adjusting the sign for any row exchanges, at a cost of roughly $n^3/3$ multiply–adds.

33.2.3.3 Multiplicativity

If $\mathbf{B}$ scales areas by $\det \mathbf{B}$ and $\mathbf{A}$ scales them by $\det \mathbf{A}$, then applying $\mathbf{B}$ followed by $\mathbf{A}$ should scale areas by the product of the two factors. Let us check two examples. For our running matrix, $\mathbf{A}^2 = \left(\begin{smallmatrix} -1 & 8 \\ -4 & 7 \end{smallmatrix}\right)$, which has $\det \mathbf{A}^2 = -7 + 32 = 25 = 5^2$. For the composite of

Section 33.2.1.2, $\det(\mathbf{R}_{90}\mathbf{T}) = 0 \cdot 1 - (-1) \cdot 1 = 1$, matching $\det \mathbf{R}_{90} \cdot \det \mathbf{T} = 1 \cdot 1$.

A simple tiling picture explains why this should hold in general. Cover any planar region with a fine grid of tiny squares. Because a linear map acts uniformly across space, it carries every square to a parallelogram whose area is $|\det \mathbf{A}|$ times that of the original square. Consequently, a linear map scales the area of *every* shape by $|\det \mathbf{A}|$. Applying $\mathbf{B}$ to a region of area V produces area $|\det \mathbf{B}|\, V$, and applying $\mathbf{A}$ next scales it to $|\det \mathbf{A}|\,|\det \mathbf{B}|\, V$. Since the composite $\mathbf{AB}$ is itself a single linear map, its scaling factor must be this product. Using the characterization from Section 33.2.3.2, we can turn that intuition into a three-line proof that handles the signs as well.

Proposition (multiplicativity of the determinant). *For square matrices* $\mathbf{A}$ *and* $\mathbf{B}$ *of the same size,*

$$\det(\mathbf{AB}) = \det(\mathbf{A})\ \det(\mathbf{B}). \tag{33.20}$$

Proof. Fix $\mathbf{A}$ and treat $D(\mathbf{B}) = \det(\mathbf{AB})$ as a function of the columns of $\mathbf{B}$. By Section 33.2.1.2, column j of $\mathbf{AB}$ is $\mathbf{Ab}_j$. Because $\mathbf{A}$ is linear and det is multilinear, D is multilinear in the columns of $\mathbf{B}$. If two columns of $\mathbf{B}$ coincide, the matching columns of $\mathbf{AB}$ coincide too, so $D(\mathbf{B}) = 0$ and D is alternating. Every multilinear alternating function of the columns is a scalar multiple of the determinant (Section 33.2.3.2), which gives

$$\det(\mathbf{AB}) = D(\mathbf{B}) = D(\mathbf{I})\ \det(\mathbf{B}) = \det(\mathbf{A})\ \det(\mathbf{B}). \qquad \blacksquare$$

Four consequences of Equation 33.20 appear repeatedly throughout the rest of this chapter:

1. *Determinants commute even when matrices do not.* Because determinants are ordinary scalars, $\det(\mathbf{AB}) = \det \mathbf{A}\ \det \mathbf{B} = \det \mathbf{B}\ \det \mathbf{A} = \det(\mathbf{BA})$. For our rotation and shear, $\mathbf{R}_{90}\mathbf{T} \neq \mathbf{T}\mathbf{R}_{90}$, yet both products have determinant 1.

2. *Similarity invariance.* For any invertible matrix $\mathbf{V}$, applying consequence 1 to the factors $\mathbf{VA}$ and $\mathbf{V}^{-1}$ gives $\det(\mathbf{VAV}^{-1}) = \det(\mathbf{V}^{-1}\mathbf{VA}) = \det \mathbf{A}$. The matrix $\mathbf{VAV}^{-1}$ is simply the map $\mathbf{A}$ written in the coordinate system whose axes are the columns of $\mathbf{V}^{-1}$, and changing coordinates cannot alter the volume scaling factor.

3. *Inverses.* If $\mathbf{A}$ is invertible, setting $\mathbf{B} = \mathbf{A}^{-1}$ yields $\det \mathbf{A}\ \det \mathbf{A}^{-1} = \det \mathbf{I} = 1$. Therefore every invertible matrix satisfies $\det \mathbf{A} \neq 0$ and $\det \mathbf{A}^{-1} = 1/\det \mathbf{A}$ (for our running matrix, $1/5 = 0.2$).

4. *Orthogonal matrices.* Combining multiplicativity with $\det \mathbf{Q}^{\top} = \det \mathbf{Q}$ on $\mathbf{Q}^{\top}\mathbf{Q} = \mathbf{I}$ gives

$$\det(\mathbf{Q})^2 = \det(\mathbf{Q}^{\top})\det(\mathbf{Q}) = \det(\mathbf{Q}^{\top}\mathbf{Q}) = \det(\mathbf{I}) = 1,$$

so $\det \mathbf{Q} = \pm 1$. Rigid motions never change volume, and the sign distinguishes orientation-preserving rotations ($\det = +1$) from orientation-reversing reflections ($\det = -1$) in the plane (Section 33.2.1.3).

33.2.3.4 Invertibility and the Determinant

The determinant adds a fifth equivalent condition to the invertibility theorem of Section 33.2.2.3, and it is the only one expressed as a single number. In two dimensions the equivalence is immediate: the signed area $ps - qr$ vanishes if and only if the two columns lie on the same line through the origin (or one of them is $\mathbf{0}$), which is to say, if and only if the columns are linearly dependent. The same holds in every dimension.

Proposition (invertibility and the determinant). *An $n \times n$ matrix $\mathbf{A}$ is invertible if and only if* $\det \mathbf{A} \neq 0$. *Equivalently,* $\det \mathbf{A} = 0$ *if and only if the columns of $\mathbf{A}$ are linearly dependent.*

Proof. If $\mathbf{A}$ is invertible, then $\det \mathbf{A} \det \mathbf{A}^{-1} = 1$ by consequence 3 of multiplicativity, so $\det \mathbf{A} \neq 0$. Conversely, suppose $\mathbf{A}$ is not invertible. By the proposition in Section 33.2.2.3, its columns are linearly dependent, so some column is a combination of the others: $\mathbf{a}_j = \sum_{i \neq j} c_i \mathbf{a}_i$. Expanding column j by multilinearity gives $\det \mathbf{A} = \sum_{i \neq j} c_i \det(\dots, \mathbf{a}_i, \dots)$, where $\mathbf{a}_i$ now appears both in slot i and in slot j. Every term has two identical columns and therefore vanishes by the alternating property. ∎

For our running matrix, $\det \mathbf{A} = 5 \neq 0$ certifies invertibility; for $\mathbf{B}$, $\det \mathbf{B} = 0$ confirms singularity. Keep in mind, however, what this theorem does *not* promise: a nonzero determinant guarantees that $\mathbf{A}^{-1}$ exists mathematically, not that it is safe to compute numerically (Section 33.2.3.6).

33.2.3.5 Block Matrices and Low-Rank Updates

Often we already know the inverse of a part of a matrix: of one block, or of the matrix as it was before a small change. Can we reuse it? The answer comes from a single step of elimination, carried out on blocks instead of numbers. Split a square matrix $\mathbf{M}$ into four blocks $\mathbf{M}_{11}, \mathbf{M}_{12}, \mathbf{M}_{21}$, and $\mathbf{M}_{22}$, with $\mathbf{M}_{11}$ square and invertible. Subtracting $\mathbf{M}_{21}\mathbf{M}_{11}^{-1}$ times the first block row from the second clears the lower-left block, and the same step on the columns clears the upper-right one. Written as a product, this reads

$$\begin{bmatrix} \mathbf{M}_{11} & \mathbf{M}_{12} \\ \mathbf{M}_{21} & \mathbf{M}_{22} \end{bmatrix} = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{M}_{21}\mathbf{M}_{11}^{-1} & \mathbf{I} \end{bmatrix} \begin{bmatrix} \mathbf{M}_{11} & \mathbf{0} \\ \mathbf{0} & \mathbf{S} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{M}_{11}^{-1}\mathbf{M}_{12} \\ \mathbf{0} & \mathbf{I} \end{bmatrix}, \qquad \mathbf{S} = \mathbf{M}_{22} - \mathbf{M}_{21}\mathbf{M}_{11}^{-1}\mathbf{M}_{12}, \tag{33.21}$$

as multiplying out the three factors confirms. The matrix $\mathbf{S}$ is the *Schur complement* of $\mathbf{M}_{11}$: it is what remains of $\mathbf{M}_{22}$ once the first block has been eliminated. For our running matrix with 1×1 blocks, $\mathbf{S} = 3 - (-1) \cdot 1^{-1} \cdot 2 = 5$.

Both outer factors are triangular with ones on the diagonal, so each has determinant 1. Multiplicativity and the block rule then give $\det \mathbf{M} = \det \mathbf{M}_{11} \det \mathbf{S}$ (in the example, $1 \cdot 5$), and $\mathbf{M}$ is invertible if and only if $\mathbf{S}$ is. An outer factor is inverted by flipping the sign of its off-diagonal block. Inverting the three factors in reverse order therefore yields

$$\mathbf{M}^{-1} = \begin{bmatrix} \mathbf{I} & -\mathbf{M}_{11}^{-1}\mathbf{M}_{12} \\ \mathbf{0} & \mathbf{I} \end{bmatrix} \begin{bmatrix} \mathbf{M}_{11}^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{S}^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ -\mathbf{M}_{21}\mathbf{M}_{11}^{-1} & \mathbf{I} \end{bmatrix}. \tag{33.22}$$

The lower-right block of $\mathbf{M}^{-1}$ is simply $\mathbf{S}^{-1}$, and the upper-left block is $\mathbf{M}_{11}^{-1} + \mathbf{M}_{11}^{-1}\mathbf{M}_{12}\mathbf{S}^{-1}\mathbf{M}_{21}\mathbf{M}_{11}^{-1}$. Nothing forces us to start in the upper-left corner, however. Eliminating $\mathbf{M}_{22}$ first exchanges the roles of the blocks, and the upper-left block of $\mathbf{M}^{-1}$ then

appears as the inverse of the other Schur complement, $\mathbf{M}_{11} - \mathbf{M}_{12}\mathbf{M}_{22}^{-1}\mathbf{M}_{21}$. That matrix returns as the conditional covariance of a Gaussian in Section 36.3.3.3.

The two expressions for the upper-left block must agree, and this is surprisingly useful. Suppose that we know $\mathbf{A}^{-1}$ for an $n \times n$ matrix $\mathbf{A}$, and that $\mathbf{A}$ then changes by a matrix of rank k, which we write as $\mathbf{U}\mathbf{W}^{\top}$ with $\mathbf{U}, \mathbf{W} \in \mathbb{R}^{n \times k}$. Choose the blocks $\mathbf{M}_{11} = \mathbf{A}$, $\mathbf{M}_{12} = -\mathbf{U}$, $\mathbf{M}_{21} = \mathbf{W}^{\top}$, and $\mathbf{M}_{22} = \mathbf{I}_k$. One Schur complement is then $\mathbf{A} + \mathbf{U}\mathbf{W}^{\top}$, and the other is the $k \times k$ matrix $\mathbf{I}_k + \mathbf{W}^{\top}\mathbf{A}^{-1}\mathbf{U}$. Equating the two upper-left blocks gives the *Woodbury identity*

$$(\mathbf{A} + \mathbf{U}\mathbf{W}^{\top})^{-1} = \mathbf{A}^{-1} - \mathbf{A}^{-1}\mathbf{U}\,(\mathbf{I}_k + \mathbf{W}^{\top}\mathbf{A}^{-1}\mathbf{U})^{-1}\,\mathbf{W}^{\top}\mathbf{A}^{-1}. \tag{33.23}$$

A change of rank k in a matrix changes its inverse by a matrix of rank at most k, and finding that change requires only a $k \times k$ inverse. With $\mathbf{A}^{-1}$ in hand, the update costs on the order of $n^2 k$ multiply–adds instead of the n^3 of a fresh inversion. When $\mathbf{A}$ is diagonal, solving a system with $\mathbf{A} + \mathbf{U}\mathbf{W}^{\top}$ costs only on the order of nk^2. The two eliminations also give two expressions for $\det \mathbf{M}$, and hence $\det(\mathbf{A} + \mathbf{U}\mathbf{W}^{\top}) = \det \mathbf{A}\, \det(\mathbf{I}_k + \mathbf{W}^{\top}\mathbf{A}^{-1}\mathbf{U})$. For $k = 1$ the inner inverse is a division, and the identity is known as the *Sherman–Morrison formula*:

$$(\mathbf{A} + \mathbf{u}\mathbf{w}^{\top})^{-1} = \mathbf{A}^{-1} - \frac{\mathbf{A}^{-1}\mathbf{u}\,\mathbf{w}^{\top}\mathbf{A}^{-1}}{1 + \mathbf{w}^{\top}\mathbf{A}^{-1}\mathbf{u}}. \tag{33.24}$$

This formula is why a least-squares fit can absorb or drop one example at a time: each example changes $\mathbf{X}^{\top}\mathbf{X}$ by a rank-one term. Exercise 6 applies both the determinant and the inverse to a normalizing flow.

33.2.3.6 Limits of the Determinant

Knowing that $\det \mathbf{A} \neq 0$ tells us a matrix can be inverted, but it says nothing about how *close* the matrix is to collapsing space, or along which directions. Two stark examples make the point from opposite extremes. First, the scaled identity $0.1\,\mathbf{I}_{400}$ is as well-behaved as a matrix can be, with inverse $10\,\mathbf{I}_{400}$, yet its determinant 10^{-400} is so tiny that it underflows beneath the smallest positive double-precision floating-point number. Second, the extreme shear $\left(\begin{smallmatrix} 1 & 10^{8} \\ 0 & 1 \end{smallmatrix}\right)$ has determinant 1, yet changing its lower-left entry by just 10^{-8} makes it singular (5).

Below, we compute both determinants (using `slogdet` for the first to obtain its sign and log-magnitude safely) along with the singular values of the shear. Before running the cell, guess what rank NumPy will report for the *unchanged* shear.

```
sign, logdet = np.linalg.slogdet(0.1 * np.eye(400))
print(np.linalg.det(0.1 * np.eye(400)), sign, logdet)
shear = np.array([[1.0, 1e8], [0.0, 1.0]])
print(np.linalg.det(shear), np.linalg.matrix_rank(shear),
      np.linalg.svd(shear, compute_uv=False))
shear[1, 0] = 1e-8
print(np.linalg.det(shear), np.linalg.matrix_rank(shear))
```

```
0.0 1.0 -921.0340371976151
1.0 1 [1.e+08 1.e-08]
0.0 1
```

As expected, `det` on $0.1\,\mathbf{I}_{400}$ underflows to `0.0`, while `slogdet` computes $400 \ln 0.1 \approx -921.03$ effortlessly. The unchanged shear has determinant 1, and the perturbed shear has determinant 0 up to rounding, yet `matrix_rank` reports rank 1 for *both*. In exact arithmetic the unchanged shear has rank 2, but its two singular values are roughly 10^{8} and 10^{-8}. NumPy treats any singular value as zero once it falls below the largest singular value times the matrix size times machine precision, here $10^{8} \cdot 2 \cdot 2.2 \cdot 10^{-16} \approx 4 \cdot 10^{-8}$. Even though the shear's entries are stored exactly, floating-point arithmetic with numbers of size 10^{8} introduces rounding errors around 10^{-8}, so numerically the shear is indistinguishable from a singular matrix.

A single number simply cannot capture how a matrix stretches and compresses space along different directions. To see those directions, we need eigenvalues and singular values. For our running matrix $\mathbf{A}$, the eigenvalues are $2 \pm i$, whose product is $5 = \det \mathbf{A}$ (Section 33.3), and the singular values are roughly 3.618 and 1.382, whose product is $5 = |\det \mathbf{A}|$ (Section 33.5). In fact, for every square matrix, the determinant is the product of its eigenvalues (counted with multiplicity, including complex pairs), and $|\det \mathbf{A}|$ is the product of its singular values. It is the *ratio* of the largest to the smallest singular value, not the determinant, that measures how close a matrix is to collapsing space, and finding those directional factors is our next task.

33.2.4 Summary

A matrix is a linear map completely determined by its columns, which record where the standard coordinate axes land, and matrix multiplication is simply the composition of linear maps read from right to left. Einstein notation and `einsum` unify dot products, matrix products, traces, and multi-axis tensor contractions such as transformer attention under a single index rule.

Every $m \times n$ matrix defines a column space of reachable outputs and a null space of inputs sent to zero, linked by the rank–nullity theorem $\operatorname{rank} \mathbf{A} + \dim \ker \mathbf{A} = n$: a 256×784 layer necessarily erases at least 528 input dimensions. For a square matrix, having independent columns, trivial null space, full rank, a nonzero determinant, and an inverse are all equivalent. The determinant measures the signed factor by which a map scales volume; it multiplies under composition and equals the product of the diagonal entries for any triangular matrix. One step of block elimination produces the Schur complement, which gives the determinant and the inverse of a block matrix and, through the Woodbury identity, the inverse of a matrix after a low-rank change. Still, while a nonzero determinant guarantees that an inverse exists, it cannot tell us how close a matrix is to singularity, a question that leads directly to eigenvalues and singular values.

33.2.5 Exercises

1. **Maps that preserve angles.** Rotating every embedding vector by the same orthogonal matrix leaves all cosine similarities unchanged. This problem finds every linear map with that property.
   1. Find the condition on the columns of a square matrix $\mathbf{A}$ under which $\mathbf{A}\mathbf{e}_1$ and $\mathbf{A}\mathbf{e}_2$ are orthogonal. Show that $\mathbf{A} = \operatorname{diag}(1, 10)$ satisfies it but changes the angle between $(1, 1)$ and $(1, -1)$.
   2. Suppose that an invertible $\mathbf{A}$ preserves the angle between every pair of nonzero vectors. Apply this to the pairs $\mathbf{e}_i, \mathbf{e}_j$ and $\mathbf{e}_i + \mathbf{e}_j, \mathbf{e}_i - \mathbf{e}_j$ for $i \neq j$ to show that

$\mathbf{A}^\top\mathbf{A} = c^2\mathbf{I}$ for some $c > 0$, so that $\mathbf{A} = c\mathbf{Q}$ with $\mathbf{Q}$ orthogonal. Conversely, show that every such matrix preserves all cosine similarities.

3. Suppose instead that $\|\mathbf{Ax}\| = \|\mathbf{x}\|$ for every $\mathbf{x}$. Expand $\|\mathbf{x}+\mathbf{y}\|^2$ and $\|\mathbf{x}-\mathbf{y}\|^2$ to show that $\mathbf{A}$ preserves every dot product, and conclude that $\mathbf{A}$ is orthogonal.

2. **Rank of a product.** A linear autoencoder sends a d-dimensional input through a hidden layer of width $k < d$, $\mathbf{x} \mapsto \mathbf{W}_2\mathbf{W}_1\mathbf{x}$ with $\mathbf{W}_1 \in \mathbb{R}^{k\times d}$ and $\mathbf{W}_2 \in \mathbb{R}^{d\times k}$.
   1. Let $\mathbf{A}$ be an $m \times n$ matrix and $\mathbf{B}$ an $n \times p$ matrix. Show that the column space of $\mathbf{AB}$ lies in the column space of $\mathbf{A}$, and that the null space of $\mathbf{B}$ lies in the null space of $\mathbf{AB}$. Use the first fact, and rank–nullity with the second, to prove $\operatorname{rank}(\mathbf{AB}) \le \min(\operatorname{rank}\mathbf{A}, \operatorname{rank}\mathbf{B})$.
   2. Conclude that $\mathbf{W}_2\mathbf{W}_1$ has rank at most k. What is the smallest possible dimension of its null space? What is the largest dimension of a subspace on which the autoencoder reconstructs every input exactly?
   3. Construct a 2×3 matrix and a 3×2 matrix, both of rank two, whose 2×2 product has rank one.

3. **Matrices that commute with a rotation.** Matrix products do not commute in general. This problem finds the exceptions for $\mathbf{R}_{90}$.
   1. Find all 2×2 matrices $\mathbf{X}$ with $\mathbf{XR}_{90} = \mathbf{R}_{90}\mathbf{X}$, and show that they are $\left(\begin{smallmatrix} p & -q \\ q & p \end{smallmatrix}\right) = p\mathbf{I} + q\mathbf{R}_{90}$.
   2. Using $\mathbf{R}_{90}^2 = -\mathbf{I}$, show that $(p\mathbf{I}+q\mathbf{R}_{90})(r\mathbf{I}+s\mathbf{R}_{90}) = (pr-qs)\,\mathbf{I}+(ps+qr)\,\mathbf{R}_{90}$, so these matrices multiply like the complex numbers $p + qi$.
   3. For $(p, q) \neq (0, 0)$, show that $p\mathbf{I} + q\mathbf{R}_{90} = \sqrt{p^2+q^2}\,\mathbf{R}_\phi$ for the angle ϕ with $(\cos\phi, \sin\phi) = (p, q)/\sqrt{p^2+q^2}$, a scaled rotation. Compute its determinant, and conclude that it is invertible unless $p = q = 0$.
   4. Does the running matrix $\mathbf{A}$ commute with $\mathbf{R}_{90}$? Compute both products.

4. **Householder reflections.** Let $\mathbf{u}$ be a unit vector in $\mathbb{R}^n$ and $\mathbf{H} = \mathbf{I} - 2\mathbf{uu}^\top$.
   1. Show that $\mathbf{H}$ is symmetric and orthogonal, that $\mathbf{Hu} = -\mathbf{u}$, and that $\mathbf{Hx} = \mathbf{x}$ for every $\mathbf{x}$ perpendicular to $\mathbf{u}$, so that $\mathbf{H}$ reflects in the hyperplane with normal $\mathbf{u}$.
   2. Write $\mathbf{H} = \mathbf{I} - 2\mathbf{P}$ with $\mathbf{P} = \mathbf{uu}^\top$, and explain the formula with the projection onto $\mathbf{u}$ from Section 33.1: what does $\mathbf{x} - 2\mathbf{Px}$ do to the component of $\mathbf{x}$ along $\mathbf{u}$?
   3. Prove $\det\mathbf{H} = -1$. Extend $\mathbf{u}$ to an orthonormal basis, the columns of an orthogonal matrix $\mathbf{Q} = [\mathbf{u}\,\mathbf{q}_2 \cdots \mathbf{q}_n]$, compute $\mathbf{Q}^\top\mathbf{HQ}$, and use multiplicativity.
   4. Find the unit vector $\mathbf{u}$ whose reflection sends $(3, 4)$ to $(5, 0)$ (hint: $\mathbf{u}$ is parallel to $(3, 4) - (5, 0)$), write down $\mathbf{H}$, and check $\det\mathbf{H} = -1$. Reflections of this kind, applied column by column, are how libraries factor a matrix into an orthogonal and a triangular factor.

5. code **Determinant and near-singularity.** A square matrix is invertible if and only if its determinant is nonzero. How well does the size of the determinant measure how close a matrix is to being singular?
   1. Use multilinearity to prove $\det(c\mathbf{A}) = c^n \det\mathbf{A}$ for an $n \times n$ matrix $\mathbf{A}$ and a scalar c, and check the identity in code for the matrix $\mathbf{M}$ of Equation 33.19 with $c = 2$.
   2. Draw an $n \times n$ lower triangular matrix with independent standard Gaussian entries on and below the diagonal, for $n = 20$, 100, and 1000. Compare the logarithm that `np.linalg.slogdet` returns with the sum of the logarithms of the absolute diagonal entries, which the triangular rule makes exact up to rounding. From which n on do the two disagree, and by how much at $n = 1000$? Compute `np.linalg.cond` for $n = 20$ and $n = 100$, and explain the failure. (The routine does not know that the matrix is triangular. It factors it with row exchanges, like any other matrix.)

3. The text states that a change of 10^{-8} in the lower left entry makes the shear $\left(\begin{smallmatrix} 1 & 10^{8} \\ 0 & 1 \end{smallmatrix}\right)$ singular. Verify it, and show that no smaller change of a single entry does.

6. **Determinant of a rank-one update.** ● A *planar flow* (Rezende and Mohamed 2015) transforms $\mathbf{z} \in \mathbb{R}^d$ by $f(\mathbf{z}) = \mathbf{z} + \mathbf{u}\, h(\mathbf{w} \cdot \mathbf{z} + b)$ for vectors $\mathbf{u}, \mathbf{w}$, a scalar b, and a scalar nonlinearity h. Computing the density of $f(\mathbf{z})$ requires the determinant of the Jacobian $\mathbf{I} + h'(\mathbf{w} \cdot \mathbf{z} + b)\, \mathbf{u}\mathbf{w}^\top$.
   1. Use multilinearity and the alternating property to show $\det(\mathbf{u}\mathbf{w}^\top) = 0$ for $n \times n$ matrices with $n \geq 2$.
   2. Verify the two factorizations
$$\begin{aligned} \begin{bmatrix} \mathbf{I} & -\mathbf{u} \\ \mathbf{w}^\top & 1 \end{bmatrix} &= \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{w}^\top & 1 \end{bmatrix} \begin{bmatrix} \mathbf{I} & -\mathbf{u} \\ \mathbf{0}^\top & 1 + \mathbf{w} \cdot \mathbf{u} \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{I} & -\mathbf{u} \\ \mathbf{0}^\top & 1 \end{bmatrix} \begin{bmatrix} \mathbf{I} + \mathbf{u}\mathbf{w}^\top & \mathbf{0} \\ \mathbf{w}^\top & 1 \end{bmatrix}. \end{aligned}$$
      Use the permutation formula Equation 33.18 to show that a matrix whose last column is $\mathbf{e}_{n+1}$ has the determinant of its upper-left $n \times n$ block. Deduce $\det(\mathbf{I} + \mathbf{u}\mathbf{w}^\top) = 1 + \mathbf{w} \cdot \mathbf{u}$ from Equation 33.20 and the triangular rule.
   3. Write the logarithm of the absolute Jacobian determinant of a planar flow, and compare the cost of evaluating it with the cost of a general $d \times d$ determinant. For $h = \tanh$, which values of $\mathbf{u} \cdot \mathbf{w}$ keep the Jacobian invertible at every $\mathbf{z}$?
   4. Use the Sherman–Morrison formula Equation 33.24 to write the inverse of the Jacobian $\mathbf{I} + c\, \mathbf{u}\mathbf{w}^\top$, where $c = h'(\mathbf{w} \cdot \mathbf{z} + b)$. Check that the formula breaks down at the same values of c at which the determinant vanishes, and count the multiply–adds needed to apply the inverse to a vector. The inverse Jacobian does not invert f itself: show that recovering $\mathbf{z}$ from $f(\mathbf{z})$ reduces to solving one scalar equation for $\mathbf{w} \cdot \mathbf{z}$.

7. code **Einstein summation for attention.** Let the query, key and value tensors have the shapes (n_b, n_h, n_q, d_h), (n_b, n_h, n_k, d_h) and (n_b, n_h, n_k, d_h).
   1. Write the `einsum` strings for the scores $s_{bhit} = \sum_j q_{bhij} k_{bhtj}$ and for the weighted sum of values $o_{bhij} = \sum_t p_{bhit}\, v_{bhtj}$, where p_{bhit} are the attention weights, and check both against `@` with `swapaxes`.
   2. Count the multiply–adds of each contraction as a product of the sizes. Compare them with the multiply–adds of applying one $d_h \times d_h$ linear map to every query, and find the number of keys n_k beyond which the scores cost more.
   3. Write $\operatorname{tr}(\mathbf{A}^\top \mathbf{A})$, $\operatorname{tr}(\mathbf{A}\mathbf{A}^\top)$ and $\sum_{ij} a_{ij}^2$ as one `einsum` each for a random 3×5 matrix, and check that they agree. Which of the two equalities is an instance of Equation 33.13, and why does the other one hold?

33.3 Eigendecompositions

In Section 33.2 we asked what a matrix does to space when it is applied once. Many computations in machine learning, however, apply the same matrix over and over. A deep linear network with identical layers computes $\mathbf{A}^{50}\mathbf{x}$ after 50 layers, and gradient descent on a quadratic objective multiplies its error by the same fixed matrix at every step. In each case we want to know whether the signal grows, dies out, or settles down, and how quickly that happens. Multiplying out the matrix powers gives us the numbers, but it does not explain them.

A random walk between two web pages is the smallest version of this question. Suppose a surfer on page 1 stays on page 1 or clicks to page 2 with probability $1/2$ each; from page 2 she stays with probability $3/4$ and returns to page 1 with probability $1/4$. Let $\mathbf{p}_k$ hold the probabilities of being on each page after k clicks. Each click multiplies this vector by a fixed matrix,

$$\mathbf{p}_{k+1} = \mathbf{P}\mathbf{p}_k, \qquad \mathbf{P} = \begin{pmatrix} 1/2 & 1/4 \\ 1/2 & 3/4 \end{pmatrix},$$

whose columns record the click probabilities from each page and therefore sum to one. Starting on page 1 with $\mathbf{p}_0 = (1, 0)$, the first few distributions are $(0.5, 0.5)$, $(0.375, 0.625)$, $(0.344, 0.656)$, and $(0.336, 0.664)$. The changes shrink with every click, as if the walk were settling onto a fixed distribution. Where is the surfer after 50 clicks, and how fast does the distribution converge? PageRank asks the very same question of the entire web.

The key is to rewrite the starting vector in the coordinates of a few special directions, the eigenvectors, along which the matrix acts simply as multiplication by a number. In those coordinates, each component evolves on its own as a scalar power λ^k.

In Section 1.3 we already met eigenvectors as the directions that a matrix only stretches: the symmetric matrix $\mathbf{S} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ stretches $(1, 1)$ by 3 and $(1, -1)$ by 1, and for any symmetric matrix we had $\mathbf{A}^k\mathbf{x} = \sum_i c_i \lambda_i^k \mathbf{v}_i$. Here we drop the symmetry requirement. We learn how to find the eigenvalues of an arbitrary square matrix, see when a full set of eigenvectors exists and what replaces it when one does not, and then prove why symmetry guarantees so much more.

Three results carry the most weight: the eigenvector expansion Equation 33.28 of $\mathbf{A}^k\mathbf{x}$, the spectral theorem, and the quadratic form written as a weighted sum of squares, Equation 33.36. A reader in a hurry can jump from Section 33.3.1.3 straight to Section 33.3.2.1. We leave two practical questions to Section 33.4: how to locate and compute eigenvalues when a matrix is large, and the situations in which eigenvalues can mislead us. Throughout this section we compute with NumPy, whose `eig` function returns complex eigenvalues whenever a real matrix has them.

```
import numpy as np
```

33.3.1 Eigenvalues and Diagonalization

33.3.1.1 Eigenvectors and Eigenvalues

Certain input vectors are only rescaled by $\mathbf{P}$, as though the matrix were a single number. Applying $\mathbf{P}$ to $(1, 2)$ gives $\mathbf{P}(1, 2) = (\frac{1}{2}+\frac{1}{2},\ \frac{1}{2}+\frac{3}{2}) = (1, 2)$, leaving it completely unchanged, while applying $\mathbf{P}$ to $(1, -1)$ gives $(\frac{1}{2} - \frac{1}{4},\ \frac{1}{2} - \frac{3}{4}) = \frac{1}{4}(1, -1)$. Along the first direction $\mathbf{P}$ multiplies by 1; along the second it multiplies by $1/4$.

In general, a nonzero vector $\mathbf{v}$ is called an *eigenvector* of a square matrix $\mathbf{A}$, with corresponding *eigenvalue* λ, if

$$\mathbf{A}\mathbf{v} = \lambda\mathbf{v}. \tag{33.25}$$

In geometric terms, **A** only stretches an eigenvector by the factor λ, reversing its direction when $\lambda < 0$. For the surfer's matrix **P**, the eigenpairs $(\lambda, \mathbf{v})$ are $(1, (1, 2))$ and $(\frac{1}{4}, (1, -1))$. We exclude the zero vector from being an eigenvector because it trivially satisfies Equation 33.25 for every λ. However, all solutions of $\mathbf{Av} = \lambda\mathbf{v}$ for a fixed λ, together with $\mathbf{0}$, form a linear subspace called the *eigenspace* of λ.

The eigenvalue $\lambda = 0$, on the other hand, is perfectly valid. It means that $\mathbf{Av} = \mathbf{0}$ for some nonzero **v**, so a square matrix is singular if and only if 0 is one of its eigenvalues. Notice also that a real matrix need not have any real eigenvectors: a rotation by 90° turns every nonzero direction in the plane. Its eigenvalues turn out to be complex, a case we take up in Section 33.3.1.6.

It is tempting to confuse eigenvectors with the axes of the ellipse produced when an invertible 2×2 matrix acts on the unit circle. Figure 33.16 shows why the two concepts are distinct. For the symmetric matrix **S**, the eigenvectors do lie along the ellipse axes. For the upper-triangular matrix $\left(\begin{smallmatrix} 1 & 1 \\ 0 & 2 \end{smallmatrix}\right)$, however, they do not: its eigenvectors are $(1, 0)$ with $\lambda = 1$ and $(1, 1)$ with $\lambda = 2$, whereas the ellipse axes point at 58° and -32° (Section 33.5 shows how to compute them). The ellipse axes mark the directions of largest and smallest stretch, while the eigenvectors mark the directions that are not rotated at all. For symmetric matrices these two sets of directions always coincide, as the spectral theorem of Section 33.3.2.1 proves; for general matrices they need not.

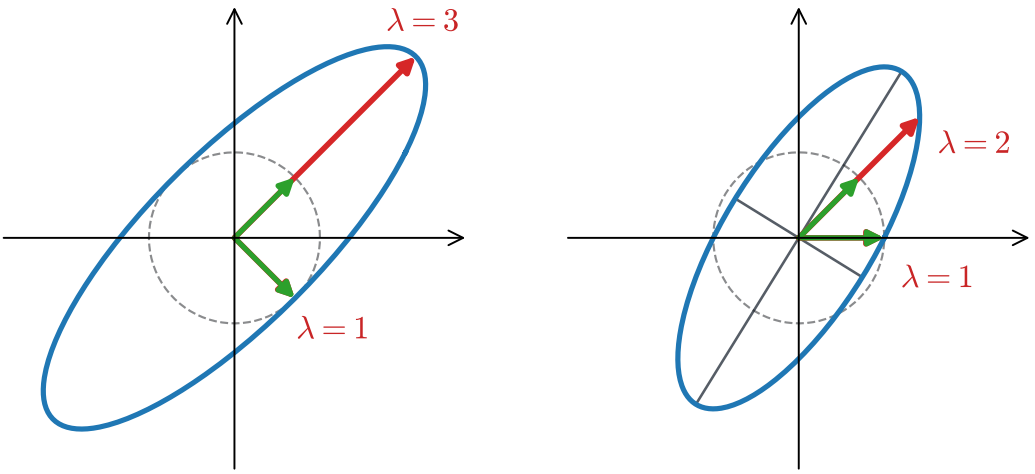

Figure 33.16: The unit circle (dashed) and its image (blue). Left: for the symmetric matrix $\left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, the unit eigenvectors (green) lie along the ellipse axes, and their images (red) are scaled by 3 and 1 (for $\lambda = 1$ the two arrows coincide). Right: for the upper-triangular matrix $\left(\begin{smallmatrix} 1 & 1 \\ 0 & 2 \end{smallmatrix}\right)$, the eigenvectors $(1, 0)$ and $(1, 1)$ do not align with the ellipse axes (grey).

33.3.1.2 The Characteristic Polynomial

We spotted the eigenvectors of **P** by inspection, which does not take us far on larger matrices. To find the eigenvalues of any square matrix systematically, move $\lambda\mathbf{v}$ to the left-hand side of Equation 33.25 and factor out **v**:

$$(\mathbf{A} - \lambda\mathbf{I})\mathbf{v} = \mathbf{0}. \tag{33.26}$$

A nonzero solution $\mathbf{v}$ exists if and only if $\mathbf{A}-\lambda\mathbf{I}$ has a nontrivial null space—that is, if and only if it is singular, so that $\det(\mathbf{A}-\lambda\mathbf{I})=0$. Expanding this determinant yields a polynomial of degree n in λ, called the *characteristic polynomial* $p(\lambda)=\det(\mathbf{A}-\lambda\mathbf{I})$. Its roots are precisely the eigenvalues of $\mathbf{A}$. Once a root λ is known, solving the homogeneous linear system Equation 33.26 gives its eigenspace.

Let us run this recipe on the surfer's matrix:

$$\det(\mathbf{P}-\lambda\mathbf{I})=\left(\tfrac{1}{2}-\lambda\right)\left(\tfrac{3}{4}-\lambda\right)-\tfrac{1}{4}\cdot\tfrac{1}{2}=\lambda^2-\tfrac{5}{4}\lambda+\tfrac{1}{4}=(\lambda-1)\left(\lambda-\tfrac{1}{4}\right).$$

The roots are 1 and $1/4$, matching the two scaling factors we noticed earlier. Because $\mathbf{P}-\lambda\mathbf{I}$ is singular at each root, a single row suffices to find the eigenvector. For $\lambda=1$, the first row of $\mathbf{P}-\mathbf{I}$ gives $-\frac{1}{2}v_1+\frac{1}{4}v_2=0$, so $v_2=2v_1$ and we may choose $\mathbf{v}=(1,2)$. For $\lambda=\frac{1}{4}$, the first row of $\mathbf{P}-\frac{1}{4}\mathbf{I}$ gives $\frac{1}{4}v_1+\frac{1}{4}v_2=0$, yielding $\mathbf{v}=(1,-1)$. Keep in mind that every eigenvector is determined only up to a nonzero scalar factor: if $\mathbf{v}$ is an eigenvector, then so is $c\mathbf{v}$ for any $c\neq 0$, since both sides of Equation 33.25 scale by c.

In practice we leave this algebra to a numerical library. NumPy's `eig` returns the eigenvalues together with a matrix whose columns are the corresponding eigenvectors; the last line below checks Equation 33.25 for all pairs at once.

```
P = np.array([[0.5, 0.25], [0.5, 0.75]])
lam, V = np.linalg.eig(P)
print('eigenvalues:', lam)
print('eigenvectors (columns):\n', V)
print('max |P V - V diag(lam)|:', np.abs(P @ V - V * lam).max())
```

```
eigenvalues: [0.25 1.  ]
eigenvectors (columns):
 [[-0.70710678 -0.4472136 ]
 [ 0.70710678 -0.89442719]]
max |P V - V diag(lam)|: 0.0
```

Order, scale, and sign are all at the library's discretion: here `eig` returns the eigenvalues as $1/4$ and 1, and the columns are unit-length vectors parallel to $(1,-1)$ and $(1,2)$.

Numerical libraries do not actually form and solve the characteristic polynomial. For $n\geq 5$ there is no general closed-form formula for polynomial roots in radicals, and even for moderate n the roots are notoriously sensitive to tiny rounding errors in the polynomial coefficients. Instead, `eig` applies a sequence of orthogonal changes of basis that gradually drive the matrix into triangular form without altering its eigenvalues. A triangular matrix displays its eigenvalues right on its diagonal: subtracting $\lambda\mathbf{I}$ keeps it triangular, and the determinant of a triangular matrix is simply the product of its diagonal entries (Section 33.2.3.2). For matrices far too large to factor at all, power iteration (Section 33.4.1.2) extracts dominant eigenvalues using only matrix–vector products.

33.3.1.3 Diagonalization

We can now answer our opening question about $\mathbf{P}^{50}\mathbf{p}_0$. Collect the two eigenvectors of $\mathbf{P}$ as the columns of a matrix $\mathbf{V}$, and place their eigenvalues on the diagonal of Λ:

$$\mathbf{V} = \begin{pmatrix} 1 & 1 \\ 2 & -1 \end{pmatrix}, \qquad \Lambda = \begin{pmatrix} 1 & 0 \\ 0 & 1/4 \end{pmatrix}.$$

Written side by side as columns, the two eigenvector equations $\mathbf{P}\mathbf{v}_i = \lambda_i \mathbf{v}_i$ compactly read $\mathbf{P}\mathbf{V} = \mathbf{V}\Lambda$. Because $\det \mathbf{V} = -1 - 2 = -3 \neq 0$, the matrix $\mathbf{V}$ is invertible, with $\mathbf{V}^{-1} = \frac{1}{3}\left(\begin{smallmatrix} 1 & 1 \\ 2 & -1 \end{smallmatrix}\right)$. Multiplying on the right by $\mathbf{V}^{-1}$ yields

$$\mathbf{P} = \mathbf{V}\Lambda\mathbf{V}^{-1}. \tag{33.27}$$

Read this factorization from right to left as three steps: change to eigenvector coordinates ($\mathbf{V}^{-1}$), scale each coordinate independently by its eigenvalue (Λ), and change back to the original coordinates ($\mathbf{V}$). A square matrix $\mathbf{A}$ that can be written as $\mathbf{A} = \mathbf{V}\Lambda\mathbf{V}^{-1}$, with $\mathbf{V}$ invertible and Λ diagonal, is called *diagonalizable*, and the factorization itself is its *eigendecomposition*. Such a factorization exists if and only if $\mathbf{A}$ has n linearly independent eigenvectors to fill the columns of $\mathbf{V}$.

Taking powers of a diagonalizable matrix now becomes effortless. In a product of k copies of $\mathbf{V}\Lambda\mathbf{V}^{-1}$, every adjacent pair $\mathbf{V}^{-1}\mathbf{V}$ cancels out:

$$\mathbf{A}^k = \overbrace{(\mathbf{V}\Lambda\mathbf{V}^{-1})\cdots(\mathbf{V}\Lambda\mathbf{V}^{-1})}^{k \text{ times}} = \mathbf{V}\overbrace{\Lambda\cdots\Lambda}^{k \text{ times}}\mathbf{V}^{-1} = \mathbf{V}\Lambda^k\mathbf{V}^{-1}.$$

Powers of a diagonalizable matrix thus reduce to powers of scalars. Applying $\mathbf{A}^k$ to a vector $\mathbf{x}$, and writing $\mathbf{c} = \mathbf{V}^{-1}\mathbf{x}$ for the coordinates of $\mathbf{x}$ in the eigenbasis (so that $\mathbf{x} = \sum_i c_i \mathbf{v}_i$), we obtain

$$\mathbf{A}^k\mathbf{x} = \mathbf{V}\Lambda^k\mathbf{c} = \sum_{i=1}^{n} c_i \lambda_i^k \mathbf{v}_i. \tag{33.28}$$

Each eigen-coordinate evolves independently as the geometric sequence $c_i\lambda_i^k$. For the surfer starting on page 1, $\mathbf{c} = \mathbf{V}^{-1}\mathbf{p}_0 = \frac{1}{3}(1,2) = (\frac{1}{3}, \frac{2}{3})$, which gives the closed-form distribution after any number of clicks k:

$$\mathbf{p}_k = \mathbf{P}^k\mathbf{p}_0 = \frac{1}{3}\begin{pmatrix}1\\2\end{pmatrix} + \frac{2}{3}\left(\frac{1}{4}\right)^k\begin{pmatrix}1\\-1\end{pmatrix}. \tag{33.29}$$

This completely settles the opening question. As k grows, the second term vanishes and the distribution approaches $\pi = (1/3, 2/3)$: in the long run, the surfer spends twice as much time on page 2 as on page 1. The remaining error is $\frac{2}{3}\,4^{-k}$ in each entry and always points along the eigenvector $(1,-1)$. Every click divides that error by 4, so after 10 clicks it has dropped to 6×10^{-7}, and after 50 clicks it is below 10^{-30}. As a sanity check, setting $k = 3$ gives $(\frac{1}{3} + \frac{1}{96},\ \frac{2}{3} - \frac{1}{96}) = (0.34375, 0.65625)$, matching the third iterate we computed at the start. Figure 33.17 illustrates the geometry: because the entries of every $\mathbf{p}_k$ sum to one, the iterates slide along the line $x + y = 1$ toward the point where the eigenvector of $\lambda = 1$ intersects it.

Let us verify that fifty matrix multiplications and the two-term eigen-expansion produce the same $\mathbf{p}_{50}$, and check the ratio of consecutive errors.

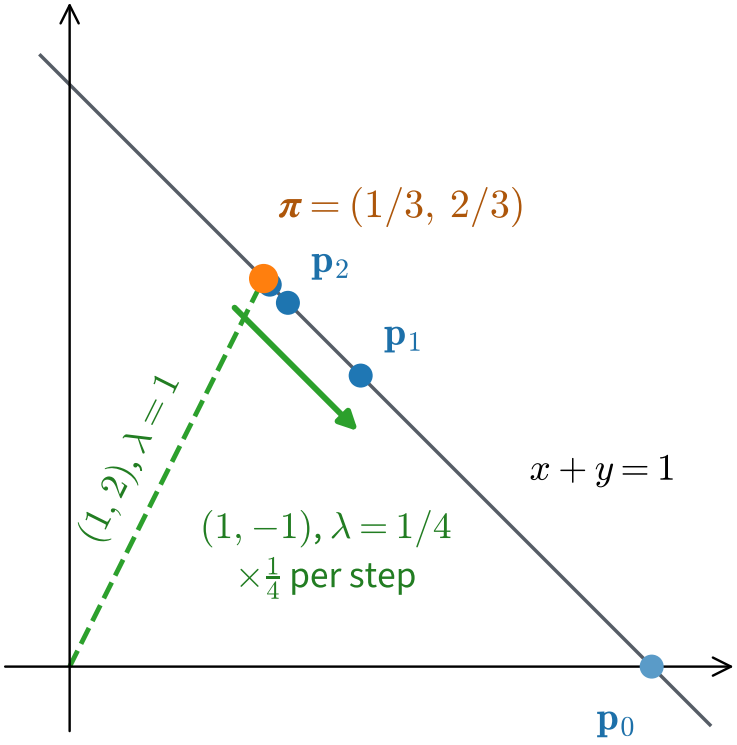

Figure 33.17: The surfer's distributions $\mathbf{p}_k$ slide along $x + y = 1$ toward $\pi = (1/3, 2/3)$, where the eigenvector $(1, 2)$ of $\lambda = 1$ meets the line. The error points along the eigenvector $(1, -1)$ of $\lambda = 1/4$ and shrinks by a factor of 4 per click.

```
p0 = np.array([1.0, 0.0])
c = np.linalg.solve(V, p0)              # coordinates of p0 in the eigenbasis
print('P^50 p0             :', np.linalg.matrix_power(P, 50) @ p0)
print('sum c_i lam_i^50 v_i:', V @ (c * lam ** 50))
pi = np.array([1 / 3, 2 / 3])
errs = np.array([np.abs(np.linalg.matrix_power(P, k) @ p0 - pi).max()
                 for k in range(8)])
print('error ratios:', np.round(errs[1:] / errs[:-1], 4))
```

```
P^50 p0             : [0.33333333 0.66666667]
sum c_i lam_i^50 v_i: [0.33333333 0.66666667]
error ratios: [0.25 0.25 0.25 0.25 0.25 0.25 0.25]
```

The two computations agree, and every consecutive error ratio is 0.25. The eigenvalue 1 governs the part of $\mathbf{p}_0$ that survives, while the eigenvalue $1/4$ governs the part that dies out.

The same recipe applies to other functions of a diagonalizable matrix. When no eigenvalue is zero, $\mathbf{A}^{-1} = \mathbf{V}\Lambda^{-1}\mathbf{V}^{-1}$: simply invert each eigenvalue on the diagonal. Similarly, the matrix exponential $e^{\mathbf{A}t} = \mathbf{V}e^{\Lambda t}\mathbf{V}^{-1}$, which solves the linear differential equation $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$, is built by exponentiating each eigenvalue; Section 38.1 develops it in detail.

Similarity. The eigendecomposition tells us that $\mathbf{P}$ and Λ represent the very same linear map written in two different bases. In general, two matrices related by $\mathbf{A}' = \mathbf{B}\mathbf{A}\mathbf{B}^{-1}$ for some invertible $\mathbf{B}$ are called *similar*. The next proposition confirms that changing basis cannot alter a matrix's eigenvalues. It relies on the multiplicativity of the determinant from Section 33.2,

$$\det(\mathbf{X}\mathbf{Y}) = \det\mathbf{X}\,\det\mathbf{Y},$$

which in particular gives $\det(\mathbf{B}^{-1}) = 1/\det\mathbf{B}$ from $\mathbf{B}\mathbf{B}^{-1} = \mathbf{I}$.

Proposition (similar matrices share the characteristic polynomial). *For every square* $\mathbf{A}$ *and every invertible* $\mathbf{B}$*,*

$$\det(\mathbf{B}\mathbf{A}\mathbf{B}^{-1} - \lambda\mathbf{I}) = \det(\mathbf{A} - \lambda\mathbf{I}). \tag{33.30}$$

Proof. Rewrite $\lambda\mathbf{I} = \mathbf{B}(\lambda\mathbf{I})\mathbf{B}^{-1}$ and factor out $\mathbf{B}$ and $\mathbf{B}^{-1}$: $\det(\mathbf{B}\mathbf{A}\mathbf{B}^{-1} - \lambda\mathbf{I}) = \det\big(\mathbf{B}(\mathbf{A} - \lambda\mathbf{I})\mathbf{B}^{-1}\big) = \det\mathbf{B}\,\det(\mathbf{A} - \lambda\mathbf{I})\,\det\mathbf{B}^{-1} = \det(\mathbf{A} - \lambda\mathbf{I})$. ∎

Similar matrices therefore have the same eigenvalues with the same multiplicities as roots, and any quantity determined by the characteristic polynomial is a *similarity invariant*. The two most useful invariants are the determinant and the trace. For any diagonalizable matrix,

$$\det(\mathbf{A}) = \det(\mathbf{V}\Lambda\mathbf{V}^{-1}) = \det(\mathbf{V})\det(\Lambda)\det(\mathbf{V}^{-1}) = \det(\Lambda) = \lambda_1\lambda_2\cdots\lambda_n. \tag{33.31}$$

Thus the determinant is the product of the eigenvalues: whatever volume distortion $\mathbf{V}$ introduces, $\mathbf{V}^{-1}$ undoes, leaving only the axis scaling of Λ. For the trace, we use its cyclic property (Section 33.2.1.4),

$$\operatorname{tr}(\mathbf{X}\mathbf{Y}) = \operatorname{tr}(\mathbf{Y}\mathbf{X}),$$

which holds for any $\mathbf{X}$ and $\mathbf{Y}$ whose products are square. Setting $\mathbf{X} = \mathbf{V}$ and $\mathbf{Y} = \Lambda\mathbf{V}^{-1}$ gives

$$\operatorname{tr}(\mathbf{A}) = \operatorname{tr}(\mathbf{V}\Lambda\mathbf{V}^{-1}) = \operatorname{tr}(\Lambda\mathbf{V}^{-1}\mathbf{V}) = \operatorname{tr}(\Lambda) = \lambda_1 + \cdots + \lambda_n. \tag{33.32}$$

Thus the trace is the sum of the eigenvalues. On the surfer's matrix we can check both identities at a glance: $\operatorname{tr}\mathbf{P} = \frac{1}{2} + \frac{3}{4} = \frac{5}{4} = 1 + \frac{1}{4}$ and $\det\mathbf{P} = \frac{3}{8} - \frac{1}{8} = \frac{1}{4} = 1 \cdot \frac{1}{4}$. For any 2×2 matrix, these two numbers fix both eigenvalues directly as the roots of $\lambda^2 - (\operatorname{tr})\lambda + \det$.

In fact, both identities hold for *every* square matrix, diagonalizable or not, provided we count the eigenvalues over $\mathbb{C}$ with their multiplicities as roots. By the *fundamental theorem of algebra* (which we take as given), every degree-n polynomial factors completely over $\mathbb{C}$:

$$\det(\mathbf{A} - \lambda\mathbf{I}) = \prod_{i=1}^{n} (\lambda_i - \lambda).$$

Setting $\lambda = 0$ immediately yields $\det\mathbf{A} = \prod_i \lambda_i$. For the trace, compare the coefficients of λ^{n-1} on both sides. On the right-hand side the coefficient is $(-1)^{n-1}\sum_i \lambda_i$. On the left-hand side, only the product of the diagonal entries of $\mathbf{A} - \lambda\mathbf{I}$ reaches degree $n-1$, giving $(-1)^{n-1}\sum_i a_{ii}$. Hence $\operatorname{tr}\mathbf{A} = \sum_i \lambda_i$. Because any non-real eigenvalues of a real matrix come in complex conjugate pairs, both the sum and the product remain real.

Finally, the rank of a diagonalizable matrix equals its number of nonzero eigenvalues, counted with multiplicity: multiplying by the invertible matrices $\mathbf{V}$ and $\mathbf{V}^{-1}$ preserves dimensions, so $\operatorname{rank}\mathbf{A} = \operatorname{rank}\Lambda$. Exercise 2 examines what happens when a matrix is not diagonalizable.

33.3.1.4 Algebraic and Geometric Multiplicity

The surfer's matrix had two distinct eigenvalues and yielded two linearly independent eigenvectors. That was no coincidence: distinct eigenvalues always produce independent eigenvectors.

Proposition (distinct eigenvalues give independent eigenvectors). *Eigenvectors belonging to distinct eigenvalues are linearly independent. In particular, any $n \times n$ matrix with n distinct eigenvalues is diagonalizable.*

Proof. Suppose, for the sake of contradiction, that some eigenvectors $\mathbf{v}_1, \dots, \mathbf{v}_m$ with distinct eigenvalues $\lambda_1, \dots, \lambda_m$ are linearly dependent. Among all nontrivial dependence relations, choose one with the fewest nonzero coefficients, $\sum_{i=1}^{m} c_i\mathbf{v}_i = \mathbf{0}$, and relabel if needed so that $c_m \neq 0$. Such a relation must have at least two nonzero coefficients, since $c_m\mathbf{v}_m = \mathbf{0}$ alone would force $\mathbf{v}_m = \mathbf{0}$. Now apply $\mathbf{A}$ to the relation and subtract λ_m times the original relation:

$$\mathbf{0} = \mathbf{A}\sum_i c_i\mathbf{v}_i - \lambda_m\sum_i c_i\mathbf{v}_i = \sum_{i=1}^{m-1} c_i(\lambda_i - \lambda_m)\,\mathbf{v}_i.$$

The $\mathbf{v}_m$ term drops out, leaving a shorter relation. Yet it is still nontrivial: any other nonzero coefficient c_i ($i < m$) survives as $c_i(\lambda_i - \lambda_m) \neq 0$ because the eigenvalues are distinct. This contradicts the minimality of our chosen relation. When $\mathbf{A}$ has n distinct eigenvalues, its n

independent eigenvectors form a basis of $\mathbb{C}^n$ (or of $\mathbb{R}^n$ when all eigenvalues are real), so $\mathbf{V}$ is invertible. ■

When eigenvalues repeat, we have to keep track of two different counts. The number of times λ appears as a root of the characteristic polynomial is its *algebraic multiplicity* $a(\lambda)$. The dimension of its eigenspace—the number of linearly independent eigenvectors it contributes—is its *geometric multiplicity* $g(\lambda)$.

Proposition. *For every eigenvalue λ of a square matrix, $1 \le g(\lambda) \le a(\lambda)$.*

Proof. Because $\mathbf{A} - \lambda\mathbf{I}$ is singular, its null space is nontrivial, which gives $g \ge 1$. For the upper bound, pick a basis $\mathbf{v}_1, \dots, \mathbf{v}_g$ of the eigenspace, extend it to a basis of $\mathbb{C}^n$, and place these basis vectors as the columns of $\mathbf{B}$. The first g columns of $\mathbf{AB}$ are simply $\lambda\mathbf{v}_1, \dots, \lambda\mathbf{v}_g$, so in this new basis the matrix takes a block upper-triangular form:

$$\mathbf{B}^{-1}\mathbf{A}\mathbf{B} = \begin{pmatrix} \lambda\mathbf{I}_g & \mathbf{X} \\ \mathbf{0} & \mathbf{Y} \end{pmatrix}.$$

By Equation 33.30, this matrix has the same characteristic polynomial p as $\mathbf{A}$. Let us write the polynomial variable as t, since λ now stands for our fixed eigenvalue. Subtracting $t\mathbf{I}$ preserves the block upper-triangular structure, with diagonal blocks $(\lambda - t)\mathbf{I}_g$ and $\mathbf{Y} - t\mathbf{I}$. Because the determinant of a block upper-triangular matrix is the product of the determinants of its diagonal blocks (Section 33.2.3.2), we get $p(t) = (\lambda - t)^g \det(\mathbf{Y} - t\mathbf{I})$. Thus $(\lambda - t)^g$ divides the characteristic polynomial, which means $a \ge g$. ■

An eigenvalue can never supply more independent eigenvectors than its multiplicity as a root, though it can supply fewer. Now pick a basis for each eigenspace and pool all the chosen vectors together. They are jointly independent: if a linear combination of them equals zero, group the terms by eigenvalue; each group is either zero or an eigenvector, and the proposition on distinct eigenvalues forces every group to vanish. A matrix therefore possesses at most $\sum_\lambda g(\lambda)$ linearly independent eigenvectors. Over $\mathbb{C}$, the algebraic multiplicities sum to n and $g(\lambda) \le a(\lambda)$ for every λ, which gives a crisp criterion: *the eigenvectors of $\mathbf{A}$ span $\mathbb{C}^n$ if and only if $g(\lambda) = a(\lambda)$ for every complex eigenvalue λ.*

For a real matrix to have a basis of *real* eigenvectors, all of its eigenvalues must also be real. The 90° rotation $\mathbf{R}_{90} = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$ shows why that extra requirement is essential: its eigenvalues $\pm i$ each satisfy $g = a = 1$, so it has a full complex eigenbasis, yet no real eigenvector at all.

When eigenvalues repeat, diagonalizability can fail altogether. The simplest counterexample is the *shear* from Section 33.2.1.2:

$$\mathbf{T} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}. \tag{33.33}$$

Its characteristic polynomial is $(1 - \lambda)^2$, so $\lambda = 1$ has algebraic multiplicity 2. Yet $(\mathbf{T} - \mathbf{I})\mathbf{v} = \mathbf{0}$ becomes $\left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)\mathbf{v} = \mathbf{0}$, which forces $v_2 = 0$. The eigenspace is only the line spanned by $(1, 0)$, so the geometric multiplicity is 1. There is no eigenbasis, and the shear is not diagonalizable. Any matrix with $g(\lambda) < a(\lambda)$ for some eigenvalue is called *defective*. Figure 33.18 makes the shortage visible: the shear slides every horizontal line sideways in proportion to its height, leaving the horizontal axis as the sole line through the origin that

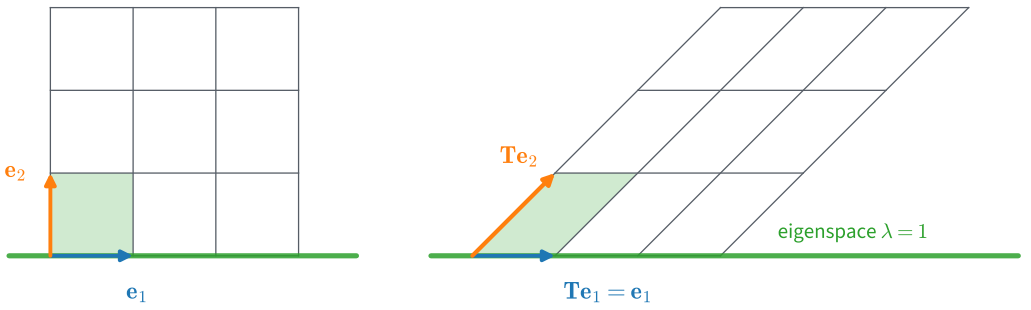

Figure 33.18: The defective shear acting on the plane. Every horizontal line slides to the right by an amount proportional to its height, tilting the grid, while the x-axis (green) maps to itself: $\mathbf{T}\mathbf{e}_1 = \mathbf{e}_1$ is the only eigendirection, with $\lambda = 1$. The other basis vector picks up a horizontal component, $\mathbf{T}\mathbf{e}_2 = (1, 1)$, so no second direction is preserved: geometric multiplicity 1 against algebraic multiplicity 2.

keeps its direction. (By contrast, a diagonalizable 2×2 matrix with a repeated eigenvalue λ would have to be $\lambda\mathbf{I}$, which preserves every direction.)

Iterating the shear shows how defectiveness changes the behavior of matrix powers: $\mathbf{T}^k = \left(\begin{smallmatrix} 1 & k \\ 0 & 1 \end{smallmatrix}\right)$, so $\mathbf{T}^k\mathbf{e}_2 = (k, 1)$ grows without bound even though the only eigenvalue is 1. No pure eigen-expansion can produce that linear factor k. The next subsection explains where it comes from.

33.3.1.5 The Jordan Normal Form

When geometric multiplicity falls short, no eigenbasis exists. What structure takes its place? For what follows in this book, one consequence matters most: a defective eigenvalue multiplies λ^k by a polynomial in k. Over the complex numbers, every square matrix is similar to a block-diagonal matrix built from *Jordan blocks*

$$\mathbf{J}_m(\lambda) = \begin{pmatrix} \lambda & 1 & & \\ & \lambda & \ddots & \\ & & \ddots & 1 \\ & & & \lambda \end{pmatrix},$$

which are $m \times m$ blocks carrying a single eigenvalue λ down the diagonal and 1s on the superdiagonal immediately above it. This factorization is the *Jordan normal form* (Horn and Johnson 2012), which we use without proof. By Equation 33.30, it has the same eigenvalues as the original matrix.

Each Jordan block supplies exactly one eigenvector, namely its first basis vector. The geometric multiplicity of λ is therefore the number of blocks carrying λ, while its algebraic multiplicity is the sum of their sizes. In particular, a matrix is diagonalizable if and only if every Jordan block has size 1×1. The shear $\mathbf{T}$ of Equation 33.33 is the single block $\mathbf{J}_2(1)$.

Under repeated application, a Jordan block does more than simply scale. Write $\mathbf{J}_m(\lambda) = \lambda\mathbf{I} + \mathbf{N}$, where $\mathbf{N}$ has 1s just above the diagonal and zeros everywhere else. Geometrically, $\mathbf{N}$ acts as a shift, sending each basis vector to the previous one, so $\mathbf{N}^m = \mathbf{0}$ (any matrix with

a vanishing power is called *nilpotent*). Because $\mathbf{I}$ and $\mathbf{N}$ commute, we can expand powers with the binomial theorem. For $m = 2$, every term beyond the first two contains $\mathbf{N}^2 = \mathbf{0}$, leaving

$$\mathbf{J}_2(\lambda)^k = (\lambda\mathbf{I} + \mathbf{N})^k = \lambda^k\mathbf{I} + k\lambda^{k-1}\mathbf{N}.$$

In the long run, the eigenvalue still decides between growth and decay, but it is now multiplied by a polynomial in k (of degree $m-1$ for an $m \times m$ block). When $|\lambda| = 1$, as in the shear, the iterates drift linearly. When $|\lambda|$ is slightly below 1, something more surprising happens: the upper-right entry $k\lambda^{k-1}$ initially grows, peaks near $k \approx -1/\log|\lambda|$, and only then decays toward zero. For $\lambda = 0.99$ this puts the peak near $k \approx 100$, where the entry reaches $100 \cdot 0.99^{99} \approx 37$. Let us check this prediction numerically.

```
J = np.array([[0.99, 1.], [0., 0.99]])   # the Jordan block J_2(0.99)
for k in [1, 50, 100, 200, 800]:
    Jk = np.linalg.matrix_power(J, k)
    pred = k * 0.99 ** (k - 1)   # predicted corner entry, k * lambda^(k-1)
    print(f'k = {k:3d}   ||J^k|| = {np.linalg.norm(Jk, 2):8.3f}   '
          f'k * 0.99^(k-1) = {pred:8.3f}')
```

```
k =   1   ||J^k|| =    1.609   k * 0.99^(k-1) =    1.000
k =  50   ||J^k|| =   30.568   k * 0.99^(k-1) =   30.556
k = 100   ||J^k|| =   36.977   k * 0.99^(k-1) =   36.973
k = 200   ||J^k|| =   27.067   k * 0.99^(k-1) =   27.067
k = 800   ||J^k|| =    0.260   k * 0.99^(k-1) =    0.260
```

Every eigenvalue of $\mathbf{J}$ is 0.99, yet the norm of its powers climbs to about 37 at $k = 100$ and is still 27 at $k = 200$ before the exponential factor 0.99^k finally takes over. Eigenvalues alone do not warn us about this transient growth, a phenomenon we revisit in Section 33.4.2.3.

Jordan blocks represent one way a real matrix can lack a real eigenbasis: it simply has too few eigenvectors. The second way is quite different in nature. A real matrix can lack any real eigenvector in a plane because it *rotates* that plane.

33.3.1.6 Complex Eigenvalues

Consider the planar rotation by an angle θ (Section 33.2.1.3),

$$\mathbf{R}_\theta = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}.$$

Whenever θ is not a multiple of π, $\mathbf{R}_\theta$ turns every nonzero real vector, leaving no real eigenvector. Its characteristic polynomial $\lambda^2 - 2\cos\theta\,\lambda + 1$ has the complex conjugate roots $\lambda = \cos\theta \pm i\sin\theta = e^{\pm i\theta}$. Here the modulus $|\lambda| = 1$ reflects that $\mathbf{R}_\theta$ preserves lengths, while the argument $\pm\theta$ records the rotation angle.

Now look at the chapter's running 2×2 matrix, which shows no obvious rotation in its entries:

$$\mathbf{A} = \begin{pmatrix} 1 & 2 \\ -1 & 3 \end{pmatrix}, \qquad \operatorname{tr}\mathbf{A} = 4, \quad \det\mathbf{A} = 5.$$

Its characteristic polynomial is $\lambda^2 - 4\lambda + 5$, whose roots are $\lambda = 2 \pm i = \sqrt{5}\, e^{\pm i\theta}$ with $\theta = \arctan \frac{1}{2} \approx 26.6^\circ$. To find an eigenvector for $2+i$, read off the second row of $\mathbf{A} - (2+i)\mathbf{I}$, which gives $-w_1 + (1-i)w_2 = 0$. Setting $w_2 = 1$ yields

$$\mathbf{w} = \begin{pmatrix} 1-i \\ 1 \end{pmatrix} = \underbrace{\begin{pmatrix} 1 \\ 1 \end{pmatrix}}_{\mathbf{u}} + i \underbrace{\begin{pmatrix} -1 \\ 0 \end{pmatrix}}_{\mathbf{v}}.$$

Where is the rotation hiding? Take any real matrix $\mathbf{A}$ with a complex eigenpair $\mathbf{A}\mathbf{w} = \lambda\mathbf{w}$, where $\lambda = a + ib$ and $b \neq 0$, and separate the eigenvector into its real and imaginary parts, $\mathbf{w} = \mathbf{u} + i\mathbf{v}$. Expanding $\mathbf{A}(\mathbf{u} + i\mathbf{v}) = (a+ib)(\mathbf{u} + i\mathbf{v})$ and equating real and imaginary parts gives

$$\mathbf{A}\mathbf{u} = a\mathbf{u} - b\mathbf{v}, \qquad \mathbf{A}\mathbf{v} = b\mathbf{u} + a\mathbf{v}.$$

Both images stay inside $\operatorname{span}\{\mathbf{u}, \mathbf{v}\}$, so this subspace is invariant under $\mathbf{A}$. Moreover, it is a genuine two-dimensional plane. If $\mathbf{u}$ and $\mathbf{v}$ were linearly dependent, their span would be a single line (not zero, because $\mathbf{w} \neq \mathbf{0}$) mapped into itself, on which $\mathbf{A}$ would act by multiplying by some real scalar μ. That would force $\mathbf{A}\mathbf{w} = \mu\mathbf{w}$, making $\lambda = \mu$ real and contradicting $b \neq 0$. Placing $\mathbf{v}$ and $\mathbf{u}$ as the columns of $\mathbf{B} = \begin{bmatrix} \mathbf{v} & \mathbf{u} \end{bmatrix}$ turns the two identities into $\mathbf{A}\mathbf{B} = \mathbf{B} \left(\begin{smallmatrix} a & -b \\ b & a \end{smallmatrix}\right)$, or equivalently,

$$\mathbf{B}^{-1}\mathbf{A}\mathbf{B} = \begin{pmatrix} a & -b \\ b & a \end{pmatrix} = \underbrace{\sqrt{a^2+b^2}}_{r} \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}, \qquad \theta = \arg(a+ib). \tag{33.34}$$

In the basis $(\mathbf{v}, \mathbf{u})$ of its invariant plane, $\mathbf{A}$ acts as a rotation–scaling block $r\mathbf{R}_\theta$: it scales by the modulus r and rotates by the argument θ. Because the derivation used only $\mathbf{A}\mathbf{w} = \lambda\mathbf{w}$, this block is independent of how $\mathbf{w}$ is scaled or rotated in phase. The connection also works in reverse: if we identify $(x, y) \in \mathbb{R}^2$ with the complex number $x + iy$, then the block maps (x, y) to $(ax - by,\ bx + ay)$, which is simply complex multiplication by $a + ib$.

For our running matrix $\mathbf{A}$, we have $\mathbf{B} = \left(\begin{smallmatrix} -1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$ and $\mathbf{B}^{-1}\mathbf{A}\mathbf{B} = \left(\begin{smallmatrix} 2 & -1 \\ 1 & 2 \end{smallmatrix}\right)$, which scales by $\sqrt{5}$ and rotates by 26.6°. One might expect every step to lengthen a vector by the factor $\sqrt{5} \approx 2.24$. Let us compute the block from the eigenvector returned by `eig` and track the actual lengths of the iterates $\mathbf{A}^k(1, 0)$.

```
A = np.array([[1., 2.], [-1., 3.]])
lam, V = np.linalg.eig(A)
j = np.argmax(lam.imag)                  # the eigenvalue a + ib with b > 0
r, theta = np.abs(lam[j]), np.angle(lam[j])
u, v = V[:, j].real, V[:, j].imag
B = np.column_stack([v, u])              # basis (v, u) of the invariant plane
print(f'lambda = {lam[j]:.4f}   r = {r:.4f}   theta = {theta:.4f}')
print('B^-1 A B =\n', np.round(np.linalg.inv(B) @ A @ B, 4))
xs = [np.array([1., 0.])]
for _ in range(8):
    xs.append(A @ xs[-1])
norms = np.linalg.norm(xs, axis=1)
```

```
    print('norm ratios:', np.round(norms[1:] / norms[:-1], 2))
    x20 = np.linalg.matrix_power(A, 20) @ np.array([1., 0.])
    print(f'average rate ||A^20 x||^(1/20) = {np.linalg.norm(x20) ** (1 / 20):.3f}')
```

```
lambda = 2.0000+1.0000j   r = 2.2361   theta = 0.4636
B^-1 A B =
 [[ 2. -1.]
 [ 1.  2.]]
norm ratios: [1.41 2.92 3.45 2.76 2.27 1.88 1.5  1.54]
average rate ||A^20 x||^(1/20) = 2.252
```

Regardless of which eigenvector `eig` chooses, the resulting block is $\left(\begin{smallmatrix} 2 & -1 \\ 1 & 2 \end{smallmatrix}\right)$. Yet the vector lengths do *not* grow by a steady factor of 2.24 at each step. Along the trajectory $(1,0) \to (1,-1) \to (-1,-4) \to (-9,-11) \to (-31,-24)$, the per-step norm ratios swing between roughly 1.4 and 3.5. The reason is that the scaling is uniform only in the coordinates $(\mathbf{v}, \mathbf{u})$, which are not orthonormal. Back in standard coordinates, the iterates spiral outward along stretched ellipses, completing a full turn roughly every $2\pi/\theta \approx 13.6$ steps. Only the long-run geometric average $\|\mathbf{A}^k\mathbf{x}\|^{1/k}$ settles at $\sqrt{5}$ (reaching 2.25 by $k = 20$). The motion is a rigid rotation and uniform scaling in standard coordinates only when the matrix is *normal*, a property we define in Section 33.4.2.2.

Up to a real change of basis, every real square matrix is built from the three elementary behaviors we have now uncovered, alone or in combination: stretching along a line, shearing within a Jordan block, and rotating with scaling in a plane. This decomposition is known as the *real Jordan form* (Horn and Johnson 2012).

33.3.2 Symmetric Matrices and Quadratic Forms

33.3.2.1 The Spectral Theorem

Which matrices guarantee a real, orthonormal eigenbasis? Symmetry eliminates both obstacles we just encountered: it rules out complex eigenvalues as well as shortages of eigenvectors. The symmetric matrix $\mathbf{S}$ from Section 1.3 shows what happens. Its unit eigenvectors $(1,1)/\sqrt{2}$ and $(1,-1)/\sqrt{2}$ are perpendicular, giving

$$\mathbf{S} = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix} = \underbrace{\frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}}_{\mathbf{V}} \begin{pmatrix} 3 & 0 \\ 0 & 1 \end{pmatrix} \underbrace{\frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}}_{\mathbf{V}^\top}.$$

Because the eigenvector matrix $\mathbf{V}$ is orthogonal ($\mathbf{V}^\top\mathbf{V} = \mathbf{I}$), its inverse is simply its transpose. The spectral theorem guarantees that this holds for *every* real symmetric matrix. It is the central theorem of this chapter: positive definiteness, the Rayleigh quotient, and all of Section 33.5 rest on it.

Theorem (spectral theorem). *Every real symmetric matrix $\mathbf{A}$ has real eigenvalues and an orthonormal basis of real eigenvectors. Equivalently,*

$$\mathbf{A} = \mathbf{V}\Lambda\mathbf{V}^\top, \tag{33.35}$$

where $\Lambda = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$ is real and $\mathbf{V}$ is orthogonal.

We prove this in three steps: first, every eigenvalue is real; second, eigenvectors for distinct eigenvalues are orthogonal; third, a full orthonormal eigenbasis always exists. For complex vectors we use the Hermitian inner product $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{x}^* \mathbf{y}$, where $\mathbf{x}^*$ is the conjugate transpose (which reduces to the ordinary dot product on real vectors). The only external fact we borrow is that the characteristic polynomial has at least one complex root (the fundamental theorem of algebra), ensuring that at least one eigenpair exists over $\mathbb{C}$. Parts (i) and (ii) take only two lines each; the real work is in part (iii).

Proof, part (i): the eigenvalues are real. Suppose $\mathbf{A}\mathbf{v} = \lambda \mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$, allowing complex entries for the moment. Because $\mathbf{A}$ is real and symmetric, $\mathbf{A}^* = \mathbf{A}^\top = \mathbf{A}$, and therefore

$$\lambda \, \mathbf{v}^* \mathbf{v} = \mathbf{v}^* \mathbf{A} \mathbf{v} = (\mathbf{A}\mathbf{v})^* \mathbf{v} = \bar{\lambda} \, \mathbf{v}^* \mathbf{v}.$$

Since $\mathbf{v}^* \mathbf{v} = \|\mathbf{v}\|^2 > 0$, we can divide both sides by it to obtain $\lambda = \bar{\lambda}$: the eigenvalue must be real. Its eigenvector can then be chosen real as well, because it solves the real homogeneous system $(\mathbf{A} - \lambda \mathbf{I})\mathbf{v} = \mathbf{0}$. $\blacksquare$

Proof, part (ii): eigenvectors of distinct eigenvalues are orthogonal. Let $\mathbf{A}\mathbf{u} = \lambda \mathbf{u}$ and $\mathbf{A}\mathbf{v} = \mu \mathbf{v}$ with $\lambda \neq \mu$, where both eigenvalues and both eigenvectors are real by part (i). Using $\mathbf{A} = \mathbf{A}^\top$ to move $\mathbf{A}$ across the inner product,

$$\lambda \langle \mathbf{u}, \mathbf{v} \rangle = \langle \mathbf{A}\mathbf{u}, \mathbf{v} \rangle = \langle \mathbf{u}, \mathbf{A}\mathbf{v} \rangle = \mu \langle \mathbf{u}, \mathbf{v} \rangle.$$

Thus $(\lambda - \mu)\langle \mathbf{u}, \mathbf{v} \rangle = 0$. Because $\lambda \neq \mu$, we must have $\langle \mathbf{u}, \mathbf{v} \rangle = 0$. $\blacksquare$

Proof, part (iii): an orthonormal eigenbasis. We argue by induction on n; for $n = 1$ the claim is immediate. For $n > 1$, part (i) supplies a real eigenpair $(\lambda_1, \mathbf{v}_1)$ with $\|\mathbf{v}_1\| = 1$. Consider the $(n-1)$-dimensional orthogonal complement $U = \mathbf{v}_1^\perp$. Symmetry ensures that $\mathbf{A}$ maps U back into itself: for any $\mathbf{x} \in U$,

$$\langle \mathbf{A}\mathbf{x}, \mathbf{v}_1 \rangle = \langle \mathbf{x}, \mathbf{A}\mathbf{v}_1 \rangle = \lambda_1 \langle \mathbf{x}, \mathbf{v}_1 \rangle = 0.$$

Choose an orthonormal basis of U and assemble its vectors as the columns of $\mathbf{Q} \in \mathbb{R}^{n \times (n-1)}$. Because every column of $\mathbf{A}\mathbf{Q}$ lies in U, we can write $\mathbf{A}\mathbf{Q} = \mathbf{Q}\mathbf{C}$ where $\mathbf{C} = \mathbf{Q}^\top \mathbf{A} \mathbf{Q}$ represents $\mathbf{A}$ restricted to U. Notice that $\mathbf{C}$ is symmetric, $\mathbf{C}^\top = \mathbf{Q}^\top \mathbf{A}^\top \mathbf{Q} = \mathbf{C}$, and has size $(n-1) \times (n-1)$. By the inductive hypothesis, $\mathbf{C} = \mathbf{V}' \Lambda' \mathbf{V}'^\top$ for an orthogonal matrix $\mathbf{V}'$. Now look at the columns of $\mathbf{Q}\mathbf{V}'$: they are orthonormal because $(\mathbf{Q}\mathbf{V}')^\top \mathbf{Q}\mathbf{V}' = \mathbf{V}'^\top \mathbf{V}' = \mathbf{I}$; they lie in U, so they are orthogonal to $\mathbf{v}_1$; and they are eigenvectors of $\mathbf{A}$, because $\mathbf{A}\mathbf{Q}\mathbf{V}' = \mathbf{Q}\mathbf{C}\mathbf{V}' = \mathbf{Q}\mathbf{V}'\Lambda'$. Appending them to $\mathbf{v}_1$ gives the orthogonal matrix $\mathbf{V} = [\mathbf{v}_1 \;\; \mathbf{Q}\mathbf{V}']$ satisfying $\mathbf{A}\mathbf{V} = \mathbf{V}\Lambda$. $\blacksquare$

Geometrically, Equation 33.35 breaks any symmetric linear map into three clean actions. First, $\mathbf{V}^\top$ aligns the orthonormal eigenvectors with the coordinate axes—a pure rotation, possibly combined with a reflection (for $\mathbf{S}$ above, $\det \mathbf{V} = -1$). Next, Λ stretches each coordinate axis by its eigenvalue. Finally, $\mathbf{V}$ turns the axes back. This proves what the left panel of Figure 33.16 illustrated for $\mathbf{S}$, now for every symmetric matrix.

Every matrix $\mathbf{A}$, rectangular or square, produces a symmetric matrix $\mathbf{A}^\top \mathbf{A}$. Its quadratic form $\mathbf{x}^\top \mathbf{A}^\top \mathbf{A} \mathbf{x} = \|\mathbf{A}\mathbf{x}\|^2$ can never be negative—a property that we name, test, and exploit next.

33.3.2.2 Positive Definiteness

Can the quadratic form $\mathbf{x}^\top \mathbf{A}\mathbf{x}$ ever turn negative? This single question decides whether a critical point of a loss surface is a minimum, whether a matrix is a valid covariance, and whether a least-squares problem has a unique solution. A symmetric matrix $\mathbf{A}$ is *positive semidefinite* (PSD), written $\mathbf{A} \succeq 0$, if

$$\mathbf{x}^\top \mathbf{A}\mathbf{x} \geq 0 \quad \text{for all } \mathbf{x},$$

and *positive definite* (PD), written $\mathbf{A} \succ 0$, if the inequality is strict for every nonzero $\mathbf{x}$. For instance, $\mathbf{x}^\top \mathbf{S}\mathbf{x} = 2x_1^2 + 2x_1x_2 + 2x_2^2 = x_1^2 + x_2^2 + (x_1 + x_2)^2$ is strictly positive whenever $\mathbf{x} \neq \mathbf{0}$, so $\mathbf{S} \succ 0$, whereas $\left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$ is neither PD nor PSD because $\mathbf{e}_2$ gives -1. Completing the square by hand quickly becomes impractical in higher dimensions, but the eigenvalues settle the question cleanly for any symmetric matrix.

Proposition (definiteness from eigenvalues). *For symmetric* $\mathbf{A}$*,*

$$\mathbf{A} \succeq 0 \iff \lambda_i \geq 0 \text{ for all } i, \qquad \mathbf{A} \succ 0 \iff \lambda_i > 0 \text{ for all } i.$$

Proof. Apply the spectral theorem to write $\mathbf{A} = \mathbf{V}\Lambda\mathbf{V}^\top$, and switch to eigenvector coordinates $\mathbf{y} = \mathbf{V}^\top \mathbf{x}$—an orthogonal change of basis that preserves lengths. Then

$$\mathbf{x}^\top \mathbf{A}\mathbf{x} = \mathbf{x}^\top \mathbf{V}\Lambda\mathbf{V}^\top \mathbf{x} = \mathbf{y}^\top \Lambda \mathbf{y} = \sum_{i=1}^{n} \lambda_i \, y_i^2 = \sum_{i=1}^{n} \lambda_i \, (\mathbf{v}_i^\top \mathbf{x})^2. \tag{33.36}$$

In eigenvector coordinates, the quadratic form is simply a weighted sum of squares whose weights are the eigenvalues. If every $\lambda_i \geq 0$, this sum is clearly non-negative. Conversely, plugging in $\mathbf{x} = \mathbf{v}_j$ gives $\mathbf{y} = \mathbf{e}_j$ and $\mathbf{v}_j^\top \mathbf{A}\mathbf{v}_j = \lambda_j$, forcing $\lambda_j \geq 0$. The positive definite case follows by the same argument with strict inequalities, since $\mathbf{y} \neq \mathbf{0}$ whenever $\mathbf{x} \neq \mathbf{0}$. ∎

Let us check Equation 33.36 on $\mathbf{S}$ with $\mathbf{x} = \mathbf{e}_1$: the eigen-coordinates are $\mathbf{y} = \mathbf{V}^\top \mathbf{e}_1 = (1/\sqrt{2}, 1/\sqrt{2})$, and the weighted sum gives $3 \cdot \tfrac{1}{2} + 1 \cdot \tfrac{1}{2} = 2$, matching $\mathbf{e}_1^\top \mathbf{S}\mathbf{e}_1 = s_{11}$. Three consequences account for most appearances of positive definiteness in deep learning:

- **PD implies invertible.** If $\mathbf{A} \succ 0$ and $\mathbf{A}\mathbf{x} = \mathbf{0}$, then $\mathbf{x}^\top \mathbf{A}\mathbf{x} = 0$, which forces $\mathbf{x} = \mathbf{0}$.
- **Gram and covariance matrices are PSD.** For any matrix $\mathbf{X}$, $\mathbf{x}^\top \mathbf{X}^\top \mathbf{X}\mathbf{x} = \|\mathbf{X}\mathbf{x}\|^2 \geq 0$, so $\mathbf{X}^\top \mathbf{X} \succeq 0$. It is strictly PD if and only if $\mathbf{X}$ has full column rank (so that $\mathbf{X}\mathbf{x} = \mathbf{0}$ implies $\mathbf{x} = \mathbf{0}$). Because the sample covariance of centered data is a Gram matrix divided by the number of samples, it is always PSD.
- **A PD Hessian guarantees a strict local minimum.** Suppose f is twice continuously differentiable with $\nabla f(\mathbf{x}^*) = \mathbf{0}$, and its Hessian $\nabla^2 f(\mathbf{x}^*)$ (the symmetric matrix of second partial derivatives) is PD. For any small step δ, the second-order Taylor expansion (Section 34.2.3.2) reads $f(\mathbf{x}^* + \delta) = f(\mathbf{x}^*) + \tfrac{1}{2}\delta^\top \nabla^2 f(\mathbf{x}^*)\delta + o(\|\delta\|^2)$. By Equation 33.36, the quadratic term is at least $\tfrac{1}{2}\lambda_{\min}\|\delta\|^2 > 0$, so $\mathbf{x}^*$ is a strict local minimum. Note that this condition is sufficient rather than necessary: $f(x) = x^4$ has a strict minimum at 0 even though its second derivative there is 0.

Positive definiteness also admits a fast algorithmic test, the *Cholesky factorization*: $\mathbf{A} \succ 0$ if and only if $\mathbf{A} = \mathbf{L}\mathbf{L}^\top$ for a lower-triangular matrix $\mathbf{L}$ with positive diagonal entries. One direction is immediate: such an $\mathbf{L}$ is invertible, so $\mathbf{x}^\top \mathbf{A}\mathbf{x} = \|\mathbf{L}^\top \mathbf{x}\|^2 > 0$ for every nonzero

x. Attempting a Cholesky factorization is the standard numerical way to test positive definiteness, and it is considerably cheaper than computing all eigenvalues. As a bonus, the same factor **L** transforms independent standard Gaussian samples **z** into samples **Lz** with covariance $\mathbf{L}\mathbf{L}^\top = \mathbf{A}$.

Geometrically, the signs of the eigenvalues govern the shape of the surface $z = \mathbf{x}^\top \mathbf{A}\mathbf{x}$ (Figure 33.19): a bowl when all eigenvalues are positive, a trough that is flat along any zero-eigenvalue direction, and a saddle when signs are mixed.

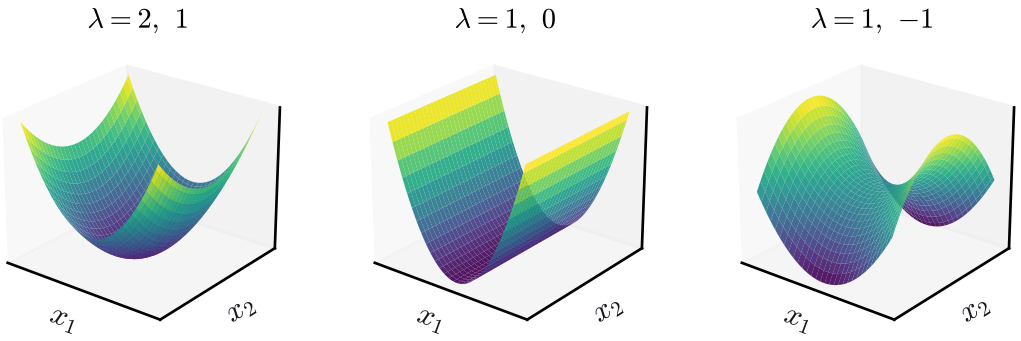

Figure 33.19: The quadratic-form surface $z = \mathbf{x}^\top \mathbf{A}\mathbf{x}$ for three diagonal matrices takes its shape from the eigenvalue signs: a bowl when all $\lambda_i > 0$ (positive definite), a trough when one $\lambda_i = 0$ (positive semidefinite), and a saddle for mixed signs (indefinite).

We can see the rank condition for Gram matrices directly in their eigenvalues. Below we compare a tall matrix **X** with independent columns, whose $\mathbf{X}^\top \mathbf{X}$ should be PD, against one whose second column is twice the first, which should yield a PSD matrix with a zero eigenvalue.

```
X_full = np.array([[1., 0.], [1., 1.], [0., 1.], [2., 1.]])  # rank 2
X_dep = np.array([[1., 2.], [1., 2.], [0., 0.], [2., 4.]])   # col 2 = 2*col 1
for X, name in [(X_full, 'full column rank'), (X_dep, 'dependent columns')]:
    eigvals = np.linalg.eigvalsh(X.T @ X).round(4)
    eigvals[np.abs(eigvals) < 1e-9] = 0.0  # clean up tiny round-off / -0.0
    print(f'{name}: eigenvalues of X^T X = {eigvals}')
```

```
full column rank: eigenvalues of X^T X = [1.1459 7.8541]
dependent columns: eigenvalues of X^T X = [ 0. 30.]
```

Both eigenvalues are strictly positive in the full-rank case. In the dependent case, one drops to zero: the quadratic form vanishes along $(2, -1)$, the very direction that **X** maps to zero.

33.3.2.3 The Rayleigh Quotient

Identity Equation 33.36 does more than test signs: it turns the largest and smallest eigenvalues into the solutions of optimization problems. For a symmetric matrix **A**, define the *Rayleigh quotient*

$$R(\mathbf{x}) = \frac{\mathbf{x}^\top \mathbf{A}\mathbf{x}}{\mathbf{x}^\top \mathbf{x}}, \qquad \mathbf{x} \neq \mathbf{0}.$$

This measures the quadratic form per unit squared length, and whenever $\mathbf{x}$ is an eigenvector, $R(\mathbf{x})$ equals its eigenvalue. Throughout this subsection we order the eigenvalues by their signed values, $\lambda_1 \geq \cdots \geq \lambda_n$, rather than by magnitude.

Proposition (Rayleigh). *For symmetric* $\mathbf{A}$ *with eigenvalues* $\lambda_1 \geq \cdots \geq \lambda_n$*,*

$$\lambda_1 = \max_{\mathbf{x} \neq \mathbf{0}} R(\mathbf{x}), \qquad \lambda_n = \min_{\mathbf{x} \neq \mathbf{0}} R(\mathbf{x}),$$

with the maximum and minimum attained at the corresponding eigenvectors.

Proof. Rescaling $\mathbf{x}$ leaves $R(\mathbf{x})$ unchanged, so we may restrict attention to unit vectors. Setting $\mathbf{y} = \mathbf{V}^\top \mathbf{x}$ preserves the norm ($\|\mathbf{y}\| = \|\mathbf{x}\| = 1$) and turns Equation 33.36 into $R(\mathbf{x}) = \sum_i \lambda_i y_i^2$. This is a weighted average of the eigenvalues with non-negative weights y_i^2 summing to 1. Every average lies between its smallest and largest values, so $\lambda_n \leq R(\mathbf{x}) \leq \lambda_1$. Putting all the weight onto a single coordinate, at $\mathbf{x} = \mathbf{v}_1$ or $\mathbf{x} = \mathbf{v}_n$, attains the two bounds. ■

For our running symmetric matrix $\mathbf{S}$, this tells us that $R(\mathbf{x})$ ranges over $[1, 3]$, peaking along the eigenvector at 45° and reaching its minimum along the eigenvector at 135°. Every intermediate direction blends the eigenvalues 1 and 3 in proportion to its squared eigencoordinates.

Maximizing over subspaces recovers all intermediate eigenvalues as well: the *Courant–Fischer theorem* states that $\lambda_j = \max_{\dim U = j} \min_{\mathbf{0} \neq \mathbf{x} \in U} R(\mathbf{x})$, the highest guaranteed Rayleigh quotient across all j-dimensional subspaces U (Exercise 4d guides you through the proof).

Two applications of the extreme eigenvalues recur throughout this book. First, for any matrix $\mathbf{A}$, the largest Rayleigh quotient of $\mathbf{A}^\top \mathbf{A}$ is $\max_{\mathbf{x} \neq \mathbf{0}} \|\mathbf{A}\mathbf{x}\|^2 / \|\mathbf{x}\|^2$, the square of the largest factor by which $\mathbf{A}$ can stretch a vector. Second, consider gradient descent on a convex quadratic $f(\mathbf{x}) = \frac{1}{2}\mathbf{x}^\top \mathbf{A}\mathbf{x}$ with $\mathbf{A} \succ 0$, whose update is $\mathbf{x} \leftarrow (\mathbf{I} - \eta \mathbf{A})\mathbf{x}$. By Equation 33.28, each eigen-coordinate is multiplied by $1 - \eta\lambda_i$ at every step, so the iteration converges from every starting point if and only if $|1 - \eta\lambda_i| < 1$ for all i—that is, $0 < \eta < 2/\lambda_{\max}$. The largest eigenvalue thus caps the step size (it is the smoothness constant L of Section 35.1), and for step sizes $\eta \leq 1/\lambda_{\max}$ the smallest eigenvalue dictates the slowest contraction rate, $1 - \eta\lambda_{\min}$. Their ratio $\lambda_{\max}/\lambda_{\min}$ is the condition number of $\mathbf{A}$, which Section 33.5.3.2 generalizes to arbitrary matrices.

33.3.2.4 Sample Covariance and the Marchenko–Pastur Law

When we look for structure in high-dimensional data, we inspect the largest eigenvalues of the sample covariance matrix. To judge which eigenvalues are truly large, however, we first need a baseline: what do the eigenvalues look like when the data contain no structure at all? Suppose we draw n samples of pure noise in d dimensions, with independent coordinates of mean 0 and variance 1 (so the true covariance is $\mathbf{I}$), and stack them as the rows of $\mathbf{X} \in \mathbb{R}^{n \times d}$. Do the eigenvalues of the sample covariance $\mathbf{C} = \frac{1}{n}\mathbf{X}^\top \mathbf{X}$ cluster near 1? For any unit vector $\mathbf{w}$, the Rayleigh quotient $\mathbf{w}^\top \mathbf{C}\mathbf{w}$ is the sample variance of the data projected onto $\mathbf{w}$. The extreme eigenvalues of $\mathbf{C}$ are therefore the sample variances along the most and least variable directions—the very quantities that principal component analysis interprets as structure (Section 33.5.2.2).

Surprisingly, they do *not* cluster near 1. Let $d, n \to \infty$ while holding the *aspect ratio* $c = d/n \le 1$ fixed. Then the histogram of eigenvalues of $\mathbf{C}$ converges to a deterministic density supported on the interval

$$\left[(1-\sqrt{c})^2,\ (1+\sqrt{c})^2\right],$$

known as the *Marchenko–Pastur bulk* (Marchenko and Pastur 1967), and provided the noise has a finite fourth moment, the extreme eigenvalues converge right to its edges. When $c > 1$, the matrix $\mathbf{C}$ has rank at most $n < d$, so at least $d - n$ eigenvalues are identically zero in addition to the bulk. Even with four samples per dimension ($c = 1/4$), pure-noise eigenvalues spread all the way across $[0.25, 2.25]$: the sample variance along the loudest random direction is more than double the true variance, while along the quietest it is only a quarter. At $n = 4000$ and $d = 1000$, this asymptotic limit is already strikingly accurate. Let us test it.

```
n, d = 4000, 1000                       # aspect ratio c = d / n = 1/4
X = np.random.randn(n, d)               # pure noise: true covariance I
ev = np.linalg.eigvalsh(X.T @ X / n)
c = d / n
print(f'eigenvalues of C: min {ev.min():.3f}, max {ev.max():.3f}')
print(f'Marchenko-Pastur edges: {(1 - c ** 0.5) ** 2:.3f}, '
      f'{(1 + c ** 0.5) ** 2:.3f}')
```

```
eigenvalues of C: min 0.252, max 2.234
Marchenko-Pastur edges: 0.250, 2.250
```

On every run, the smallest and largest eigenvalues land within a few hundredths of the predicted edges 0.25 and 2.25. Any eigenvalue falling inside this bulk is indistinguishable from pure noise; only an eigenvalue clearly above the upper edge provides evidence of genuine structure. Exercise 5 explores how strong a signal must be before its eigenvalue escapes the bulk.

Throughout this section we took two things for granted: that we can actually compute the eigenvalues of a matrix, and that those eigenvalues tell us what its powers do after a handful of steps just as well as after many. For large matrices and for matrices far from symmetric, neither assumption is safe. Section 33.4 takes up both.

33.3.3 Summary

In eigenvector coordinates, a diagonalizable matrix acts as a list of scalars, $\mathbf{A}^k\mathbf{x} = \sum_i c_i \lambda_i^k \mathbf{v}_i$, explaining repeated application in Markov chains, deep linear networks, and gradient descent on quadratics. A full eigenbasis exists over $\mathbb{C}$ if and only if every eigenvalue's geometric multiplicity matches its algebraic multiplicity; otherwise Jordan blocks introduce polynomial factors in k that can cause transient growth, while complex conjugate pairs correspond to rotation and scaling in an invariant plane. Real symmetric matrices avoid both pitfalls: they always have real eigenvalues and an orthonormal eigenbasis. Their quadratic forms become weighted sums of squares, so eigenvalue signs determine positive definiteness and the extreme eigenvalues are the extremes of the Rayleigh quotient. Finally, the eigenvalues of a pure-noise sample covariance spread across the Marchenko–Pastur interval, meaning that only eigenvalues above the upper bulk edge signal real structure.

33.3.4 Exercises

1. **Trace, determinant, and definiteness.** The identities Equation 33.31 and Equation 33.32 fix both eigenvalues of a 2×2 matrix through their sum and product.
   1. Find the eigenvalues of $\left(\begin{smallmatrix} 4 & 1 \\ 1 & 4 \end{smallmatrix}\right)$ from its trace and determinant alone, without forming the characteristic polynomial. Then find its eigenvectors. Do the same for the surfer's matrix $\mathbf{P}$, whose trace is $5/4$ and determinant $1/4$.
   2. Show that a symmetric 2×2 matrix is positive definite if and only if its trace and its determinant are both positive. Which sign conditions on trace and determinant characterize positive semidefiniteness?
   3. Each of the matrices $\left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$, $\left(\begin{smallmatrix} 1 & 2 \\ 2 & 1 \end{smallmatrix}\right)$, and $\left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$ is the Hessian of the quadratic $f(\mathbf{x}) = \frac{1}{2}\mathbf{x}^\top \mathbf{A}\mathbf{x}$ at its critical point $\mathbf{0}$. Use (b) to decide for each f whether the origin is a strict minimum, a minimum that is not strict, or a saddle point. For the saddle point, give a direction along which f decreases.
   4. Show that the Cholesky factor $\mathbf{L}$ of $\left(\begin{smallmatrix} a & b \\ b & c \end{smallmatrix}\right)$ has the diagonal entries $\sqrt{a}$ and $\sqrt{(ac - b^2)/a}$. Why do the conditions under which a factor with positive diagonal exists coincide with the test of (b)?

2. **Rank and zero eigenvalues.** The section shows that the rank of a diagonalizable matrix equals the number of its nonzero eigenvalues, counted with multiplicity.
   1. Find the rank and the eigenvalues of $\mathbf{N} = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$. Which step of the argument for diagonalizable matrices fails for $\mathbf{N}$?
   2. Let g_0 be the geometric multiplicity of the eigenvalue 0 of an $n \times n$ matrix $\mathbf{A}$, with $g_0 = 0$ when 0 is not an eigenvalue. Show that $\operatorname{rank} \mathbf{A} = n - g_0$ for every square matrix. Conclude that the rank is at least the number of nonzero eigenvalues counted with algebraic multiplicity, with equality if and only if the eigenvalue 0 is not defective.
   3. The *singular values* of a matrix are $\sigma_i = \sqrt{\lambda_i(\mathbf{A}^\top \mathbf{A})}$, the square roots of the eigenvalues of the PSD matrix $\mathbf{A}^\top \mathbf{A}$. Find the singular values of $\mathbf{N}$ and of the Jordan block $\mathbf{J}_m(0)$ of Section 33.3.1.5. Compare the number of nonzero singular values with the rank and with the number of nonzero eigenvalues.

3. **The centering matrix.** Let $\mathbf{1} \in \mathbb{R}^n$ be the all-ones vector and $\mathbf{H} = \mathbf{I} - \frac{1}{n}\mathbf{1}\mathbf{1}^\top$.
   1. Show that $n\mathbf{I} - \mathbf{1}\mathbf{1}^\top$ is positive semidefinite by writing $\mathbf{x}^\top(n\mathbf{I} - \mathbf{1}\mathbf{1}^\top)\mathbf{x}$ as a sum of squares of the differences $x_i - x_j$. Then find all eigenvalues of $n\mathbf{I} - \mathbf{1}\mathbf{1}^\top$ and their eigenvectors.
   2. Show that $\mathbf{H}$ is symmetric with $\mathbf{H}^2 = \mathbf{H}$, and deduce its eigenvalues and its rank from (a).
   3. Let the rows of $\mathbf{X} \in \mathbb{R}^{n \times d}$ be n samples. Subtracting the sample mean from every row gives $\mathbf{H}\mathbf{X}$, so that the sample covariance is $\mathbf{C} = \frac{1}{n}\mathbf{X}^\top \mathbf{H}\mathbf{X}$. Show that $\mathbf{C} \succeq 0$ and $\operatorname{rank} \mathbf{C} \le n - 1$. How many zero eigenvalues does the sample covariance of 512-dimensional embeddings computed from a minibatch of 256 examples have at least? This is the case $c = d/n > 1$ of Section 33.3.2.4. Which operations on $\mathbf{C}$ does it rule out?

   Adapted from Gilbert Strang, MIT 18.065 Problem Sets, Problems for Lecture 13, Problem 4.

4. code **Accuracy of computed eigenvalues.** ● The algorithm behind `np.linalg.eigvals` is backward stable: it returns the exact eigenvalues of a matrix $\mathbf{A} + \mathbf{E}$ with $\|\mathbf{E}\|_2$ of the order of $\epsilon_{\text{mach}}\|\mathbf{A}\|_2$, where $\epsilon_{\text{mach}} \approx 2.2 \times 10^{-16}$ in double precision (Golub and

Van Loan 1996). A small perturbation can move a defective eigenvalue by a fractional power of ε.

1. Let $\mathbf{e}_1, \dots, \mathbf{e}_m$ be the standard basis vectors. Show that $\mathbf{J}_m(\lambda) + \varepsilon\, \mathbf{e}_m \mathbf{e}_1^{\top}$, which places ε in the lower-left corner of the Jordan block, has the eigenvalues $\lambda + \varepsilon^{1/m}\omega$, where ω ranges over the m-th roots of unity.
2. For $m = 1, \dots, 4$, form $\mathbf{Q}\mathbf{J}_m(2)\mathbf{Q}^{\top}$ with an orthogonal $\mathbf{Q}$ taken from the QR factorization of a Gaussian matrix, and record the median over 20 draws of $\max_i |\widehat{\lambda}_i - 2|$ for the computed eigenvalues $\widehat{\lambda}_i$. Compare with $\epsilon_{\text{mach}}^{1/m}$. Repeat with the symmetric matrix $\mathbf{Q}(2\mathbf{I})\mathbf{Q}^{\top}$.
3. Let $\mathbf{A}$ and $\mathbf{E}$ be symmetric. Use the Rayleigh proposition of Section 33.3.2.3 to show that $\lambda_{\max}(\mathbf{A} + \mathbf{E}) \le \lambda_{\max}(\mathbf{A}) + \|\mathbf{E}\|_2$ and $\lambda_{\min}(\mathbf{A} + \mathbf{E}) \ge \lambda_{\min}(\mathbf{A}) - \|\mathbf{E}\|_2$. How does this explain the symmetric result of (b)?
4. Prove the Courant–Fischer theorem $\lambda_j = \max_{\dim U = j} \min_{\mathbf{0} \neq \mathbf{x} \in U} R(\mathbf{x})$ for symmetric $\mathbf{A}$ with $\lambda_1 \ge \cdots \ge \lambda_n$. For the upper bound, intersect U with $\operatorname{span}(\mathbf{v}_j, \dots, \mathbf{v}_n)$, which has dimension $n - j + 1$, so the intersection is at least a line; for the lower bound take $U = \operatorname{span}(\mathbf{v}_1, \dots, \mathbf{v}_j)$. Deduce Weyl's inequality $|\lambda_j(\mathbf{A} + \mathbf{E}) - \lambda_j(\mathbf{A})| \le \|\mathbf{E}\|_2$ for every j, which extends (c) to all eigenvalues.

5. code **Spikes above the bulk.** ● Section 33.3.2.4 treats the Marchenko–Pastur bulk as the range of pure-noise eigenvalues. Suppose that the data contain one real direction: the n samples have independent Gaussian coordinates of variance 1, except the first coordinate, whose variance is $1 + \beta$. For $n \to \infty$ with $c = d/n$ fixed, Baik and Silverstein (2006) show that the largest eigenvalue of $\mathbf{C} = \frac{1}{n}\mathbf{X}^{\top}\mathbf{X}$ converges to

$$\lambda_{\max} \to \begin{cases} (1 + \sqrt{c})^2, & \beta \le \sqrt{c}, \\ (1 + \beta)\,(1 + c/\beta)\,, & \beta > \sqrt{c}. \end{cases}$$

   1. For $n = 2000$ and $d = 500$, compute the largest eigenvalue of $\mathbf{C}$ for $\beta \in \{0, 0.3, 0.5, 0.7, 1, 2\}$, averaged over five draws, and compare with the prediction.
   2. Fix $d = 500$ and $\beta = 0.4$. Use the formula to find the sample size n above which the largest eigenvalue leaves the bulk. Then increase the number of samples through $n \in \{500, 1000, 2000, 4000, 8000\}$, and compare the largest eigenvalue with the bulk edge, with the prediction, and with the largest eigenvalue for $\beta = 0$ at the same n. Why is the separation hard to see at $n = 4000$?
   3. A practitioner keeps the principal components whose eigenvalues exceed the bulk edge. How large must the variance of a direction be at $c = 1/4$ for it to be kept? How many samples per dimension are needed to detect a direction whose variance exceeds the others by 10%?

33.4 Spectra in Practice

In Section 33.3, our matrices were small enough to factor by hand, and their eigenvalues delivered on every promise: the surfer's error shrank by $1/4$ at every click, just as the second eigenvalue predicted. Outside textbook examples, both comforts vanish. The link matrix of the web has billions of rows, so nobody writes down its characteristic polynomial or computes a full eigendecomposition. Even when eigenvalues are known, they promise less than they appear to. A Jordan block whose eigenvalues are both 0.99 still grew to norm 37 before

decaying (Section 33.3.1.5), and backpropagation through a recurrent network multiplies a gradient by fifty *different* matrices rather than applying one matrix fifty times.

This section takes up those two problems in turn. First, what can we learn about the eigenvalues of a matrix that is far too large to factor? Surprisingly much: the entries alone confine all eigenvalues to a few discs in the complex plane, and repeated matrix–vector multiplication, the one operation that remains cheap at scale, finds the largest eigenvalue and its eigenvector. That is how PageRank was originally computed. Second, what do eigenvalues leave unsaid about a finite number of steps, or about a product of changing matrices? Here the answer is sobering. Eigenvalues govern the long-run behavior of powers of a single matrix; for anything else we need matrix norms, and ultimately the singular values of Section 33.5.

Not every topic below carries the same weight in deep learning, and it helps to know where to focus. Three ideas recur throughout the book. Power iteration (Section 33.4.1.2) estimates the largest stretch of a layer, which is the workhorse behind spectral normalization (Section 33.5.4.3). Transient growth and products of Jacobians (Section 33.4.2.3, Section 33.4.2.5) supply the mathematics behind the exploding and vanishing gradients of Section 8.5. And the random matrices of Section 33.4.2.6 model the weight matrices of Section 4.4 at initialization. Gershgorin's theorem and PageRank are classical highlights that appear less often in deep learning, so a reader in a hurry may skim both; pseudospectra (Section 33.4.2.4) are a specialized diagnostic that can likewise be skipped on a first reading. All numerical examples below use NumPy.

```
import numpy as np
```

33.4.1 Locating and Computing Eigenvalues

33.4.1.1 Gershgorin Discs

Can we tell roughly where the eigenvalues of a matrix lie without ever computing them? For a diagonal matrix, the eigenvalues are simply the diagonal entries. Intuition suggests that if the off-diagonal entries are small, the eigenvalues should stay close to those diagonal entries. The following theorem makes that intuition exact, and its proof takes only three lines.

Theorem (Gershgorin (Gershgorin 1931)**).** *Let $\mathbf{A} = (a_{ij})$ be any $n \times n$ matrix, and for each row i let $r_i = \sum_{j \neq i} |a_{ij}|$ be the sum of the absolute values of its off-diagonal entries. Let $\mathcal{D}_i$ be the closed disc in the complex plane with centre a_{ii} and radius r_i. Then every eigenvalue of $\mathbf{A}$ lies in the union $\bigcup_i \mathcal{D}_i$.*

Proof. Suppose $\mathbf{A}\mathbf{v} = \lambda \mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$, and pick an index i where $\mathbf{v}$ has its largest entry in magnitude, so that $|v_i| \geq |v_j|$ for all j and $v_i \neq 0$. Reading off row i of $\mathbf{A}\mathbf{v} = \lambda \mathbf{v}$ gives

$$\sum_j a_{ij} v_j = \lambda v_i \quad \Longrightarrow \quad (\lambda - a_{ii})\, v_i = \sum_{j \neq i} a_{ij} v_j .$$

Dividing both sides by v_i and taking absolute values, we use the fact that $|v_j / v_i| \leq 1$ for every j:

$$|\lambda - a_{ii}| = \Big|\sum_{j\neq i} a_{ij}\,\tfrac{v_j}{v_i}\Big| \le \sum_{j\neq i} |a_{ij}| = r_i,$$

which says that $\lambda \in \mathcal{D}_i$. $\blacksquare$

Notice what the proof actually tells us: each eigenvalue falls into the disc of the row where its eigenvector is largest. Because we do not know that row in advance, the theorem guarantees only that every eigenvalue lies somewhere in the union of all n discs. To see this in action, consider the non-symmetric matrix

$$\mathbf{A} = \begin{pmatrix} 4 & 1 & 0 \\ -1 & 4 & 0.5 \\ 0.5 & 0 & 1 \end{pmatrix}. \tag{33.37}$$

Its three discs have centres 4, 4, and 1, with radii 1, 1.5, and 0.5. The two discs centred at 4 overlap (in fact, one sits inside the other), whereas the disc centred at 1 is completely separated from them, because $|4-1| = 3 > 1.5 + 0.5$. The actual eigenvalues are $3.99 \pm 0.96i$ and 1.03: the complex conjugate pair sits inside the two discs centred at 4, and the real eigenvalue sits inside the isolated disc centred at 1. Figure 33.20 displays the discs alongside the eigenvalues.

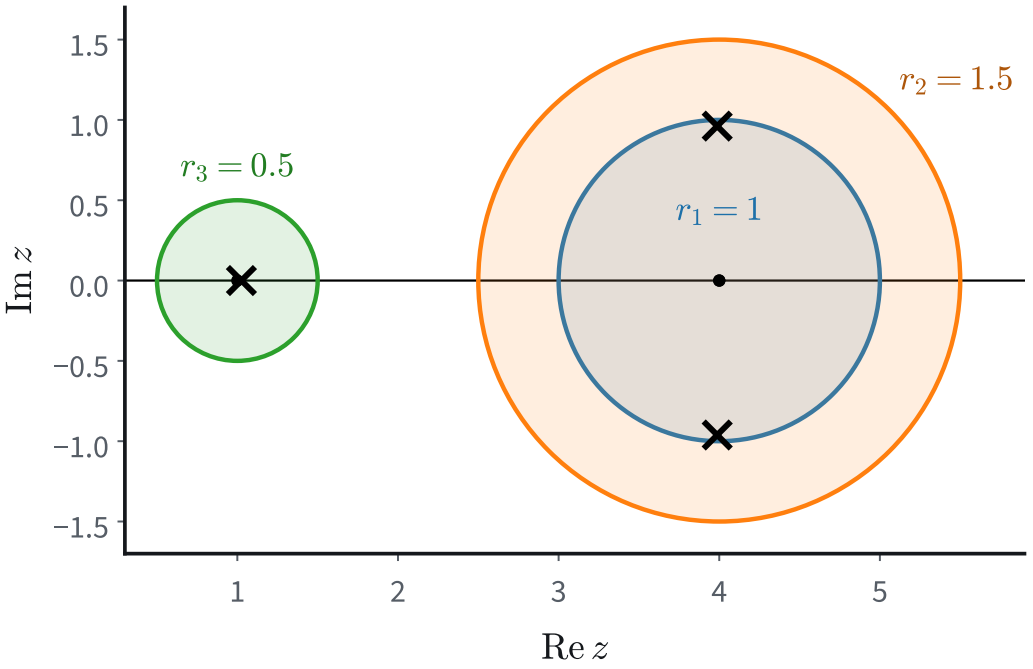

Figure 33.20: Gershgorin discs of the 3×3 matrix in the text (centres at the diagonal entries, radii given by the sums of the absolute off-diagonal entries in each row) and its eigenvalues (crosses). The two overlapping discs centred at 4 together hold two eigenvalues, the complex pair; the disjoint disc centred at 1 holds the third.

That split, with two eigenvalues in the overlapping pair and one in the isolated disc, is no accident. *If a union of m discs is connected and disjoint from all the remaining discs, it contains exactly m eigenvalues*, counted with multiplicity. The reason is continuity: as we scale the off-diagonal entries from zero up to their actual values, the eigenvalues start at the diagonal entries and move continuously, so they can never jump across the empty gap between separated groups of discs (Horn and Johnson 2012). Let us verify the centres, radii, and eigenvalues numerically.

```
A = np.array([[4.0, 1.0, 0.0],
              [-1.0, 4.0, 0.5],
              [0.5, 0.0, 1.0]])
centres = np.diag(A)
radii = np.abs(A).sum(axis=1) - np.abs(centres)
print('centres:', centres, '  radii:', radii)
for z in np.linalg.eigvals(A):
    print(f'eigenvalue {z:.3f}   distances to the centres: '
          f'{np.abs(z - centres).round(2)}')
```

```
centres: [4. 4. 1.]   radii: [1.  1.5 0.5]
eigenvalue 3.987+0.961j   distances to the centres: [0.96 0.96 3.14]
eigenvalue 3.987-0.961j   distances to the centres: [0.96 0.96 3.14]
eigenvalue 1.025+0.000j   distances to the centres: [2.97 2.97 0.03]
```

Here the complex pair sits at distance 0.96 from 4, right near the rim of the inner disc of radius 1, showing that Gershgorin's bound can be nearly tight.

One immediate corollary requires no computation at all. If $\mathbf{A}$ is *strictly diagonally dominant* with positive diagonal entries, meaning $a_{ii} > r_i$ for every i, then every disc lies strictly in the open right half-plane. Zero cannot be an eigenvalue, so $\mathbf{A}$ is automatically invertible. If $\mathbf{A}$ is also symmetric, its eigenvalues are real and strictly positive, which makes it positive definite.

33.4.1.2 Power Iteration

Gershgorin discs locate eigenvalues only roughly. What if we want an accurate eigenvalue of a matrix with a billion rows? Factoring such a matrix is out of the question, yet if it is sparse we can still multiply it by a vector cheaply. What happens if we start with a vector $\mathbf{v}_0$ and simply multiply by $\mathbf{A}$ over and over again?

The power expansion $\mathbf{A}^k\mathbf{x} = \sum_i c_i \lambda_i^k \mathbf{v}_i$ of Section 33.3.1.3 gives the answer. Suppose $\mathbf{A}$ is diagonalizable with eigenvectors $\mathbf{v}_i$, ordered by the magnitude of their eigenvalues, and suppose the largest eigenvalue is *strictly dominant*, meaning $|\lambda_1| > |\lambda_2| \geq \cdots \geq |\lambda_n|$. (When $\mathbf{A}$ is real, strict dominance forces λ_1 to be real as well, because a complex eigenvalue would share its modulus with its complex conjugate.) Expanding $\mathbf{v}_0 = \sum_i c_i \mathbf{v}_i$ and factoring out λ_1^k yields

$$\mathbf{A}^k \mathbf{v}_0 = \sum_{i=1}^{n} c_i \lambda_i^k \mathbf{v}_i = \lambda_1^k \Big(c_1 \mathbf{v}_1 + \sum_{i \geq 2} c_i \Big(\frac{\lambda_i}{\lambda_1} \Big)^k \mathbf{v}_i \Big). \tag{33.38}$$

Every ratio $|\lambda_i / \lambda_1|$ for $i \geq 2$ is strictly less than 1, so every trailing term vanishes as k grows. Provided $c_1 \neq 0$, the bracket converges to $c_1 \mathbf{v}_1$. Thus the direction of $\mathbf{A}^k \mathbf{v}_0$ approaches the

dominant eigenvector $\mathbf{v}_1$ with an error decaying like $|\lambda_2/\lambda_1|^k$, while its length scales by a factor approaching $|\lambda_1|$ at each step. To keep the entries from overflowing or underflowing, we normalize the vector back to unit length after every multiplication; this simple loop is *power iteration* (Golub and Van Loan 1996). When $\mathbf{A}$ is symmetric, we can do even better for the eigenvalue itself: the Rayleigh quotient of the current iterate converges to λ_1 at the squared rate $|\lambda_2/\lambda_1|^{2k}$. Because the eigenvectors of a symmetric matrix are orthogonal, a directional misalignment of size δ shifts the Rayleigh quotient only by $O(\delta^2)$ (Exercise 2).

We can see both rates in a concrete 2×2 example. In Section 1.3, we computed the iterates of $\mathbf{S} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ starting from $\mathbf{e}_1$: $(2,1)$, $(5,4)$, $(14,13)$, and in general $((3^k+1)/2,\ (3^k-1)/2)$. In terms of the unit eigenvectors $\mathbf{v}_1 = (1,1)/\sqrt{2}$ and $\mathbf{v}_2 = (1,-1)/\sqrt{2}$, we have $\mathbf{e}_1 = (\mathbf{v}_1+\mathbf{v}_2)/\sqrt{2}$, so

$$\mathbf{S}^k\mathbf{e}_1 = \frac{3^k\mathbf{v}_1 + \mathbf{v}_2}{\sqrt{2}}, \qquad \tan\angle(\mathbf{S}^k\mathbf{e}_1, \mathbf{v}_1) = 3^{-k}, \qquad 3 - R(\mathbf{S}^k\mathbf{e}_1) = \frac{2}{9^k+1}.$$

With $|\lambda_2/\lambda_1| = 1/3$, the directional error drops by a factor of 3 at every step: the sine of the angle to $\mathbf{v}_1$ is 0.316, 0.110, and 0.037 for $k = 1, 2, 3$. Meanwhile the Rayleigh-quotient error drops by a factor of 9 per step: 0.2, 0.024, and 0.0027. Figure 33.21 plots both curves on a logarithmic scale.

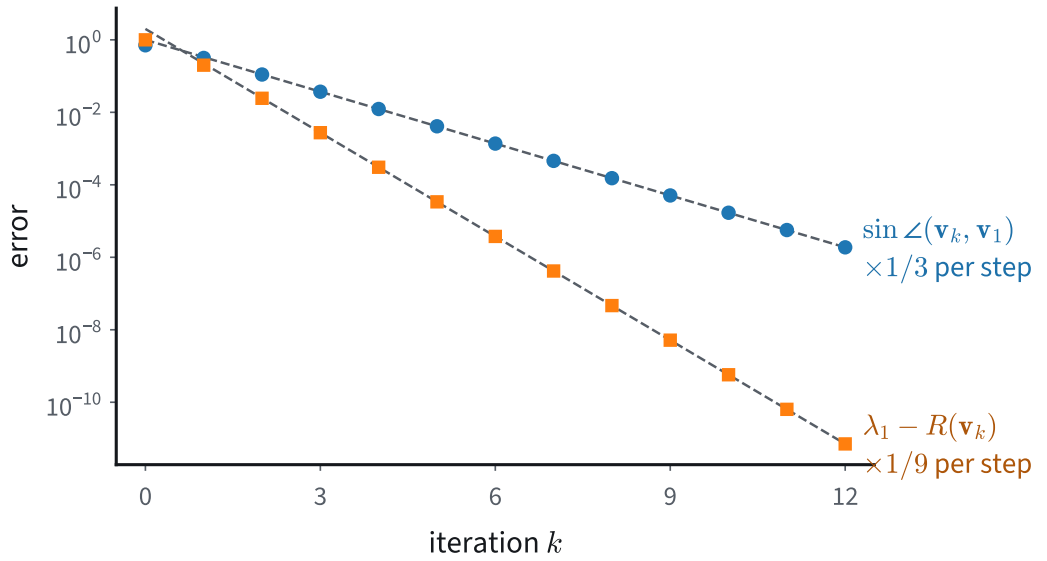

Figure 33.21: Power iteration on $\mathbf{S} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ starting from $\mathbf{e}_1$. The direction error drops by a factor of 3 per step, whereas the eigenvalue estimate improves by a factor of 9 per step, the squared rate that comes from orthogonal eigenvectors. Dashed lines show 3^{-k} and $2\cdot 9^{-k}$.

When can power iteration fail? Two assumptions in Equation 33.38 matter. First, the starting vector needs a nonzero component along $\mathbf{v}_1$ ($c_1 \neq 0$); choosing $\mathbf{v}_0$ at random guarantees this with probability one. Second, the largest eigenvalue must be strictly dominant. If the largest modulus is shared by a complex conjugate pair, the dominant component of the iterate rotates indefinitely instead of settling on a single line. The ratio of consecutive norms

then oscillates forever, just as it did for the running matrix of Section 33.3.1.6. Even in that case, however, the geometric average $\|\mathbf{A}^k\mathbf{v}_0\|^{1/k}$ still converges to the largest modulus.

Matrices with strictly positive entries avoid this trouble altogether: as we will see in Section 33.4.1.3, the Perron–Frobenius theorem guarantees a real, simple, strictly dominant eigenvalue. Let us test this by running 200 steps of power iteration on a random 5×5 matrix with entries drawn uniformly from $[0, 1]$, starting from a random vector, and comparing the final norm ratio with the true largest eigenvalue modulus.

```
A = np.random.rand(5, 5)                # positive entries
v = np.random.randn(5)
for _ in range(200):
    Av = A @ v
    ratio = np.linalg.norm(Av) / np.linalg.norm(v)
    v = Av / np.linalg.norm(Av)
mods = np.sort(np.abs(np.linalg.eigvals(A)))[::-1]
print(f'norm ratio after 200 steps = {ratio:.10f}')
print(f'largest |eigenvalue|       = {mods[0]:.10f}')
print(f'|lambda_2| / |lambda_1|    = {mods[1] / mods[0]:.3f}')
```

```
norm ratio after 200 steps = 1.9587653322
largest |eigenvalue|       = 1.9587653322
|lambda_2| / |lambda_1|    = 0.370
```

On every draw, the norm ratio matches the largest eigenvalue modulus to all printed digits. To see how typical this fast convergence is, let us compute the gap ratio $|\lambda_2/\lambda_1|$ across 10,000 such positive matrices. For comparison, we also draw 10,000 matrices with standard Gaussian entries, which have no positivity guarantee, and measure how often their dominant eigenvalues form a complex conjugate pair.

```
mods = np.sort(np.abs(np.linalg.eigvals(np.random.rand(10000, 5, 5))), axis=1)
print('uniform entries, gap ratio |lambda_2| / |lambda_1|, 5% and 95% quantiles:',
      np.quantile(mods[:, -2] / mods[:, -1], [0.05, 0.95]).round(2))
lam = np.linalg.eigvals(np.random.randn(10000, 5, 5))
top = lam[np.arange(10000), np.abs(lam).argmax(axis=1)]   # a dominant eigenvalue
print('Gaussian entries, fraction with a complex dominant pair:',
      np.mean(top.imag != 0).round(2))
```

```
uniform entries, gap ratio |lambda_2| / |lambda_1|, 5% and 95% quantiles: [0.14 0.36]
Gaussian entries, fraction with a complex dominant pair: 0.43
```

For uniform positive entries, the gap ratio falls between roughly 0.14 and 0.37 in nine draws out of ten, so 200 iterations drive the direction error far below floating-point precision. For Gaussian entries, by contrast, about four draws in ten have a complex dominant pair, and on those matrices the norm ratio never settles.

33.4.1.3 PageRank

For matrices with non-negative entries, the dominant eigenvector is often the very object we care about, and power iteration is how we compute it. To state when that eigenvector is unique and well behaved, call a non-negative matrix *irreducible* if, in the directed graph that places an edge $j \to i$ whenever $a_{ij} > 0$, every node can reach every other node. The *Perron–*

Frobenius theorem (Horn and Johnson 2012) guarantees that any irreducible non-negative matrix has a real, positive eigenvalue equal to the largest modulus among all its eigenvalues, that this eigenvalue is simple, and that its eigenvector can be chosen with strictly positive entries. If every entry of the matrix is strictly positive, this eigenvalue is also strictly dominant, meaning every other eigenvalue has strictly smaller modulus.

Google's original PageRank algorithm (Brin and Page 1998) turns web ranking into exactly such an eigenvector problem. Consider a miniature web of three pages with links $1 \to 2$, $2 \to 1$, and $2 \to 3$. A random surfer follows an outgoing link chosen uniformly at random. Page 3 has no outgoing links, so we repair that dead end by letting the surfer jump from page 3 to any page with equal probability. The repaired transition matrix $\mathbf{P}$ is column-stochastic, with column j holding the click probabilities out of page j:

$$\mathbf{P} = \begin{pmatrix} 0 & \tfrac{1}{2} & \tfrac{1}{3} \\ 1 & 0 & \tfrac{1}{3} \\ 0 & \tfrac{1}{2} & \tfrac{1}{3} \end{pmatrix}.$$

In the long run, the fraction of time the surfer spends on each page is the stationary distribution π satisfying $\mathbf{P}\pi = \pi$. We can solve this by hand: rows 1 and 3 both give $\pi_1 = \tfrac{1}{2}\pi_2 + \tfrac{1}{3}\pi_3 = \pi_3$, and substituting $\pi_1 = \pi_3$ back into row 1 gives $\pi_2 = \tfrac{4}{3}\pi_3$. Normalizing the entries to sum to 1 yields $\pi = (0.3, 0.4, 0.3)$. Page 2 ranks first because page 1 sends it all of its clicks, whereas page 2 splits its clicks between pages 1 and 3. The eigenvalues of $\mathbf{P}$ are 1, $-\tfrac{2}{3}$, and 0, so power iteration from any initial distribution converges at the rate $2/3$ per step.

In fact, *every* column-stochastic matrix has 1 as an eigenvalue of largest modulus. First, because every column sums to 1, we have $\mathbf{1}^{\top}\mathbf{P} = \mathbf{1}^{\top}$, which means 1 is an eigenvalue of $\mathbf{P}^{\top}$, and therefore also of $\mathbf{P}$ (a matrix and its transpose share the same characteristic polynomial, because $\det \mathbf{X}^{\top} = \det \mathbf{X}$). Second, applying Gershgorin's theorem to $\mathbf{P}^{\top}$, whose rows are the columns of $\mathbf{P}$, places every eigenvalue inside a disc with centre $p_{ii} \geq 0$ and radius $1 - p_{ii}$; every such disc sits inside the unit disc.

The real web, however, is messier than our three-page example: it contains link cycles and isolated pockets of pages from which a surfer cannot escape. The repaired matrix $\mathbf{P}$ can then fail to be irreducible or can have several eigenvalues of modulus 1. For instance, a simple cycle of four pages has eigenvalues ± 1 and $\pm i$, so undamped power iteration on it never settles (Exercise 4). PageRank solves both problems at once by iterating the *damped* matrix

$$\mathbf{G} = \alpha \mathbf{P} + (1 - \alpha)\tfrac{1}{n}\mathbf{1}\mathbf{1}^{\top}, \qquad \alpha = 0.85,$$

which describes a surfer who follows a random link with probability 0.85 and teleports to a uniformly random page with probability 0.15. Because every entry of $\mathbf{G}$ is strictly positive, the Perron–Frobenius theorem applies by construction. Better still, Haveliwala and Kamvar (2003) show that $|\lambda_2(\mathbf{G})| \leq \alpha$, so the error of power iteration shrinks by at least a factor of 0.85 at every step, no matter how tangled the link graph is. That single bound made web-scale PageRank practical: fifty sweeps cut the error by more than a factor of 3000 ($0.85^{50} \approx 3 \times 10^{-4}$), regardless of how many billions of pages are in the graph.

At web scale, $\mathbf{P}$ is stored sparsely as one entry per link, and the dense matrix $\mathbf{G}$ is never formed explicitly. For any probability vector $\mathbf{p}$ (where $\mathbf{1}^{\top}\mathbf{p} = 1$), we can evaluate $\mathbf{G}\mathbf{p} =$

$\alpha \mathbf{P}\mathbf{p} + (1-\alpha)\frac{1}{n}\mathbf{1}$ using just one sparse matrix–vector product plus a constant shift. The dead-end repair for pages with no outgoing links is a rank-one term handled in the same way.

33.4.2 Iteration and Stability

33.4.2.1 The Spectral Radius

Power iteration singled out one number: the largest eigenvalue modulus. That number is called the *spectral radius*, $\rho(\mathbf{A}) = \max_i |\lambda_i|$, and it governs the long-run growth rate of the powers of a single fixed matrix. Gelfand's formula makes this exact: for every square matrix $\mathbf{A}$ and every matrix norm,

$$\lim_{k \to \infty} \|\mathbf{A}^k\|^{1/k} = \rho(\mathbf{A}).$$

The easier half of this statement, $\rho(\mathbf{A}) \le \|\mathbf{A}^k\|^{1/k}$ for every $k \ge 1$, is Exercise 1.

What Gelfand's formula does *not* tell us is what happens at any fixed, finite step k, and we have already met two matrices where that gap matters. The shear $\mathbf{T} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$ has $\rho(\mathbf{T}) = 1$, yet its powers $\mathbf{T}^k = \left(\begin{smallmatrix} 1 & k \\ 0 & 1 \end{smallmatrix}\right)$ grow without bound, so $\rho \le 1$ does not even keep the iterates bounded. The Jordan block $\mathbf{J}_2(0.99)$ has $\rho < 1$ and must eventually decay to zero, yet its powers climb to norm 37 before turning downward, so $\rho < 1$ does not rule out large transient growth. When, then, do the eigenvalues control *every* step rather than only the distant limit?

33.4.2.2 Normal Matrices

Both of our counterexamples, the shear and the Jordan block, are defective: they lack enough eigenvectors to form a basis. Let us go straight to the opposite extreme and consider matrices that admit an *orthonormal* basis of eigenvectors. Such a matrix acts independently along mutually perpendicular directions, so its eigenvalues ought to tell the whole story at every step.

A real matrix is called *normal* if it commutes with its transpose, $\mathbf{A}^\top \mathbf{A} = \mathbf{A}\mathbf{A}^\top$ (for a complex matrix, we replace the transpose by the conjugate transpose $\mathbf{A}^*$, requiring $\mathbf{A}^*\mathbf{A} = \mathbf{A}\mathbf{A}^*$). Symmetric matrices, orthogonal matrices, and the rotation–scaling blocks $r\mathbf{R}_\theta$ of Section 33.3.1.6 are all normal. By contrast, our running example $\mathbf{A} = \left(\begin{smallmatrix} 1 & 2 \\ -1 & 3 \end{smallmatrix}\right)$ is not normal: $\mathbf{A}\mathbf{A}^\top = \left(\begin{smallmatrix} 5 & 5 \\ 5 & 10 \end{smallmatrix}\right)$, whereas $\mathbf{A}^\top\mathbf{A} = \left(\begin{smallmatrix} 2 & -1 \\ -1 & 13 \end{smallmatrix}\right)$. That failure to commute is the reason its iterates spiraled along ellipses rather than circles.

The *complex spectral theorem* (Horn and Johnson 2012) characterizes this class completely: a matrix is normal if and only if it has an orthonormal eigenbasis over $\mathbb{C}$, meaning $\mathbf{A} = \mathbf{U}\Lambda\mathbf{U}^*$ with $\mathbf{U}$ unitary ($\mathbf{U}^*\mathbf{U} = \mathbf{I}$). The proof follows the same inductive argument as the real spectral theorem in Section 33.3.2.1.

To measure the worst-case amplification in a single step, write $\|\mathbf{X}\|_2 = \max_{\|\mathbf{x}\|=1} \|\mathbf{X}\mathbf{x}\|$ for the *spectral norm* of $\mathbf{X}$, the largest factor by which $\mathbf{X}$ can stretch a vector. Because a unitary change of basis preserves Euclidean lengths, every power of a normal matrix satisfies

$$\|\mathbf{A}^k\|_2 = \|\mathbf{U}\Lambda^k\mathbf{U}^*\|_2 = \max_i |\lambda_i|^k = \rho(\mathbf{A})^k. \tag{33.39}$$

For a normal matrix, the eigenvalues control the worst-case amplification at every single step k, not just asymptotically.

What happens when $\mathbf{A}$ is diagonalizable, $\mathbf{A} = \mathbf{V}\Lambda\mathbf{V}^{-1}$, but not normal? Now the eigenvector matrix $\mathbf{V}$ is no longer orthogonal, and submultiplicativity of the spectral norm gives only the upper bound

$$\|\mathbf{A}^k\|_2 \le \underbrace{\|\mathbf{V}\|_2\|\mathbf{V}^{-1}\|_2}_{\kappa_2(\mathbf{V})}\,\rho(\mathbf{A})^k. \tag{33.40}$$

The prefactor $\kappa_2(\mathbf{V})$ is the condition number (Section 33.5.3.2) of the eigenvector matrix. It equals 1 when the eigenvectors are orthogonal, and grows arbitrarily large when two eigenvectors point in nearly the same direction. The transient growth it permits has a clean geometric cause: cancellation. When eigenvectors are nearly parallel, an ordinary unit vector can only be expressed as a combination of huge eigen-components that nearly cancel each other out. As we apply $\mathbf{A}$ repeatedly, those components decay at different rates, the delicate cancellation comes undone, and the iterate balloons in length before the common exponential decay finally takes over.

33.4.2.3 Transient Growth

The simplest matrix that displays this transient growth is the upper-triangular 2×2 matrix

$$\mathbf{M} = \begin{pmatrix} 0.9 & 4 \\ 0 & 0.8 \end{pmatrix}. \tag{33.41}$$

Its eigenvalues are its diagonal entries 0.9 and 0.8. Both lie safely inside the unit circle, and because they are distinct, $\mathbf{M}$ is diagonalizable. Let us compute its eigenvectors by hand and expand the unit vector $\mathbf{e}_2 = (0, 1)$ in them. For $\lambda = 0.9$, the second row of $\mathbf{M} - 0.9\mathbf{I}$ reads $-0.1v_2 = 0$, giving $\mathbf{v}_1 = (1, 0)$. For $\lambda = 0.8$, the first row of $\mathbf{M} - 0.8\mathbf{I}$ reads $0.1v_1 + 4v_2 = 0$, giving $\mathbf{v}_2 = (-40, 1)$. Notice how close these two directions are: the angle between them is only $\arctan(1/40) \approx 1.4^\circ$. Expanding $\mathbf{e}_2$ in this nearly parallel basis gives $\mathbf{e}_2 = 40\mathbf{v}_1 + \mathbf{v}_2$, and applying the eigenvector power expansion (Section 33.3.1.3) yields

$$\mathbf{M}^k\mathbf{e}_2 = 40 \cdot 0.9^k\,\mathbf{v}_1 + 0.8^k\,\mathbf{v}_2 = \begin{pmatrix} 40\,(0.9^k - 0.8^k) \\ 0.8^k \end{pmatrix}. \tag{33.42}$$

At $k = 0$, a vector of length 1 is formed as the difference of two eigen-components of length roughly 40. Both components decay at every step, yet because 0.8^k falls faster than 0.9^k, their cancellation unravels and the sum initially grows. The first coordinate $40(0.9^k - 0.8^k)$ peaks where its derivative with respect to k vanishes, namely where $(9/8)^k = \ln 0.8 / \ln 0.9$, which occurs at $k \approx 6.4$ with a height of about 10.8. Figure 33.22 illustrates the two components at $k = 0$ and at $k = 6$. For comparison, the general bound Equation 33.40 with unit eigenvectors has $\kappa_2(\mathbf{V}) = 80$ and predicts $\|\mathbf{M}^6\|_2 \le 80 \cdot 0.9^6 \approx 42.5$. The bound holds, though it is conservative by a factor of four compared with the true peak of 10.8.

Let us check this calculation numerically and compare $\mathbf{M}$ against the diagonal matrix $\Lambda = \mathrm{diag}(0.9, 0.8)$, which has the exact same eigenvalues but is normal.

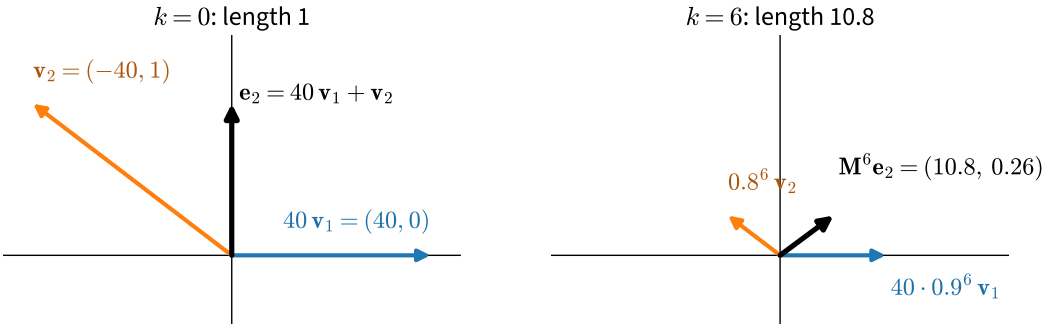

Figure 33.22: Growth of $\mathbf{M}^k\mathbf{e}_2$ before decay. Left: at $k = 0$, the unit vector $\mathbf{e}_2$ is the difference of two eigen-components of length about 40 that nearly cancel. Right: six steps later the two components have decayed by 0.9^6 and 0.8^6, breaking the cancellation and producing a vector more than ten times longer. The vertical axis is stretched about 30-fold; drawn to scale, $\mathbf{v}_1$ and $\mathbf{v}_2$ are only 1.4° apart.

```
M = np.array([[0.9, 4.0], [0.0, 0.8]])
Lam = np.diag([0.9, 0.8])                  # same eigenvalues, normal
lam, V = np.linalg.eig(M)                  # unit eigenvectors as columns
print('eigenvalues:', lam)
print('coefficients of e_2 on the unit eigenvectors:',
      np.linalg.solve(V, [0., 1.]))
ks = np.arange(61)
norm_M = [np.linalg.norm(np.linalg.matrix_power(M, k), 2) for k in ks]
norm_L = [np.linalg.norm(np.linalg.matrix_power(Lam, k), 2) for k in ks]
k_peak = int(np.argmax(norm_M))
print(f'max ||M^k|| = {norm_M[k_peak]:.3f} at k = {k_peak};  '
      f'max ||Lambda^k|| = {max(norm_L):.3f}')
print(f'kappa_2(V) = {np.linalg.cond(V):.1f}')
```

```
eigenvalues: [0.9 0.8]
coefficients of e_2 on the unit eigenvectors: [40.         40.01249805]
max ||M^k|| = 10.788 at k = 6;  max ||Lambda^k|| = 1.000
kappa_2(V) = 80.0
```

Expressed in the unit eigenvectors, $\mathbf{e}_2$ carries two coefficients of magnitude about 40, matching the lengths of $40\mathbf{v}_1$ and $\mathbf{v}_2$. The spectral norm $\|\mathbf{M}^k\|_2$ climbs to 10.8 at $k = 6$, whereas $\|\Lambda^k\|_2$ never exceeds its starting value of 1. Even though both matrices share the same eigenvalues, the normal matrix contracts from the very first step while the non-normal matrix grows more than ten-fold before decaying. The left panel of Figure 33.23 plots both trajectories on a logarithmic scale; past the peak, both curves eventually descend with the same slope $\log 0.9$, just as Gelfand's formula guarantees.

33.4.2.4 Pseudospectra

This subsection adds a diagnostic for non-normality rather than a new phenomenon, and may be skipped on a first pass. Beyond transient growth, a second symptom of non-normality is extreme sensitivity of the eigenvalues to small perturbations. To make that

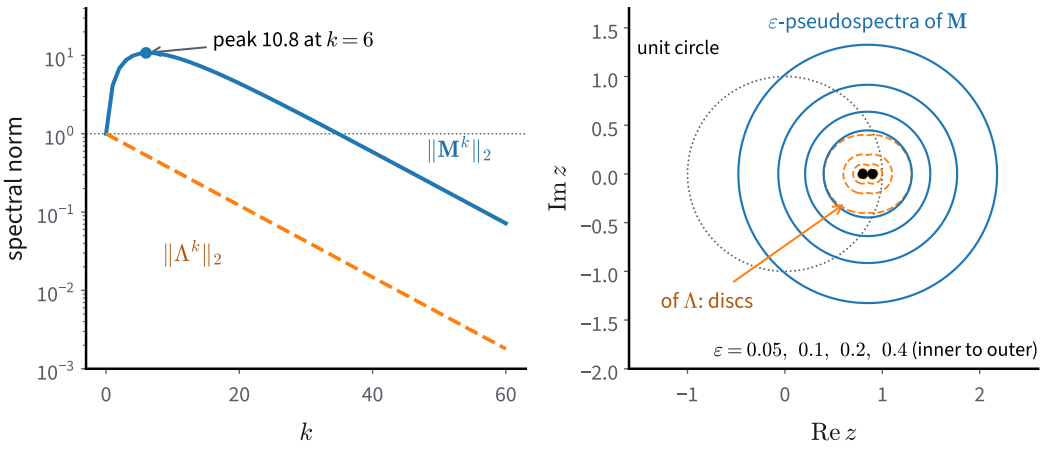

Figure 33.23: Left: $\|\mathbf{M}^k\|_2$ and $\|\Lambda^k\|_2$ for the same eigenvalues 0.9 and 0.8; $\mathbf{M}$ climbs to 10.8 at $k = 6$ before both curves decay with slope $\log 0.9$. Right: the ε-pseudospectra for $\varepsilon = 0.05, 0.1, 0.2, 0.4$; around the normal matrix Λ they are simply discs of radius ε, whereas around $\mathbf{M}$ they bulge far past the unit circle.

sensitivity visible, the *ε-pseudospectrum* collects every complex number that becomes an eigenvalue of $\mathbf{A} + \mathbf{E}$ for some perturbation $\mathbf{E}$ of spectral norm at most ε. Conveniently, the same set can be computed directly from the *resolvent* $(z\mathbf{I} - \mathbf{A})^{-1}$:

$$\begin{aligned} \Lambda_\varepsilon(\mathbf{A}) &= \{z \in \mathbb{C} : z \text{ is an eigenvalue of } \mathbf{A} + \mathbf{E} \text{ for some } \|\mathbf{E}\|_2 \le \varepsilon\} \\ &= \{z \in \mathbb{C} : \|(z\mathbf{I} - \mathbf{A})^{-1}\|_2 \ge 1/\varepsilon\}, \end{aligned} \tag{33.43}$$

where the resolvent norm is taken to be infinite at the eigenvalues of $\mathbf{A}$ itself. Proving the equivalence of these two descriptions is Exercise 3. For a normal matrix, the resolvent norm at z is simply the reciprocal of the distance from z to the nearest eigenvalue, so $\Lambda_\varepsilon(\mathbf{A})$ is just the union of discs of radius ε around the eigenvalues. For a non-normal matrix like $\mathbf{M}$, the resolvent norm can be vastly larger, as we can check at $z = 1$ on the unit circle.

```
I = np.eye(2)
print(f'||(I - M)^-1||      = {np.linalg.norm(np.linalg.inv(I - M), 2):.1f}')
print(f'||(I - Lambda)^-1|| = {np.linalg.norm(np.linalg.inv(I - Lam), 2):.1f}')
```

```
||(I - M)^-1||      = 200.3
||(I - Lambda)^-1|| = 10.0
```

For Λ the resolvent norm is 10, the reciprocal of the distance 0.1 from 1 to the eigenvalue 0.9. For $\mathbf{M}$ it jumps to 200.3: a tiny perturbation of size $1/200.3 \approx 0.005$ already pushes an eigenvalue of $\mathbf{M}$ onto the unit circle, whereas Λ requires a perturbation twenty times larger, of size 0.1 (right panel of Figure 33.23). Because floating-point rounding acts like a small perturbation to the matrix entries, the numerically computed eigenvalues of a strongly non-normal matrix can be surprisingly inaccurate. Section 33.6 follows this thread further with the Kreiss matrix theorem.

33.4.2.5 Products of Jacobians

So far we have multiplied a vector by the *same* matrix repeatedly. Recurrent neural networks (Section 8.5) break even that assumption. A recurrent layer updates its hidden state as $\mathbf{h}_t = \phi(\mathbf{W}\mathbf{h}_{t-1} + \cdots)$, using the same weight matrix $\mathbf{W}$ at every step, yet backpropagation through time multiplies the gradient by the sequence of per-step Jacobians $\mathbf{D}_t = \partial \mathbf{h}_t / \partial \mathbf{h}_{t-1}$:

$$\nabla_{\mathbf{h}_0} \mathcal{L} = \mathbf{D}_1^\top \mathbf{D}_2^\top \cdots \mathbf{D}_T^\top \nabla_{\mathbf{h}_T} \mathcal{L}.$$

Because the nonlinearity ϕ is evaluated at a different hidden state at each time step, the Jacobians $\mathbf{D}_1, \dots, \mathbf{D}_T$ are different matrices, and the theory of powers of a single matrix no longer applies.

In fact, the spectral radii of the individual factors tell us nothing at all about their product. Consider the two 2×2 matrices

$$\mathbf{D}_1 = \begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix}, \qquad \mathbf{D}_2 = \begin{pmatrix} 0 & 0 \\ 2 & 0 \end{pmatrix}, \qquad \mathbf{D}_2 \mathbf{D}_1 = \begin{pmatrix} 0 & 0 \\ 0 & 4 \end{pmatrix}.$$

Both $\mathbf{D}_1$ and $\mathbf{D}_2$ are nilpotent with $\rho = 0$, so every power of either matrix vanishes by the second step. Yet their product has $\rho = 4$: $\mathbf{D}_1$ copies the second coordinate into the first while doubling it, and $\mathbf{D}_2$ copies it straight back while doubling it again.

It is therefore helpful to keep three distinct quantities straight when studying iterated linear maps. The *spectral radius* gives the asymptotic growth rate of powers of one fixed matrix. The *spectral norm* bounds any finite product of changing matrices, because submultiplicativity gives $\|\mathbf{D}_T \cdots \mathbf{D}_1\|_2 \le \prod_t \|\mathbf{D}_t\|_2$ (in our example, $4 \le 2 \cdot 2$). Finally, the *top Lyapunov exponent*

$$\mu = \lim_{T \to \infty} \frac{1}{T} \log \|\mathbf{D}_T \cdots \mathbf{D}_1 \mathbf{x}_0\|$$

measures the average logarithmic growth rate per step along a long product of changing matrices. When the factors are independent and identically distributed random matrices, this limit exists with probability one under mild conditions (Furstenberg and Kesten 1960).

When a gradient passes backward through a sequence of Jacobians with $\mu > 0$, it grows exponentially and explodes; when $\mu < 0$, it shrinks exponentially and vanishes (Bengio et al. 1994; Pascanu et al. 2013). Notice that the standard remedies in deep learning target norms and Jacobians rather than eigenvalues. Orthogonal initialization (Saxe et al. 2014) chooses an orthogonal weight matrix so that a linear recurrence preserves the Euclidean length of every vector at every step, a much stronger guarantee than $\rho = 1$. Gradient clipping caps the norm of the gradient directly after backpropagation. Gated architectures such as LSTMs and GRUs alter the Jacobians themselves, creating pathways along which selected directions pass through with factors close to 1 (Section 8.5.1.1).

33.4.2.6 Random Matrices at Initialization

How large are the spectral radius and spectral norm for the random weight matrices of a freshly initialized neural network? Consider an $n \times n$ matrix $\mathbf{A}$ with independent standard

Gaussian entries, known as the real *Ginibre ensemble* (Ginibre 1965). As $n \to \infty$, the eigenvalues rescaled by $1/\sqrt{n}$ spread uniformly over the unit disc in the complex plane. This is the *circular law*, which Tao and Vu (2010) proved in general for independent, identically distributed entries of mean 0 and variance 1. The circular law tells us where almost all eigenvalues live, though by itself it does not rule out a few stray outliers. A separate theorem establishes that no outlier escapes the unit circle, so $\rho(\mathbf{A})/\sqrt{n} \to 1$ with probability one (Geman 1986).

The spectral norm behaves quite differently: $\|\mathbf{A}\|_2/\sqrt{n} \to 2$ (Yin et al. 1988). This is a special case of the Marchenko–Pastur law (Section 33.3.2.4) at aspect ratio $c = 1$: the largest eigenvalue of $\frac{1}{n}\mathbf{A}^\top\mathbf{A}$ converges to the upper edge $(1+\sqrt{c})^2 = 4$, and $\|\mathbf{A}\|_2^2$ is simply n times that eigenvalue. Even at $n = 1000$, a single random draw sits right next to both asymptotic limits.

```
n = 1000
A = np.random.randn(n, n)
print(f'rho(A) / sqrt(n)       = {np.abs(np.linalg.eigvals(A)).max() / n ** 0.5:.3f}')
print(f'sigma_max(A) / sqrt(n) = {np.linalg.norm(A, 2) / n ** 0.5:.3f}')
```

```
rho(A) / sqrt(n)       = 1.021
sigma_max(A) / sqrt(n) = 1.975
```

At large n, the spectral radius lands within a few percent of $\sqrt{n}$ while the largest stretch sits close to $2\sqrt{n}$: a random Gaussian matrix stretches certain vectors twice as far as its eigenvalues would lead you to expect. Standard initialization schemes divide random weights by $\sqrt{\text{fan-in}}$ for a different reason altogether. With entries of variance $1/n$, we get $\mathbb{E}\|\mathbf{Ax}\|^2 = \|\mathbf{x}\|^2$ for every fixed vector $\mathbf{x}$, so squared lengths are preserved on average. Having a spectral radius near 1 is merely a side effect, and as Section 33.4.2.5 showed, it does not control a product of different matrices. Surprisingly, a long product of independent matrices with this exact scaling *shrinks* a typical vector, giving $\mu < 0$, even though every individual factor preserves squared length on average. The reason is the concavity of the logarithm: for a unit vector $\mathbf{x}$, the expectation of $\log\|\mathbf{Ax}\|^2$ lies strictly below the logarithm of the expectation of $\|\mathbf{Ax}\|^2$ (which is $\log 1 = 0$), and it is the logarithms that add up along a deep product (Exercise 5).

Both the non-normal matrix $\mathbf{M}$ and the random Gaussian matrix point to the same conclusion: eigenvalues tell us little about how much a matrix stretches vectors over a finite number of steps, and for rectangular matrices eigenvalues do not even exist. To measure stretching directly, for any matrix of any shape, we turn next to the singular values of Section 33.5.

33.4.3 Summary

Even without factoring a matrix, Gershgorin discs locate its eigenvalues directly from its entries, and power iteration extracts the dominant eigenpair at the geometric rate $|\lambda_2/\lambda_1|$, the mechanism behind PageRank. The spectral radius $\rho(\mathbf{A})$ governs the long-run rate of powers of a single fixed matrix and nothing more: a non-normal matrix can grow dramatically before it decays, and the eigenvalues of individual factors reveal nothing about a product of changing matrices. For products of changing maps, the spectral norm bounds finite steps and the top Lyapunov exponent gives the average long-run rate. A random $n \times n$ Gaussian matrix at initialization makes the gap between eigenvalues and stretching concrete:

its spectral radius is close to $\sqrt{n}$, whereas its spectral norm is close to $2\sqrt{n}$.

33.4.4 Exercises

1. **Spectral radius and norms.** The spectral radius bounds every power of a matrix from below, and for normal matrices it also bounds them from above.

   1. Show that $\rho(\mathbf{A}) \le \|\mathbf{A}^k\|_2^{1/k}$ for every square matrix $\mathbf{A}$ and every $k \ge 1$.
   2. The chain Equation 33.39 uses two facts without proof. Show that $\|\mathbf{U}\mathbf{X}\mathbf{U}^*\|_2 = \|\mathbf{X}\|_2$ for every unitary $\mathbf{U}$ and every square $\mathbf{X}$, and that the spectral norm of a diagonal matrix is the largest modulus of its diagonal entries.
   3. Show that the converse of Equation 33.39 fails: find a 3×3 matrix that is not normal but satisfies $\|\mathbf{A}^k\|_2 = \rho(\mathbf{A})^k$ for every $k \ge 1$.
   4. For a given $t > 0$, construct a diagonalizable 2×2 matrix with spectral radius $1/2$ and $\|\mathbf{A}\|_2 > t$.

2. code **Power-iteration rates.** Let $\mathbf{S}$ be the matrix of Figure 33.21.

   1. By Equation 33.38, the misalignment between the iterate and $\mathbf{v}_1$ decays at the rate $|\lambda_2/\lambda_1| = 1/3$. How many iterations reduce it by a factor of 100?
   2. Let $\mathbf{A}$ be symmetric with unit eigenvector $\mathbf{v}_1$ for λ_1, and let $\mathbf{x} = \mathbf{v}_1 + \delta\mathbf{u}$ for a unit vector $\mathbf{u}$ orthogonal to $\mathbf{v}_1$. Show that the Rayleigh quotient of Section 33.3.2.3 satisfies $R(\mathbf{x}) - \lambda_1 = O(\delta^2)$, with no term linear in δ. At which rate does the Rayleigh quotient of the power iterates therefore approach λ_1? Where does the argument use that $\mathbf{A}$ is symmetric?
   3. Repeat the experiment of Figure 33.21 for $\left(\begin{smallmatrix} 1 & 0.1 \\ 0.1 & 1 \end{smallmatrix}\right)$, which has the same eigenvectors as $\mathbf{S}$ and the eigenvalues 1.1 and 0.9, from a random start. Plot the sine of the angle to $\mathbf{v}_1$ and the error of the Rayleigh quotient on a logarithmic scale for 30 steps. Predict both slopes and the number of steps each error needs to shrink by a factor of 100, and explain why this matrix converges so much more slowly than $\mathbf{S}$.

3. code **Pseudospectra and transient growth.** ● Let $\mathbf{M}$ be the non-normal matrix Equation 33.41 and $\Lambda = \operatorname{diag}(0.9, 0.8)$ the normal matrix with the same eigenvalues, as in Section 33.4.2.3.

   1. Prove the equality of the two sets in Equation 33.43. First show that $\|(z\mathbf{I} - \mathbf{A})^{-1}\|_2 = 1/\sigma_{\min}(z\mathbf{I} - \mathbf{A})$, where $\sigma_{\min}(\mathbf{X}) = \min_{\|\mathbf{x}\|=1} \|\mathbf{X}\mathbf{x}\|$. For one inclusion, take unit vectors $\mathbf{u}$, $\mathbf{v}$ with $(z\mathbf{I} - \mathbf{A})\mathbf{v} = \sigma\mathbf{u}$, $\sigma = \sigma_{\min}(z\mathbf{I} - \mathbf{A})$, and show that z is an eigenvalue of $\mathbf{A} + \sigma\mathbf{u}\mathbf{v}^*$. For the other, apply $(z\mathbf{I} - \mathbf{A})\mathbf{x} = \mathbf{E}\mathbf{x}$ to an eigenvector $\mathbf{x}$ of $\mathbf{A} + \mathbf{E}$. Using the resolvent norms printed in Section 33.4.2.4, how large a perturbation makes $z = 1$ an eigenvalue of a perturbed $\mathbf{M}$, and how large for Λ?
   2. Suppose that $\|\mathbf{A}^k\|_2 \le K_0$ for all $k \ge 0$. Show that for $|z| > 1$ the series $\sum_{k \ge 0} \mathbf{A}^k / z^{k+1}$ converges to $(z\mathbf{I} - \mathbf{A})^{-1}$, and conclude that

   $$\sup_{k \ge 0} \|\mathbf{A}^k\|_2 \;\ge\; K(\mathbf{A}) = \sup_{|z| > 1} \left(|z| - 1\right) \|(z\mathbf{I} - \mathbf{A})^{-1}\|_2 .$$

   The quantity $K(\mathbf{A})$ is called the Kreiss constant. Restate the bound in terms of pseudospectra: if $\Lambda_\varepsilon(\mathbf{A})$ contains a point at distance δ outside the unit circle, how large must some power of $\mathbf{A}$ be?

3. Evaluate $K(\mathbf{M})$ numerically on a grid of points z with $|z| > 1$, and compare it with the largest $\|\mathbf{M}^k\|_2$ printed in Section 33.4.2.3. Find $K(\Lambda)$ by hand.

4. code **Damping in PageRank.** ● Let $\mathbf{P}$ be a column-stochastic $n \times n$ matrix and $\mathbf{G} = \alpha\mathbf{P} + (1-\alpha)\frac{1}{n}\mathbf{1}\mathbf{1}^\top$ with $0 < \alpha < 1$, the damped matrix of Section 33.4.1.3.

   1. Let $\mathbf{P}\mathbf{x} = \lambda\mathbf{x}$. Show that $\mathbf{1}^\top\mathbf{x} = 0$ whenever $\lambda \neq 1$, and that $\mathbf{G}\mathbf{x} = \alpha\lambda\mathbf{x}$ whenever $\mathbf{1}^\top\mathbf{x} = 0$.
   2. The eigenvalue 1 of $\mathbf{P}$ can be repeated, as it is when the links split into disconnected pockets. You may use that every column-stochastic $\mathbf{P}$ has a non-negative eigenvector for the eigenvalue 1 (a stationary distribution). Show that the vectors $\mathbf{x}$ of this eigenspace with $\mathbf{1}^\top\mathbf{x} = 0$ form a subspace of dimension one less than the eigenspace. Conclude that for diagonalizable $\mathbf{P}$ the eigenvalues of $\mathbf{G}$ are 1 and $\alpha\lambda_2(\mathbf{P}), \dots, \alpha\lambda_n(\mathbf{P})$, which gives the bound $|\lambda_2(\mathbf{G})| \le \alpha$ of Haveliwala and Kamvar (2003) .
   3. Four pages link in a cycle, $1 \to 2 \to 3 \to 4 \to 1$. Find the eigenvalues of their link matrix $\mathbf{P}$. Why does undamped power iteration started at page 1 never converge?
   4. With $\alpha = 0.85$ and the cycle of (c), run power iteration on $\mathbf{G}$ from page 1, and count the iterations until the ℓ_1 distance to the stationary distribution falls below 10^{-8}. Compare with the prediction $0.85^k \le 10^{-8}$ from (b).
   5. Check numerically on the three-page example of Section 33.4.1.3 that the eigenvalues of $\mathbf{G}$ are α times those of $\mathbf{P}$, apart from the eigenvalue 1, and that the stationary distribution moves from $(0.3, 0.4, 0.3)$ to about $(0.303, 0.394, 0.303)$. Why does damping move it toward uniform?

5. code **Lyapunov exponents of random products.** ●● Let $\mathbf{D}_1, \mathbf{D}_2, \dots$ be independent $n \times n$ matrices with independent $\mathcal{N}(0, 1/n)$ entries, a linear model of the Jacobians of a deep network at fan-in initialization, and let $\mathbf{x}_0$ be a unit vector. By Section 33.4.2.6, each factor has spectral radius close to 1 for large n. Section 33.4.2.5 summarizes the growth of the product by its top Lyapunov exponent

$$\mu = \lim_{T \to \infty} \frac{1}{T} \log \|\mathbf{D}_T \cdots \mathbf{D}_1 \mathbf{x}_0\|,$$

   which exists with probability one by the theorem of Furstenberg and Kesten.

   1. Show that $\mathbb{E}\|\mathbf{D}\mathbf{x}\|^2 = \|\mathbf{x}\|^2$ for every fixed $\mathbf{x}$, so that this scaling preserves squared norms on average.
   2. Let $\mathbf{u}_0 = \mathbf{x}_0$ and $\mathbf{u}_t = \mathbf{x}_t / \|\mathbf{x}_t\|$ for the iterates $\mathbf{x}_t = \mathbf{D}_t \cdots \mathbf{D}_1 \mathbf{x}_0$. Given $\mathbf{D}_1, \dots, \mathbf{D}_{t-1}$, what is the distribution of $n\|\mathbf{D}_t \mathbf{u}_{t-1}\|^2$? Use the answer to write $\log \|\mathbf{D}_T \cdots \mathbf{D}_1 \mathbf{x}_0\|$ as a sum of independent terms. With $\mathbb{E} \log \chi^2_n = \psi(n/2) + \log 2$, where ψ is the digamma function, derive the closed form of Cohen and Newman (1984)

$$\mu = \tfrac{1}{2}\big(\psi(n/2) + \log 2 - \log n\big).$$

   3. Show that $\mu < 0$ for every n, although (a) holds. Evaluate μ in closed form for $n = 1$, using $\psi(1/2) = -\gamma_{\mathrm{E}} - 2\log 2$ with Euler's constant $\gamma_{\mathrm{E}} \approx 0.5772$. Using $\psi(x) = \log x - \frac{1}{2x} + O(x^{-2})$, show that $\mu \approx -1/(2n)$ for large n.

4. Simulate $T = 10^4$ steps with renormalization for $n \in \{1, 2, 5, 50\}$, and compare the measured exponent with (b) and with the logarithms of the spectral radius and of the largest singular value of single factors. By which factor does a typical input shrink in a linear network of width 50 and depth 100 at this initialization? What does the comparison say about the three quantities of Section 33.4.2.5?

33.5 Singular Value Decomposition and Low-Rank Approximation

In Section 33.3, we saw how the eigendecomposition describes a square matrix in terms of the directions it merely stretches, turning powers of a matrix into simple powers of numbers. Most matrices in deep learning, however, are not like that. A weight matrix maps inputs of one width to outputs of another, and a data matrix has one row per example and one column per feature. Neither is applied repeatedly to its own output, and neither needs to be square. Even when a matrix *is* square, eigenvalues can still let us down. The shear $\mathbf{T} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$ is *defective*, having only a single eigenvector direction where the plane needs two, and in Section 33.4 we met a matrix whose sixth power stretches a vector ten-fold even though both of its eigenvalues are smaller than 1. We need a factorization that exists for *every* matrix, measures stretching directly, and tells us how few numbers are needed to approximate a large matrix well.

A concrete photograph makes that last requirement easy to appreciate. A grayscale picture of a cat, 400×500 pixels, is simply a matrix of 200,000 numbers. Like any matrix, it can be written as a sum of rank-one pieces, each formed by the outer product of a single column and a single row. Remarkably, just twenty well-chosen pieces (18,020 numbers, or 9% of the original data) reproduce the photograph with a relative error of only 8% (Figure 33.28). Which twenty pieces achieve this, and could any other twenty do better? That same question arises across deep learning: it tells us how many parameters a fine-tuning adapter for a large model needs, and which directions in a dataset are actually worth keeping.

The key idea is to stop asking a single basis to serve for both the inputs and the outputs. If we allow one orthonormal basis for the input space and a separate orthonormal basis for the output space, then *every* matrix reduces to a list of independent non-negative stretches $\sigma_1 \geq \sigma_2 \geq \cdots \geq 0$. From that single list we can read off a matrix's rank, its best low-rank approximation, principal component analysis, least-squares solutions, and how sensitive a linear system is to measurement error. Recall that Section 1.3 introduced two ways to measure the size of a matrix: the Frobenius norm $\|\mathbf{A}\|_F$ (the square root of the sum of squared entries) and the spectral norm $\|\mathbf{A}\|_2$ (the largest factor by which $\mathbf{A}$ can stretch a unit vector). In this section, both become simple functions of the singular values σ_i.

Two main results anchor what follows: the existence of the singular value decomposition for any matrix, and the Eckart–Young theorem, which guarantees that truncating the decomposition gives the best approximation of every rank. From there, the pseudoinverse and the condition number follow in just a few lines. The final subsection connects these tools to modern deep learning and can be skipped on a first reading. All numerical experiments below use NumPy; throughout, $\mathbf{T}$ denotes the shear matrix and $\mathbf{A}$ denotes a general matrix unless stated otherwise.

33.5.1 The Singular Value Decomposition

33.5.1.1 The Factorization and Its Geometry

In Section 1.3, we saw that the symmetric matrix $\left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ maps the unit circle to an ellipse whose semi-axes lie along its eigenvectors $(1,1)$ and $(-1,1)$, with half-lengths 3 and 1. Remarkably, a *non-symmetric* matrix also maps the unit circle to an ellipse (or flattens it to a line segment if the matrix is singular), as we will prove shortly. The difference is that the orthogonal input directions landing on the axes of this ellipse are no longer the axes themselves. Instead, there are two orthonormal frames, one for the input space and one for the output space, and the singular value decomposition names both.

Theorem (singular value decomposition). *Every real $m \times n$ matrix $\mathbf{A}$ can be written as*

$$\mathbf{A} = \mathbf{U}\,\Sigma\,\mathbf{V}^{\top}, \tag{33.44}$$

where $\mathbf{U} \in \mathbb{R}^{m\times m}$ and $\mathbf{V} \in \mathbb{R}^{n\times n}$ are orthogonal ($\mathbf{U}^{\top}\mathbf{U} = \mathbf{I}$, $\mathbf{V}^{\top}\mathbf{V} = \mathbf{I}$) and $\Sigma \in \mathbb{R}^{m\times n}$ is zero except for the non-negative entries $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_{\min(m,n)} \geq 0$ on its main diagonal. The columns $\mathbf{v}_i$ of $\mathbf{V}$ are the *right singular vectors*, the columns $\mathbf{u}_i$ of $\mathbf{U}$ are the *left singular vectors*, and the diagonal entries σ_i are the *singular values*.

In geometric terms, *every* matrix, regardless of its shape, is simply an orthogonal transformation, followed by a diagonal stretch, followed by a second orthogonal transformation. Writing $\mathbf{AV} = \mathbf{U}\Sigma$ and reading off column i makes the action explicit one direction at a time:

$$\mathbf{A}\mathbf{v}_i = \sigma_i\,\mathbf{u}_i, \qquad i \leq \min(m,n). \tag{33.45}$$

Each input direction $\mathbf{v}_i$ is sent to the corresponding output direction $\mathbf{u}_i$, stretched by σ_i; when $n > m$, the extra input directions $\mathbf{v}_{m+1}, \dots, \mathbf{v}_n$ are collapsed to zero. Reading Equation 33.44 from right to left, applying $\mathbf{A}$ to a vector $\mathbf{x}$ unfolds in three stages:

1. $\mathbf{V}^{\top}$ rotates the input so that each right singular vector $\mathbf{v}_i$ aligns with the coordinate axis $\mathbf{e}_i$;
2. Σ stretches axis i by σ_i and, when $m \neq n$, either appends zero coordinates or drops excess ones to match the output dimension;
3. $\mathbf{U}$ rotates the stretched axes so that axis i points along $\mathbf{u}_i$.

Here "rotation" is convenient shorthand for an orthogonal map, which may also include a reflection.

Figure 33.24 illustrates these three stages for the shear $\mathbf{T}$. Its singular values are $\sigma_1 = 1.618$ and $\sigma_2 = 0.618$; the first right singular vector $\mathbf{v}_1$ points at 58.3° above the x-axis, while its image direction $\mathbf{u}_1$ points at 31.7°. Because the input and output frames differ, $\mathbf{U} \neq \mathbf{V}$. We will derive these exact numbers in Section 33.5.1.2.

In n dimensions, the same three stages deform the unit sphere into an ellipsoid whose semi-axes are the vectors $\sigma_i\mathbf{u}_i$. If only $r < n$ of the input directions have positive singular values, the remaining $n - r$ directions collapse to zero, and the image is a flat r-dimensional ellipsoid lying inside the span of $\mathbf{u}_1, \dots, \mathbf{u}_r$.

Compact and thin forms. Let r be the number of positive singular values (in Section 33.5.1.5 we will verify that r is precisely the rank of $\mathbf{A}$). Every row and column of Σ beyond the

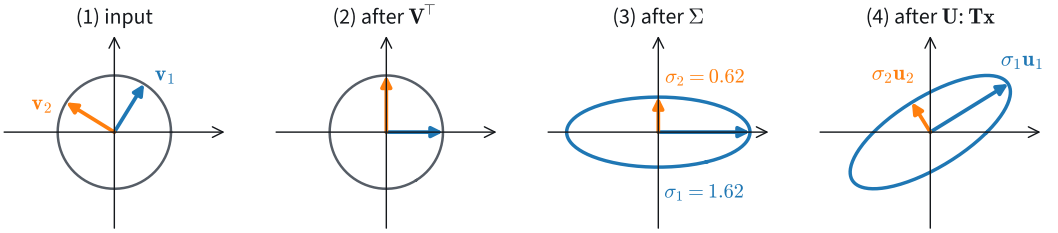

Figure 33.24: The shear $\mathbf{T} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right) = \mathbf{U}\Sigma\mathbf{V}^\top$ acting on the unit circle, read left to right: $\mathbf{V}^\top$ rotates by $-58.3°$, Σ stretches by $\varphi = 1.618$ along x and by $1/\varphi = 0.618$ along y, and $\mathbf{U}$ rotates by $31.7°$. The input frame $\{\mathbf{v}_i\}$ and the output frame $\{\mathbf{u}_i\}$ differ.

first r is zero, so the singular vectors paired with them contribute nothing to the product. Dropping those zero entries yields the *compact SVD*, $\mathbf{A} = \mathbf{U}_r\Sigma_r\mathbf{V}_r^\top$, where $\mathbf{U}_r \in \mathbb{R}^{m\times r}$ and $\mathbf{V}_r \in \mathbb{R}^{n\times r}$ hold the first r singular vectors and $\Sigma_r = \operatorname{diag}(\sigma_1, \dots, \sigma_r)$. Between the full and compact forms sits the *thin SVD*, the default reduced form that numerical libraries return on request, which keeps $\min(m, n)$ columns in $\mathbf{U}$ and $\mathbf{V}$ and still records any zero singular values when $r < \min(m, n)$. For a 3×2 matrix of rank 2, the full factors have shapes 3×3, 3×2, and 2×2, whereas the thin factors have shapes 3×2, 2×2, and 2×2 (matching the compact SVD here because the matrix has full column rank). The full and thin forms differ whenever the matrix is not square, and the thin and compact forms whenever it is rank-deficient. Figure 33.25 draws a 6×4 matrix of rank 3, for which all three differ.

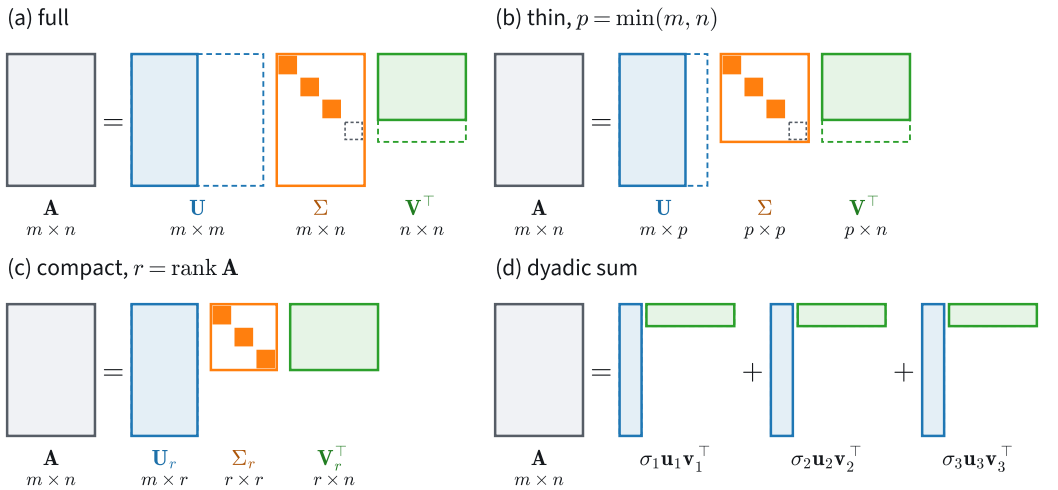

Figure 33.25: Shapes of the SVD factors of an $m \times n$ matrix of rank r, drawn to scale for $m = 6$, $n = 4$, and $r = 3$: (a) full, (b) thin, (c) compact, and (d) the dyadic sum of r rank-one terms. Filled squares on the diagonal of Σ are positive singular values, and the dashed square is a zero singular value. The dashed parts of $\mathbf{U}$ and $\mathbf{V}^\top$ multiply only zeros of Σ, so each smaller form drops some of them without changing the product.

The dyadic sum. Multiplying out the compact SVD column by row expresses $\mathbf{A}$ as a weighted sum of rank-one matrices, often called *dyads*:

$$\mathbf{A} = \sum_{i=1}^{r} \sigma_i \, \mathbf{u}_i \mathbf{v}_i^\top . \tag{33.46}$$

Each term $\mathbf{u}_i \mathbf{v}_i^\top$ is the outer product of an output direction and an input direction, scaled by its singular value, and the terms are already sorted from heaviest to lightest. For the shear, $\mathbf{T} = \varphi \, \mathbf{u}_1 \mathbf{v}_1^\top + \varphi^{-1} \, \mathbf{u}_2 \mathbf{v}_2^\top$, splitting the matrix into one piece of weight 1.618 and a second of weight 0.618. Keeping only the heaviest pieces is the idea behind low-rank approximation in Section 33.5.2.1.

33.5.1.2 Existence

Where do the σ_i, $\mathbf{v}_i$, and $\mathbf{u}_i$ come from, and why should the output directions come out orthonormal? The spectral theorem of Section 33.3.2.1 guarantees that every symmetric matrix has an orthonormal basis of eigenvectors with real eigenvalues. We can apply it to the *Gram matrix* $\mathbf{A}^\top \mathbf{A}$, the $n \times n$ matrix of dot products between the columns of $\mathbf{A}$. This matrix is symmetric, and it is positive semidefinite (Section 33.3.2.2) because $\mathbf{x}^\top \mathbf{A}^\top \mathbf{A} \mathbf{x} = \|\mathbf{A}\mathbf{x}\|^2 \geq 0$ for every vector $\mathbf{x}$.

Proof of Equation 33.44 (existence). By the spectral theorem, $\mathbf{A}^\top \mathbf{A}$ has an orthonormal basis of eigenvectors $\mathbf{v}_1, \dots, \mathbf{v}_n$ with eigenvalues $\lambda_1 \geq \cdots \geq \lambda_n$. Every eigenvalue is nonnegative because $\lambda_i = \mathbf{v}_i^\top \mathbf{A}^\top \mathbf{A} \mathbf{v}_i = \|\mathbf{A}\mathbf{v}_i\|^2$. Define

$$\sigma_i = \sqrt{\lambda_i}, \qquad r = \#\{i : \sigma_i > 0\}.$$

Thus the singular values are the square roots of the eigenvalues of the Gram matrix, and r counts the positive ones. For each $i \leq r$, set $\mathbf{u}_i = \mathbf{A}\mathbf{v}_i / \sigma_i$. The crucial check is that these pushed-through vectors are automatically orthonormal, which follows from $\mathbf{v}_j$ being an eigenvector of $\mathbf{A}^\top \mathbf{A}$ and the $\mathbf{v}_i$ being orthonormal:

$$\mathbf{u}_i^\top \mathbf{u}_j = \frac{1}{\sigma_i \sigma_j} \mathbf{v}_i^\top \mathbf{A}^\top \mathbf{A} \, \mathbf{v}_j = \frac{\lambda_j}{\sigma_i \sigma_j} \mathbf{v}_i^\top \mathbf{v}_j = \frac{\lambda_j}{\sigma_i \sigma_j} \delta_{ij} = \delta_{ij}.$$

Orthonormality of the input frame therefore passes directly through $\mathbf{A}^\top \mathbf{A}$ to the output frame. Next we check the dimensions. Since the r orthonormal vectors $\mathbf{u}_1, \dots, \mathbf{u}_r$ lie in $\mathbb{R}^m$, we have $r \leq m$, and since there are n eigenvalues in total, $r \leq n$; hence $r \leq \min(m, n)$, and $\lambda_i = 0$ for every $i > r$. Complete $\mathbf{u}_1, \dots, \mathbf{u}_r$ to an orthonormal basis $\mathbf{u}_1, \dots, \mathbf{u}_m$ of $\mathbb{R}^m$ (for example, by applying Gram–Schmidt to any completion). For $r < i \leq n$, $\|\mathbf{A}\mathbf{v}_i\|^2 = \lambda_i = 0$, so $\mathbf{A}\mathbf{v}_i = \mathbf{0}$. Comparing $\mathbf{AV}$ with $\mathbf{U}\Sigma$ column by column, column i of $\mathbf{U}\Sigma$ is $\sigma_i \mathbf{u}_i$ for $i \leq \min(m, n)$ (which vanishes when $i > r$) and $\mathbf{0}$ for $i > m$ (where Σ has no diagonal entry). In every case, column i of $\mathbf{AV}$ matches column i of $\mathbf{U}\Sigma$. Hence $\mathbf{AV} = \mathbf{U}\Sigma$, and right-multiplying by $\mathbf{V}^\top = \mathbf{V}^{-1}$ yields $\mathbf{A} = \mathbf{U}\Sigma\mathbf{V}^\top$. ■

This proof is also a recipe: diagonalize the symmetric matrix $\mathbf{A}^\top \mathbf{A}$, take square roots to get the singular values, and map the eigenvectors through $\mathbf{A}$ to obtain the left singular vectors.

Let us work through the shear by hand to see every step in action. For $\mathbf{T} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$, the Gram matrix is $\mathbf{T}^\top \mathbf{T} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right)$. It has trace 3 and determinant 1, so its characteristic polynomial is $\lambda^2 - 3\lambda + 1$, giving eigenvalues $(3 \pm \sqrt{5})/2$. Introducing the golden ratio $\varphi = (1 + \sqrt{5})/2$,

which satisfies $\varphi^2 = \varphi + 1$, these eigenvalues simplify neatly to φ^2 and φ^{-2}. The singular values are therefore $\sigma_1 = \varphi \approx 1.618$ and $\sigma_2 = 1/\varphi \approx 0.618$, and their product is $1 = |\det \mathbf{T}|$.

Now we find the singular vectors. For the first right singular vector (x, y), the first row of $(\mathbf{T}^\top\mathbf{T} - \varphi^2\mathbf{I})(x, y) = \mathbf{0}$ reads $(1 - \varphi^2)x + y = 0$; using $\varphi^2 - 1 = \varphi$ gives $y = \varphi x$, so $\mathbf{v}_1 \propto (1, \varphi)$. Applying $\mathbf{T}$ yields $\mathbf{T}(1, \varphi) = (1 + \varphi, \varphi) = \varphi\,(\varphi, 1)$, so $\mathbf{u}_1 \propto (\varphi, 1)$. Both vectors have length $\sqrt{1 + \varphi^2} = \sqrt{\varphi + 2}$, giving $\mathbf{v}_1 \approx (0.526, 0.851)$ at angle $\arctan\varphi = 58.3^\circ$ and $\mathbf{u}_1 \approx (0.851, 0.526)$ at 31.7°. The second pair follows by orthogonality, $\mathbf{v}_2 = (-\varphi, 1)/\sqrt{\varphi + 2}$ and $\mathbf{u}_2 = (-1, \varphi)/\sqrt{\varphi + 2}$, and indeed $\mathbf{T}\mathbf{v}_2 = (1 - \varphi, 1)/\sqrt{\varphi + 2} = \varphi^{-1}\mathbf{u}_2$ since $(1 - \varphi)\varphi = -1$. Both $\mathbf{V}$ and $\mathbf{U}$ are rotations $\mathbf{R}_\theta = \left(\begin{smallmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{smallmatrix}\right)$, so the shear factors as

$$\mathbf{T} = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix} = \mathbf{R}_{31.7^\circ} \begin{bmatrix} \varphi & 0 \\ 0 & 1/\varphi \end{bmatrix} \mathbf{R}_{58.3^\circ}^\top. \tag{33.47}$$

Geometrically, the shear rotates the plane by -58.3°, stretches it by 1.618 along the x-axis and 0.618 along the y-axis, and rotates it back by only 31.7°. The two angles sum to 90° because $\mathbf{u}_1$ is simply $\mathbf{v}_1$ with its coordinates swapped, reflecting the symmetry $\mathbf{T}^\top = \mathbf{J}\mathbf{T}\mathbf{J}$ for the swap matrix $\mathbf{J} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$.

Does NumPy's `np.linalg.svd` agree with our hand calculation? Because singular vectors are only determined up to sign (Section 33.5.1.3), the cell below stores the shear as `A` and first fixes signs so that $\mathbf{u}_1$ lies in the first quadrant and $\mathbf{U}$ is a proper rotation.

```
A = np.array([[1., 1.], [0., 1.]])
U, s, Vt = np.linalg.svd(A)
if U[0, 0] < 0:                          # joint sign choice: u_1 in the first quadrant
    U[:, 0], Vt[0] = -U[:, 0], -Vt[0]
if np.linalg.det(U) < 0:                 # joint sign choice: U a rotation (then so is V)
    U[:, 1], Vt[1] = -U[:, 1], -Vt[1]
phi = (1 + np.sqrt(5)) / 2
print('singular values', s.round(4), '  phi, 1/phi', np.array([phi, 1 / phi]).round(4))
print('U =', U.round(3).tolist(), '  Vt =', Vt.round(3).tolist())
print('angles of u_1, v_1 (degrees):', np.degrees(np.arctan2(U[1, 0], U[0, 0])).round(1),
      np.degrees(np.arctan2(Vt[0, 1], Vt[0, 0])).round(1))
print('A v_1 = sigma_1 u_1:', np.allclose(A @ Vt[0], s[0] * U[:, 0]),
      '  sigma_1 sigma_2 =', s.prod().round(6))
```

```
singular values [1.618 0.618]   phi, 1/phi [1.618 0.618]
U = [[0.851, -0.526], [0.526, 0.851]]   Vt = [[0.526, 0.851], [-0.851, 0.526]]
angles of u_1, v_1 (degrees): 31.7 58.3
A v_1 = sigma_1 u_1: True   sigma_1 sigma_2 = 1.0
```

It matches: the library returns φ and $1/\varphi$ together with the two rotations of Equation 33.47.

The same construction works unchanged for a rectangular matrix. Consider the 3×2 matrix with rows $(3, 1)$, $(1, 3)$, and $(0, 2)$. Its Gram matrix is $\left(\begin{smallmatrix} 10 & 6 \\ 6 & 14 \end{smallmatrix}\right)$, with eigenvalues $12 \pm \sqrt{40}$. The next cell carries out the proof's three steps directly (eigenvectors of $\mathbf{A}^\top\mathbf{A}$, square roots, and $\mathbf{u}_i = \mathbf{A}\mathbf{v}_i/\sigma_i$) and compares the result against `np.linalg.svd`.

```
A = np.array([[3., 1.], [1., 3.], [0., 2.]])
lam, V = np.linalg.eigh(A.T @ A)
lam, V = lam[::-1], V[:, ::-1]                    # descending order
sigma = np.sqrt(lam)
U = A @ V / sigma                                  # u_i = A v_i / sigma_i
U_lib, s_lib, Vt_lib = np.linalg.svd(A, full_matrices=False)
print('sigma from eigh:', sigma.round(5), '  from svd:', s_lib.round(5))
print('U orthonormal:', np.allclose(U.T @ U, np.eye(2)), '  same U, V up to sign:',
      np.allclose(abs(U), abs(U_lib)), np.allclose(abs(V), abs(Vt_lib.T)))
print('rebuild error:', np.linalg.norm((U * sigma) @ V.T - A).round(12))
```

```
sigma from eigh: [4.28072 2.38232]   from svd: [4.28072 2.38232]
U orthonormal: True   same U, V up to sign: True True
rebuild error: 0.0
```

Both routes yield $\sigma_1 = \sqrt{12+\sqrt{40}} \approx 4.281$ and $\sigma_2 = \sqrt{12-\sqrt{40}} \approx 2.382$. As the proof promised, the pushed-through vectors $\mathbf{u}_i$ come out orthonormal, and both $\mathbf{U}$ and $\mathbf{V}$ agree with the library's output up to sign.

33.5.1.3 Uniqueness and the Largest Stretch

Is the SVD of a matrix unique? The singular *values* are always unique, because they are the square roots of the eigenvalues of $\mathbf{A}^\top\mathbf{A}$, which $\mathbf{A}$ determines completely. The singular *vectors*, by contrast, have three kinds of freedom:

- For a simple (unrepeated) $\sigma_i > 0$, the only choice is a joint sign flip $(\mathbf{u}_i, \mathbf{v}_i) \to (-\mathbf{u}_i, -\mathbf{v}_i)$. Both vectors must flip together, because flipping only one side would violate $\mathbf{A}\mathbf{v}_i = \sigma_i \mathbf{u}_i$.
- For a repeated singular value $\sigma > 0$ with index set $\mathcal{J}$, the columns $\mathbf{V}_\mathcal{J}$ may be rotated by any orthogonal matrix $\mathbf{Q}$ of matching size, becoming $\mathbf{V}_\mathcal{J}\mathbf{Q}$, provided $\mathbf{U}_\mathcal{J}$ is rotated by the *same* $\mathbf{Q}$ to preserve $\mathbf{U}_\mathcal{J} = \mathbf{A}\mathbf{V}_\mathcal{J}/\sigma$.
- For $\sigma = 0$, the null-space vectors $\mathbf{v}_{r+1}, \dots, \mathbf{v}_n$ and left-null-space vectors $\mathbf{u}_{r+1}, \dots, \mathbf{u}_m$ can be rotated completely independently, since they do not appear in the dyadic sum Equation 33.46.

This freedom explains why two numerical libraries, or even the same library on two different machines, may return opposite signs for the singular vectors, and why our code cells fix a sign convention before printing vectors.

Beyond factoring $\mathbf{A}$, the top singular value has a direct geometric meaning: it is the largest factor by which $\mathbf{A}$ can stretch any unit vector,

$$\sigma_1 = \max_{\|\mathbf{x}\|=1} \|\mathbf{A}\mathbf{x}\| = \|\mathbf{A}\|_2. \tag{33.48}$$

This follows immediately from the Rayleigh proposition of Section 33.3.2.3, which states that over unit vectors $\mathbf{x}$, the quadratic form $\mathbf{x}^\top\mathbf{S}\mathbf{x}$ of a symmetric matrix $\mathbf{S}$ is maximized by its top eigenvector with value equal to its top eigenvalue. Taking $\mathbf{S} = \mathbf{A}^\top\mathbf{A}$, we see that $\|\mathbf{A}\mathbf{x}\|^2 = \mathbf{x}^\top\mathbf{A}^\top\mathbf{A}\mathbf{x}$ is maximized at $\mathbf{x} = \mathbf{v}_1$ with value $\lambda_1 = \sigma_1^2$. Thus σ_1 is precisely the spectral norm $\|\mathbf{A}\|_2$ from Section 1.3: for the shear, no unit vector is stretched by more than $\varphi = 1.618$, and $\mathbf{v}_1$ achieves that stretch. The remaining singular values solve the same maximization problem once the earlier right singular vectors are ruled out, a procedure

called *deflation*: $\sigma_k = \max\{\|\mathbf{A}\mathbf{x}\| : \|\mathbf{x}\| = 1,\ \mathbf{x} \perp \mathbf{v}_1, \dots, \mathbf{v}_{k-1}\}$. In fact, Exercise 1a reverses this logic and constructs the entire SVD from the maximum stretch alone, without invoking the spectral theorem.

33.5.1.4 Singular Values and Eigenvalues

How do singular values relate to eigenvalues? Substituting Equation 33.44 into the two Gram matrices and using $\mathbf{U}^\top\mathbf{U} = \mathbf{I}$ and $\mathbf{V}^\top\mathbf{V} = \mathbf{I}$ gives

$$\mathbf{A}^\top\mathbf{A} = \mathbf{V}\,\Sigma^\top\Sigma\,\mathbf{V}^\top, \qquad \mathbf{A}\mathbf{A}^\top = \mathbf{U}\,\Sigma\Sigma^\top\,\mathbf{U}^\top. \tag{33.49}$$

Both expressions are symmetric eigendecompositions: the right singular vectors are the eigenvectors of $\mathbf{A}^\top\mathbf{A}$, the left singular vectors are the eigenvectors of $\mathbf{A}\mathbf{A}^\top$, and the squares σ_i^2 are the nonzero eigenvalues that the two Gram matrices share. When $\mathbf{A}$ is symmetric positive semidefinite, its SVD and eigendecomposition coincide, with $\mathbf{U} = \mathbf{V}$.

For any other matrix, however, the two decompositions differ, and it is a common mistake to assume that singular values equal eigenvalue magnitudes. Consider the chapter's running matrix $\mathbf{A} = \left(\begin{smallmatrix} 1 & 2 \\ -1 & 3 \end{smallmatrix}\right)$, whose eigenvalues are $2 \pm i$, both of modulus $\sqrt{5} \approx 2.236$ (Section 33.3). Its Gram matrix $\mathbf{A}^\top\mathbf{A} = \left(\begin{smallmatrix} 2 & -1 \\ -1 & 13 \end{smallmatrix}\right)$ has trace 15 and determinant 25, yielding $\sigma_{1,2}^2 = (15 \pm 5\sqrt{5})/2$ and therefore $\sigma_{1,2} = (5 \pm \sqrt{5})/2 \approx 3.618,\ 1.382$, far from 2.236. Still, one clean identity links the two lists for every square matrix:

$$|\det \mathbf{A}| = \prod_i \sigma_i = \prod_i |\lambda_i|.$$

The first equality holds because orthogonal matrices have determinant ± 1, and the second because the determinant is the product of all eigenvalues. For a 2×2 matrix with a conjugate pair of eigenvalues of common modulus $|\lambda|$, this forces $|\lambda| = \sqrt{\sigma_1\sigma_2}$; here indeed $\sqrt{3.618 \cdot 1.382} = \sqrt{5}$. The identity also recovers the volume interpretation of the determinant from Section 33.2: rotations preserve area, so the diagonal stretch Σ accounts for the entire change of area, and our running matrix maps the unit square to a parallelogram of area $3.618 \cdot 1.382 = 5$.

Computing the SVD in practice. Although our existence proof constructs the SVD from $\mathbf{A}^\top\mathbf{A}$, numerical libraries never form that product. Forming $\mathbf{A}^\top\mathbf{A}$ squares the condition number (Section 33.5.3.2), which can wipe out small singular values in floating-point arithmetic. Instead, libraries apply orthogonal transformations directly to $\mathbf{A}$ to reduce it to bidiagonal form (Golub–Kahan bidiagonalization) and then diagonalize that bidiagonal matrix (Golub and Van Loan 1996).

33.5.1.5 The Four Fundamental Subspaces

Which inputs does $\mathbf{A}$ collapse to zero, and which outputs can it reach? In Section 33.2, we named these sets the null space and the column space, and defined the rank as the number of linearly independent columns. Because $\mathbf{U}$ and $\mathbf{V}$ are invertible, multiplying by them leaves all dimensions unchanged, so $\operatorname{rank}\mathbf{A} = \operatorname{rank}\Sigma$, which is simply the count of nonzero diagonal entries:

$$\operatorname{rank}\mathbf{A} = \#\{i : \sigma_i > 0\} = r. \tag{33.50}$$

In other words, the rank counts the directions that survive without collapsing. Paired with a rounding tolerance (below), counting singular values is the most numerically reliable way to determine rank. It costs more than Gaussian elimination, but it is far more stable: a perturbation $\mathbf{E}$, such as floating-point rounding error, shifts no singular value by more than $\|\mathbf{E}\|_2$ (Weyl's inequality in Section 33.5.2.1). A clear gap between large and tiny singular values can therefore be trusted.

Even better, splitting the singular vectors at the index r gives explicit orthonormal bases for all four fundamental subspaces of $\mathbf{A}$ directly from the dyadic sum Equation 33.46:

- The **column space** (range) of $\mathbf{A}$ is $\operatorname{span}\{\mathbf{u}_1, \dots, \mathbf{u}_r\}$, because every output $\mathbf{Ax} = \sum_{i \le r} \sigma_i (\mathbf{v}_i^\top \mathbf{x}) \mathbf{u}_i$ is a linear combination of these vectors, and each one is attained via $\mathbf{u}_i = \mathbf{A}(\mathbf{v}_i/\sigma_i)$.
- The **null space** of $\mathbf{A}$ is $\operatorname{span}\{\mathbf{v}_{r+1}, \dots, \mathbf{v}_n\}$, because by the same formula $\mathbf{Ax} = \mathbf{0}$ holds if and only if $\mathbf{v}_i^\top \mathbf{x} = 0$ for every $i \le r$ (the $\mathbf{u}_i$ are independent and the σ_i are positive), meaning $\mathbf{x}$ is orthogonal to $\mathbf{v}_1, \dots, \mathbf{v}_r$.
- The **row space** (column space of $\mathbf{A}^\top$) is $\operatorname{span}\{\mathbf{v}_1, \dots, \mathbf{v}_r\}$ and the **left null space** (null space of $\mathbf{A}^\top$) is $\operatorname{span}\{\mathbf{u}_{r+1}, \dots, \mathbf{u}_m\}$, by applying the same two arguments to $\mathbf{A}^\top = \mathbf{V}\Sigma^\top \mathbf{U}^\top$, which simply swaps the roles of the $\mathbf{u}_i$ and $\mathbf{v}_i$.

This gives a remarkably clean picture of any linear map. The input space splits into two orthogonal pieces: the r-dimensional row space and the $(n-r)$-dimensional null space. Likewise, the output space splits into the r-dimensional column space and the $(m-r)$-dimensional left null space. On the row space, $\mathbf{A}$ maps each $\mathbf{v}_i$ to $\sigma_i \mathbf{u}_i$, a one-to-one bijection onto the column space; everything in the null space is sent to zero.

To see this in the simplest nontrivial case, consider the singular matrix $\mathbf{B} = \left(\begin{smallmatrix} 2 & 1 \\ 4 & 2 \end{smallmatrix}\right)$ from Section 33.2. Its Gram matrix $\left(\begin{smallmatrix} 20 & 10 \\ 10 & 5 \end{smallmatrix}\right)$ has eigenvalues 25 and 0, so $\sigma_1 = 5$, $\sigma_2 = 0$, and $r = 1$. The four subspaces are the lines spanned by

$$\mathbf{v}_1 = \tfrac{1}{\sqrt{5}}(2,1), \quad \mathbf{v}_2 = \tfrac{1}{\sqrt{5}}(-1,2), \quad \mathbf{u}_1 = \tfrac{1}{\sqrt{5}}(1,2), \quad \mathbf{u}_2 = \tfrac{1}{\sqrt{5}}(-2,1), \qquad \mathbf{B} = 5\,\mathbf{u}_1\mathbf{v}_1^\top.$$

Here the column space is the line $y = 2x$ along $\mathbf{u}_1$, and the left null space is the perpendicular line along $\mathbf{u}_2$. In the input plane, the null space is the line along $(1,-2)$, perpendicular to the row $(2,1)$ that spans the row space. Figure 33.26 illustrates the general geometry; as we will see in Section 33.5.3.1, the pseudoinverse simply runs the bijection from the row space to the column space in reverse.

Numerical rank. In floating-point arithmetic, a matrix that is mathematically rank-deficient cannot be relied on to have singular values that are literally zero; rounding error typically leaves tiny values of order $\epsilon_{\text{mach}}\sigma_1$ instead. In practice, rank is therefore decided with a threshold. NumPy's `np.linalg.matrix_rank` counts singular values above $\sigma_1 \max(m,n)\,\epsilon_{\text{mach}}$, a tolerance that scales naturally with both the largest singular value and the matrix dimensions. Let us see what the "zero" singular values of a 4×4 matrix of rank 2 actually look like.

```
A = np.random.standard_normal((4, 2)) @ np.random.standard_normal((2, 4))   # rank <= 2
s = np.linalg.svd(A, compute_uv=False)
tol = s[0] * max(A.shape) * np.finfo(float).eps
print('singular values:', np.array2string(s, formatter={'float_kind': '{:.1e}'.format}))
```

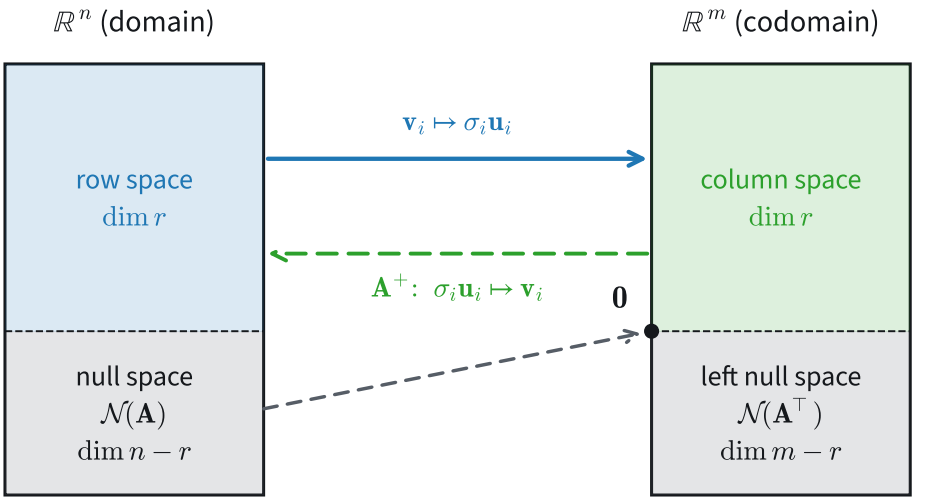

Figure 33.26: The four fundamental subspaces. $\mathbf{A}$ maps the row space $\text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_r\}$ one-to-one onto the column space $\text{span}\{\mathbf{u}_1, \dots, \mathbf{u}_r\}$ by $\mathbf{v}_i \mapsto \sigma_i \mathbf{u}_i$, and maps the null space to zero. The pseudoinverse $\mathbf{A}^+$ (dashed) runs the map backwards, $\sigma_i \mathbf{u}_i \mapsto \mathbf{v}_i$, and sends the left null space to zero.

```
print(f'tolerance {tol:.1e};  exact zeros: {(s == 0).sum()};  '
      f'numerical rank: {np.linalg.matrix_rank(A)}')
```

```
singular values: [1.0e+01 4.4e+00 6.1e-16 0.0e+00]
tolerance 9.0e-15;  exact zeros: 1;  numerical rank: 2
```

Two singular values are of order one, while the remaining two are pure rounding noise: 10^{-15} or smaller, well below the tolerance. Rounding may happen to leave one of them at exactly zero, but it rarely does so for both. Counting exact zeros would therefore misreport the rank, whereas the threshold recovers the true rank of 2.

33.5.2 Low-Rank Approximation

33.5.2.1 Best Low-Rank Approximation

We can now return to the cat photograph from the start of the section: which twenty rank-one pieces should we keep? The dyadic sum Equation 33.46 already orders the pieces of $\mathbf{A}$ from heaviest to lightest, so the natural candidate is to keep the first k terms. This gives the *truncated SVD*,

$$\mathbf{A}_k = \sum_{i=1}^{k} \sigma_i \, \mathbf{u}_i \mathbf{v}_i^\top. \tag{33.51}$$

The matrix $\mathbf{A}_k$ has rank at most k, and storing it requires only k singular values, k columns of length m, and k columns of length n, for a total of $k(m + n + 1)$ numbers instead of

mn. For our 400×500 photograph with $k = 20$, that is 18,020 numbers out of 200,000. Two questions immediately arise: how large is the approximation error, and could some cleverer rank-k matrix do even better?

Matrix norms as singular values. To measure approximation error, we need a matrix norm. The Frobenius norm from Section 1.3, $\|\mathbf{A}\|_F^2 = \sum_{ij} a_{ij}^2$, sums the squared lengths of the columns of $\mathbf{A}$, which are the diagonal entries of $\mathbf{A}^\top\mathbf{A}$; thus $\|\mathbf{A}\|_F^2 = \operatorname{tr}(\mathbf{A}^\top\mathbf{A})$. Substituting the SVD and using the cyclic property of the trace (Section 33.2) to move $\mathbf{V}$ across, we find

$$\|\mathbf{A}\|_F^2 = \operatorname{tr}(\mathbf{V}\Sigma^\top\Sigma\mathbf{V}^\top) = \operatorname{tr}(\Sigma^\top\Sigma\,\mathbf{V}^\top\mathbf{V}) = \sum_i \sigma_i^2. \tag{33.52}$$

The Frobenius norm is therefore the square root of the sum of squared singular values, which immediately tells us that multiplying on either side by an orthogonal matrix never changes it. For the shear, $1 + 1 + 0 + 1 = 3 = \varphi^2 + \varphi^{-2}$. Meanwhile, the spectral norm is simply the largest singular value, $\|\mathbf{A}\|_2 = \sigma_1$, by Equation 33.48.

With both norms expressed in terms of singular values, we can state the central approximation theorem of linear algebra.

Theorem (Eckart–Young–Mirsky). *Let $\sigma_i = 0$ for $i > r$. For every $k \geq 0$, the smallest spectral-norm error attainable by a matrix of rank at most k is*

$$\min_{\operatorname{rank}\mathbf{B}\leq k} \|\mathbf{A} - \mathbf{B}\|_2 = \sigma_{k+1}, \tag{33.53}$$

and the smallest squared Frobenius error is $\min_{\operatorname{rank}\mathbf{B}\leq k} \|\mathbf{A} - \mathbf{B}\|_F^2 = \sum_{i>k} \sigma_i^2$. Both minima are attained at the truncated SVD $\mathbf{B} = \mathbf{A}_k$.

In short, no rank-k matrix can beat the truncated SVD in either norm: the best rank-k approximation misses by the first singular value it omits (in the spectral norm), or by the combined energy of all omitted singular values (in the Frobenius norm). Eckart and Young proved the Frobenius case (Eckart and Young 1936), and Mirsky later extended it to every norm that is invariant under orthogonal multiplication on both sides (Mirsky 1960). We prove the spectral-norm bound first; the Frobenius bound then follows cleanly from one extra ingredient, Weyl's inequality, which drops right out of the same argument.

Before writing the general proof, picture $n = 3$ and $k = 1$. Any matrix $\mathbf{B}$ of rank one collapses an entire plane of inputs to zero, while the top two right singular vectors of $\mathbf{A}$ span another plane. In $\mathbb{R}^3$, two planes through the origin must intersect in at least a line. Along that line, $\mathbf{B}$ outputs zero while $\mathbf{A}$ stretches every vector by at least σ_2, so $\mathbf{A} - \mathbf{B}$ must stretch some unit vector by at least σ_2 (Figure 33.27). The proof below simply carries this dimension count into n dimensions.

Proof (spectral norm). *First, the truncation achieves σ_{k+1}.* The residual $\mathbf{A} - \mathbf{A}_k = \sum_{i>k} \sigma_i \mathbf{u}_i \mathbf{v}_i^\top$ is already in compact SVD form with largest singular value σ_{k+1}, so $\|\mathbf{A} - \mathbf{A}_k\|_2 = \sigma_{k+1}$ by Equation 33.48. Likewise, Equation 33.52 gives $\|\mathbf{A} - \mathbf{A}_k\|_F^2 = \sum_{i>k} \sigma_i^2$.

Second, no matrix of rank at most k can do better. If $k \geq r$ the error is zero and there is nothing to prove, so assume $k < r$ and let $\operatorname{rank}\mathbf{B} \leq k$. By rank–nullity (Section 33.2), the null space $\mathcal{K} = \ker\mathbf{B}$ has dimension at least $n - k$. Meanwhile, the span $\mathcal{V} = \operatorname{span}\{\mathbf{v}_1, \dots, \mathbf{v}_{k+1}\}$ of

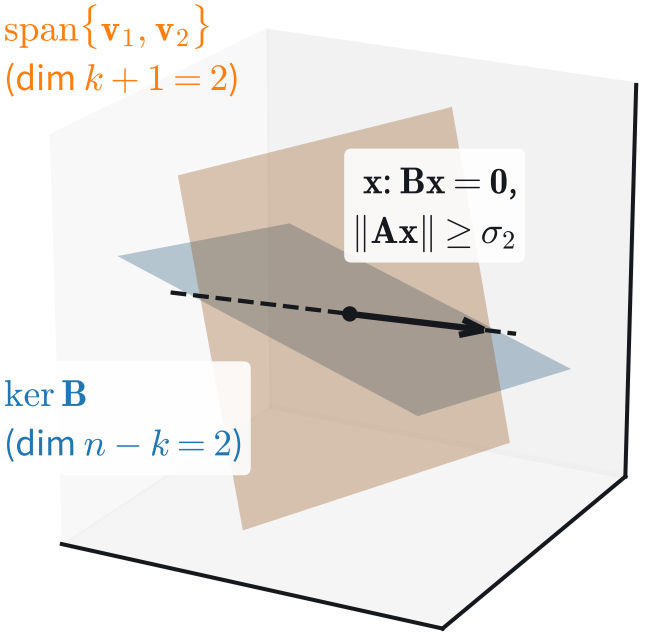

Figure 33.27: The dimension count behind Eckart–Young for $n = 3$, $k = 1$: the plane $\ker \mathbf{B}$ and the plane spanned by the top two right singular vectors must meet in a line. On that line $\mathbf{B}$ vanishes while $\mathbf{A}$ still stretches by at least σ_2.

the top $k+1$ right singular vectors has dimension $k+1$. Because these two dimensions add to more than n, the subspaces must share a nonzero vector:

$$\dim(\mathcal{K} \cap \mathcal{V}) = \dim \mathcal{K} + \dim \mathcal{V} - \dim(\mathcal{K} + \mathcal{V}) \geq (n-k) + (k+1) - n = 1,$$

where the equality is the dimension formula for two subspaces and the inequality uses $\dim(\mathcal{K}+\mathcal{V}) \leq n$. (To verify the dimension formula, extend a basis of $\mathcal{K} \cap \mathcal{V}$ separately to a basis of $\mathcal{K}$ and a basis of $\mathcal{V}$; the combined vectors are linearly independent, span $\mathcal{K}+\mathcal{V}$, and number $\dim \mathcal{K} + \dim \mathcal{V} - \dim(\mathcal{K} \cap \mathcal{V})$.) Pick a unit vector $\mathbf{x} \in \mathcal{K} \cap \mathcal{V}$ and expand it as $\mathbf{x} = \sum_{i \leq k+1} c_i \mathbf{v}_i$ with $\sum_i c_i^2 = 1$. Then $\mathbf{B}\mathbf{x} = \mathbf{0}$, and using $\mathbf{A}\mathbf{v}_i = \sigma_i \mathbf{u}_i$ together with the orthonormality of the $\mathbf{u}_i$,

$$\|\mathbf{A}\mathbf{x}\|^2 = \Big\| \sum_{i \leq k+1} c_i \sigma_i \mathbf{u}_i \Big\|^2 = \sum_{i \leq k+1} c_i^2 \sigma_i^2 \geq \sigma_{k+1}^2 \sum_{i \leq k+1} c_i^2 = \sigma_{k+1}^2.$$

Hence $\|\mathbf{A} - \mathbf{B}\|_2 \geq \|(\mathbf{A}-\mathbf{B})\mathbf{x}\| = \|\mathbf{A}\mathbf{x}\| \geq \sigma_{k+1}$. $\blacksquare$

The geometry is worth repeating in one sentence: any rank-k competitor $\mathbf{B}$ must annihilate at least one direction inside the span of the top $k+1$ right singular vectors, and $\mathbf{A}$ stretches every direction in that span by at least σ_{k+1}. For the shear $\mathbf{T}$ with $k=1$, the truncation $\mathbf{T}_1 = \varphi\, \mathbf{u}_1 \mathbf{v}_1^{\top} = \frac{1}{\sqrt{5}} \left(\begin{smallmatrix} \varphi & \varphi^2 \\ 1 & \varphi \end{smallmatrix} \right) \approx \left(\begin{smallmatrix} 0.724 & 1.171 \\ 0.447 & 0.724 \end{smallmatrix} \right)$ misses by $1/\varphi = 0.618$ in both norms (the residual has rank one, so its spectral and Frobenius norms coincide), and no rank-one matrix can get closer.

To complete the theorem for the Frobenius norm, we first harvest a general perturbation inequality from the spectral-norm bound we just proved.

Lemma (Weyl's inequality for singular values). *For any two matrices $\mathbf{X}, \mathbf{Y}$ of the same shape and indices $i, j \geq 1$ with $i + j - 1 \leq \min(m, n)$,*

$$\sigma_{i+j-1}(\mathbf{X} + \mathbf{Y}) \leq \sigma_i(\mathbf{X}) + \sigma_j(\mathbf{Y}). \tag{33.54}$$

Proof. Let $\mathbf{X}_{i-1}$ and $\mathbf{Y}_{j-1}$ be the truncated SVDs Equation 33.51 (with $\mathbf{X}_0 = \mathbf{0}$). Their sum $\mathbf{X}_{i-1} + \mathbf{Y}_{j-1}$ has rank at most $i+j-2$, so applying the spectral-norm lower bound to $\mathbf{X}+\mathbf{Y}$ with $k = i+j-2$ gives $\sigma_{i+j-1}(\mathbf{X}+\mathbf{Y}) \leq \|\mathbf{X}+\mathbf{Y}-\mathbf{X}_{i-1}-\mathbf{Y}_{j-1}\|_2$. By the triangle inequality and the achievability half of Eckart–Young, the right-hand side is at most $\|\mathbf{X} - \mathbf{X}_{i-1}\|_2 + \|\mathbf{Y} - \mathbf{Y}_{j-1}\|_2 = \sigma_i(\mathbf{X}) + \sigma_j(\mathbf{Y})$. $\blacksquare$

In words, adding $\mathbf{Y}$ to $\mathbf{X}$ can lift the $(i+j-1)$-th singular value above the i-th singular value of $\mathbf{X}$ by at most $\sigma_j(\mathbf{Y})$. Setting $j = 1$ and applying the inequality in both directions shows that perturbing a matrix by $\mathbf{Y}$ moves no singular value by more than $\|\mathbf{Y}\|_2$ (Horn and Johnson 2012); Exercise 2 works out the details.

Proof (Frobenius norm). Apply Weyl's lemma with $\mathbf{X} = \mathbf{A} - \mathbf{B}$, $\mathbf{Y} = \mathbf{B}$, and $j = k+1$. Because $\operatorname{rank} \mathbf{B} \leq k$, we have $\sigma_{k+1}(\mathbf{B}) = 0$, which yields $\sigma_{k+i}(\mathbf{A}) \leq \sigma_i(\mathbf{A}-\mathbf{B})$ for every $i \geq 1$. Squaring and summing over i, then applying Equation 33.52,

$$\|\mathbf{A}-\mathbf{B}\|_F^2 = \sum_{i \geq 1} \sigma_i(\mathbf{A}-\mathbf{B})^2 \geq \sum_{i \geq 1} \sigma_{k+i}(\mathbf{A})^2 = \sum_{j > k} \sigma_j(\mathbf{A})^2,$$

which the truncation $\mathbf{A}_k$ attains. ■

Uniqueness of the minimizer. One subtle difference separates the two norms. In the spectral norm, the best rank-k approximation is never unique when $k \geq 1$ and $\sigma_{k+1} > 0$: for $\mathbf{A} = \operatorname{diag}(3, 2, 1)$ and $k = 1$, every matrix $\mathbf{B} = \operatorname{diag}(3 + t, 0, 0)$ with $|t| \leq 1$ gives $\|\mathbf{A} - \mathbf{B}\|_2 = \max(|t|, 2, 1) = 2 = \sigma_2$. In the Frobenius norm, by contrast, $\mathbf{A}_k$ is the *unique* minimizer whenever $\sigma_k > \sigma_{k+1}$ or $\sigma_{k+1} = 0$ (in which case $\mathbf{A}_k = \mathbf{A}$) (Golub and Van Loan 1996). This uniqueness is one reason principal component analysis, which we meet next, is formulated in the Frobenius norm.

Let us now test the theorem on our 400×500 cat photograph. Eckart–Young fixes the spectral error of every truncation at σ_{k+1}, but it does not tell us how quickly the singular values of a real image decay, nor how much worse a natural rank-k competitor performs. The cell below loads `img/cat1.jpg`, converts it to grayscale using standard luminance weights for red, green, and blue, and builds the truncations with `np.einsum` (which multiplies its inputs and sums over every index omitted after the arrow; since row i of `Vt` is $\mathbf{v}_i^\top$, `'i,mi,in->mn'` computes the dyadic sum).

```
img = d2l.plt.imread('../img/cat1.jpg') @ np.array([0.299, 0.587, 0.114])  # 400 x 500
U, s, Vt = np.linalg.svd(img, full_matrices=False)
m, n = img.shape
fro = np.linalg.norm(img)
energy = np.cumsum(s**2) / (s**2).sum()                          # energy kept at each rank
slope = np.polyfit(np.log(np.arange(1, 101)), np.log(s[:100]), 1)[0]
print(f'{m} x {n} = {m * n} numbers;  slope of log sigma_i on log i: {slope:.2f}')
print(f'energy kept at rank 1: {energy[0]:.3f}, at rank 4: {energy[3]:.3f}')
for k in [1, 5, 20, 50]:
    A_k = np.einsum('i,mi,in->mn', s[:k], U[:, :k], Vt[:k])    # first k dyads
    print(f'k={k:2d}: ||A-A_k||_2={np.linalg.norm(img - A_k, 2):6.0f}  '
          f'sigma_{k + 1}={s[k]:6.0f}  rel. err {np.linalg.norm(img - A_k) / fro:.3f}  '
          f'stores {k * (m + n + 1) / (m * n):.1%}')
cols = np.argsort(-np.linalg.norm(img, axis=0))[:20]           # 20 largest columns
C = img[:, cols]
proj = C @ np.linalg.pinv(C) @ img
print(f'projection onto the 20 largest columns: rel. err {np.linalg.norm(img - proj) /
↪  fro:.3f}')
```

```
400 x 500 = 200000 numbers;  slope of log sigma_i on log i: -1.11
energy kept at rank 1: 0.886, at rank 4: 0.955
k= 1: ||A-A_k||_2=  9234  sigma_2=  9234  rel. err 0.337  stores 0.5%
k= 5: ||A-A_k||_2=  4048  sigma_6=  4048  rel. err 0.191  stores 2.3%
k=20: ||A-A_k||_2=   874  sigma_21=   874  rel. err 0.080  stores 9.0%
k=50: ||A-A_k||_2=   342  sigma_51=   342  rel. err 0.045  stores 22.5%
projection onto the 20 largest columns: rel. err 0.310
```

The spectral error matches σ_{k+1} at every rank, as guaranteed, and rank 20 stores just 9% of the numbers at an 8% relative error. In Figure 33.28, the cat appears as a bright blur at rank 1, a recognizable silhouette with four paws at rank 5, and unmistakably a cat lying on its back by rank 20. The left panel reveals why so few pieces suffice: over the first hundred indices, the singular values decay roughly as a power law, $\sigma_i \propto i^{-1.1}$.

The energy ratio. The Frobenius error formula gives a practical rule for choosing k. The fraction of total squared "energy" $\sum_i \sigma_i^2$ retained by the rank-k truncation is

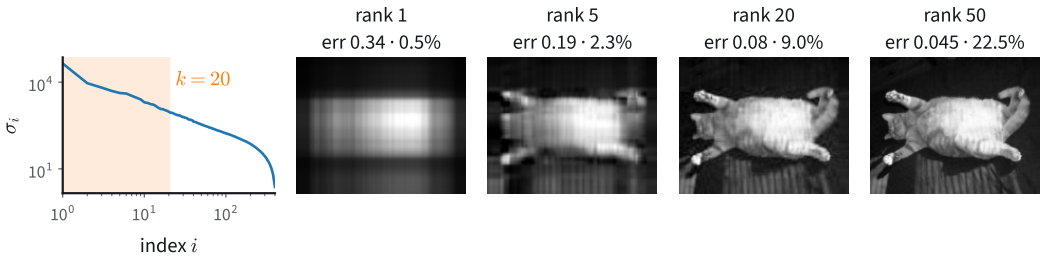

Figure 33.28: Eckart–Young on a 400×500 photograph. Left: the singular values fall roughly as a power law (log–log axes; the shaded band marks the twenty kept in the rank-20 panel). Right: the truncations $\mathbf{A}_k$ with their relative Frobenius error and the fraction $k(m+n+1)/mn$ of the original numbers they store.

$$\frac{\sum_{i \le k} \sigma_i^2}{\sum_i \sigma_i^2} = 1 - \frac{\|\mathbf{A} - \mathbf{A}_k\|_F^2}{\|\mathbf{A}\|_F^2}, \tag{33.55}$$

meaning the relative Frobenius error is the square root of one minus the energy ratio. Retaining 95% of the energy thus corresponds to a relative error of $\sqrt{0.05} \approx 22\%$, while retaining 99% brings the error down to 10%. One must read this ratio with care, however. On the photograph, σ_1^2 alone accounts for 89% of the energy because a constant image has rank one (all rows identical) and the photograph's average brightness is large, so the first dyad mostly captures that mean. Rank 4 already retains 95% of the energy (at 21% relative error), whereas once we subtract the mean pixel value, reaching 95% requires rank 8 instead of 4 (as we verify in Section 33.5.4.3). Always check whether σ_1 is dominated by a nonzero mean, or subtract the mean first, just as principal component analysis does.

To see how much Eckart–Young saves over a naive rank-20 scheme, the last lines of the cell select the 20 actual columns of the photograph with the largest norms and project every column onto their span (the idea behind CUR decompositions, which approximate a matrix using subsets of its own rows and columns). Its relative error is 0.31, nearly four times worse than the 0.08 of the truncated SVD.

Truncation as denoising. Compression is not the only reason to truncate an SVD; denoising is another. Suppose an observed $m \times n$ matrix ($m \le n$) consists of a low-rank signal plus random noise, $\mathbf{A} = \mathbf{B} + \mathbf{N}$, where the entries of $\mathbf{N}$ are independent with mean zero and standard deviation σ_{noise}. By the Marchenko–Pastur law of Section 33.3.2.4 applied to $\mathbf{N}\mathbf{N}^\top/n$, the singular values of a large noise matrix concentrate inside the interval $[(\sqrt{n} - \sqrt{m})\sigma_{\text{noise}}, (\sqrt{n} + \sqrt{m})\sigma_{\text{noise}}]$. Signal components whose singular values rise well above the upper edge stand out cleanly from the noise bulk, while weaker ones disappear into it. For square matrices with a known noise level, Gavish and Donoho proved that the asymptotically optimal hard threshold is $\frac{4}{\sqrt{3}}\sqrt{n}\,\sigma_{\text{noise}} \approx 2.309\sqrt{n}\,\sigma_{\text{noise}}$, sitting slightly above the noise edge $2\sqrt{n}\,\sigma_{\text{noise}}$ (Gavish and Donoho 2014). Exercise 8 derives the constant $4/\sqrt{3}$.

33.5.2.2 Principal Component Analysis

Suppose we are given a dataset whose examples are the rows of $\mathbf{X} \in \mathbb{R}^{n \times d}$, with n data points and d features. Often most of the variation in the data lies along just a few directions. Two natural questions arise: which unit direction captures the largest variance of the data, and which k-dimensional affine subspace approximates the points with the smallest squared error? Surprisingly, both questions have the exact same answer, and it is simply the truncated SVD of the centered data.

Centering. First fix any k-dimensional subspace with orthogonal projector $\mathbf{P}$, and ask which offset $\mathbf{c}$ minimizes the total squared reconstruction error $\sum_i \|(\mathbf{I}-\mathbf{P})(\mathbf{x}_i - \mathbf{c})\|^2$. This objective is a convex quadratic in $\mathbf{c}$, and its gradient $-2(\mathbf{I}-\mathbf{P})\sum_i(\mathbf{x}_i - \mathbf{c})$ vanishes at the sample mean $\mathbf{c} = \bar{\mathbf{x}}$, regardless of $\mathbf{P}$. The best affine subspace therefore always passes through the mean, so we begin by *centering* the data: $\tilde{\mathbf{X}} = \mathbf{X} - \mathbf{1}\bar{\mathbf{x}}^\top$. Its empirical covariance is the symmetric positive semidefinite matrix $\mathbf{C} = \frac{1}{n}\tilde{\mathbf{X}}^\top\tilde{\mathbf{X}}$. (Using the unbiased factor $\frac{1}{n-1}$ rescales every eigenvalue identically and changes neither the principal directions nor the fraction of variance they explain.)

Proposition (PCA via Rayleigh). *Over all unit vectors* $\mathbf{w}$*, the projected variance* $\frac{1}{n}\|\tilde{\mathbf{X}}\mathbf{w}\|^2 = \mathbf{w}^\top\mathbf{C}\mathbf{w}$ *is maximized by the top eigenvector of* $\mathbf{C}$*, which is the top right singular vector* $\mathbf{v}_1$ *of* $\tilde{\mathbf{X}}$*, with maximal variance* σ_1^2/n*.*

Proof. Projecting a centered point onto $\mathbf{w}$ yields the scalar coordinate $\tilde{\mathbf{x}}^\top\mathbf{w}$, whose empirical variance is $\frac{1}{n}\sum_i(\tilde{\mathbf{x}}_i^\top\mathbf{w})^2 = \frac{1}{n}\|\tilde{\mathbf{X}}\mathbf{w}\|^2 = \mathbf{w}^\top\mathbf{C}\mathbf{w}$. By the Rayleigh proposition of Section 33.3.2.3, this quadratic form is maximized by the top eigenvector of $\mathbf{C}$, with value $\lambda_1(\mathbf{C})$. By Equation 33.49, $\mathbf{C} = \frac{1}{n}\mathbf{V}\Sigma^\top\Sigma\mathbf{V}^\top$, so the eigenvectors of $\mathbf{C}$ are the right singular vectors $\mathbf{v}_i$ of $\tilde{\mathbf{X}}$ and its eigenvalues are σ_i^2/n. ■

Among unit vectors orthogonal to $\mathbf{v}_1$, the variance is maximized by $\mathbf{v}_2$, and continuing inductively gives the top k *principal directions* $\mathbf{v}_1, \dots, \mathbf{v}_k$, with component i explaining variance σ_i^2/n. Now check the reconstruction error. Projecting every centered point onto $\mathrm{span}\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$ corresponds to right-multiplying $\tilde{\mathbf{X}}$ by $\mathbf{V}_k\mathbf{V}_k^\top$. Since $\mathbf{V}^\top\mathbf{V}_k$ selects the first k columns of the identity,

$$\tilde{\mathbf{X}}\mathbf{V}_k\mathbf{V}_k^\top = \mathbf{U}\Sigma\mathbf{V}^\top\mathbf{V}_k\mathbf{V}_k^\top = \mathbf{U}_k\Sigma_k\mathbf{V}_k^\top = \tilde{\mathbf{X}}_k.$$

Projecting onto the top k principal directions is therefore identical to taking the rank-k truncated SVD of the centered data. By Eckart–Young in the Frobenius norm, no other projection, and indeed no other rank-k matrix at all, can reconstruct the centered points with smaller squared error. The discarded variance $\sum_{i>k}\sigma_i^2/n$ equals the mean squared reconstruction error, and the explained-variance ratio is simply the energy ratio Equation 33.55 of $\tilde{\mathbf{X}}$.

Figure 33.29 shows a cloud of 300 points with standard deviations 3 and 0.8 along axes rotated by $\pi/5 = 36^\circ$, together with its two principal axes. In the population, the first direction holds $9/9.64 \approx 93.4\%$ of the variance and aligns with the long axis. The cell below checks how accurately a finite sample of 300 points recovers these values.

```
theta = np.pi / 5
rot = np.array([[np.cos(theta), -np.sin(theta)], [np.sin(theta), np.cos(theta)]])
```

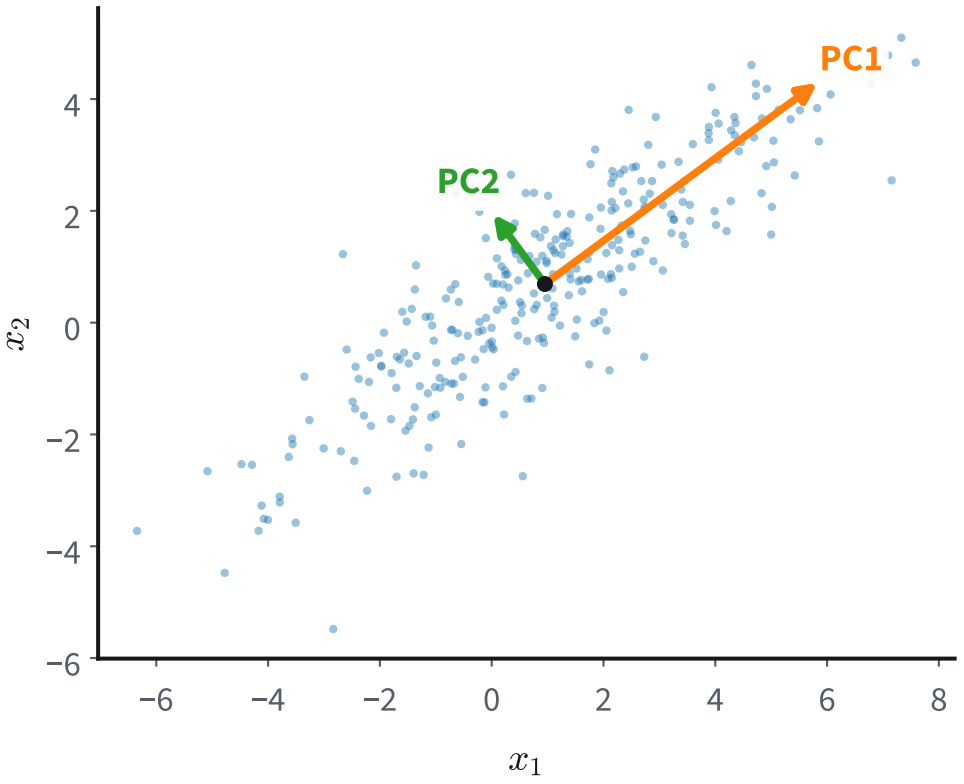

Figure 33.29: A cloud of 300 points centered at $(1, 0.6)$ with standard deviations 3 and 0.8 along axes rotated by 36°, and its principal axes drawn from the mean, each two standard deviations $2\sigma_i/\sqrt{n}$ long. The first axis points along the direction of largest variance.

```
X = np.random.standard_normal((300, 2)) * np.array([3.0, 0.8]) @ rot.T   # the cloud
Xc = X - X.mean(0)
U, s, Vt = np.linalg.svd(Xc, full_matrices=False)
X1 = np.outer(U[:, 0] * s[0], Vt[0])                                    # rank-1 reconstruction
print('explained-variance ratio:', (s**2 / (s**2).sum()).round(3), ' (population 0.934,
 ↪  0.066)')
print('angle of v_1 to the long axis:',
      np.degrees(np.arccos(abs(Vt[0] @ rot[:, 0]))).round(1), 'degrees')
print('mean squared rank-1 error:', (((Xc - X1)**2).sum() / 300).round(4),
      '  sigma_2^2 / n:', (s[1]**2 / 300).round(4))
```

```
explained-variance ratio: [0.939 0.061]  (population 0.934, 0.066)
angle of v_1 to the long axis: 0.4 degrees
mean squared rank-1 error: 0.6403   sigma_2^2 / n: 0.6403
```

Across random draws, the first principal direction explains roughly 91% to 95% of the variance and lands within a few degrees of the true long axis. If we forget to center the data, however, the first singular vector swings toward the mean of the cloud as soon as the mean's offset exceeds the spread of the points; it then describes *where* the cloud sits rather than *how* it varies. Exercise 3 quantifies this effect.

33.5.3 Solving Linear Systems with the SVD

33.5.3.1 The Pseudoinverse and Least Squares

A linear system $\mathbf{A}\mathbf{x} = \mathbf{b}$ with more equations than unknowns generally has no exact solution, while one with fewer equations than unknowns has infinitely many. In both situations, we look for the least-squares solution introduced in Section 33.1 (writing the target as $\mathbf{b}$ instead of $\mathbf{y}$),

$$\min_{\mathbf{x}} \|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2,$$

and whenever multiple $\mathbf{x}$ achieve the same minimum residual, we choose the one with the smallest norm.

Consider the simplest underdetermined example first: a single equation in two unknowns, $x_1 + x_2 = 2$. Its solutions form an entire line, and the residual is zero everywhere on it. Which point on the line should we pick? Here $\mathbf{A} = \begin{pmatrix} 1 & 1 \end{pmatrix}$, which has one nonzero singular value $\sigma_1 = \sqrt{2}$, right singular vector $\mathbf{v}_1 = (1,1)/\sqrt{2}$, and $u_1 = 1$. The equation fixes the coordinate of $\mathbf{x}$ along $\mathbf{v}_1$ to $\sqrt{2}$, while the coordinate along the null-space direction $\mathbf{v}_2 = (1,-1)/\sqrt{2}$ does not affect the residual at all. Setting that free coordinate to zero yields $(1,1)$, the foot of the perpendicular from the origin to the line, with norm $\sqrt{2}$; every other solution $(1+t, 1-t)$ has strictly larger squared norm $2 + 2t^2$ (Figure 33.30).

The general rule simply inverts every nonzero singular value and transposes the orthogonal factors. The *Moore–Penrose pseudoinverse* of $\mathbf{A}$ is

$$\mathbf{A}^{+} = \mathbf{V}\Sigma^{+}\mathbf{U}^{\top}, \qquad \Sigma^{+}_{ii} = \begin{cases} 1/\sigma_i & \sigma_i > 0, \\ 0 & \sigma_i = 0, \end{cases} \tag{33.56}$$

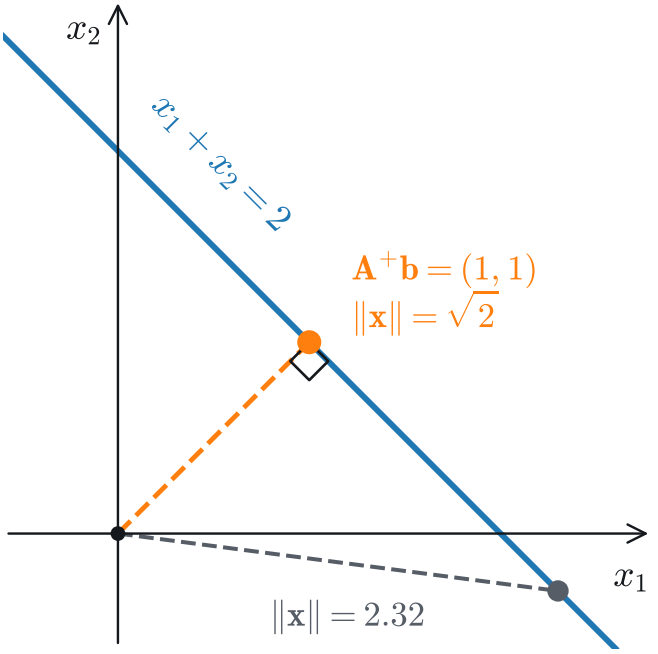

Figure 33.30: Least squares with one equation and two unknowns. Every point of the line solves $x_1 + x_2 = 2$; the pseudoinverse returns the one closest to the origin, the foot of the perpendicular.

where Σ^+ has shape $n \times m$, the transpose shape of Σ. Geometrically, $\mathbf{A}^+$ reverses every stretch that can be reversed and sends the left null space to zero. For the shear, $\mathbf{T}^+ = \mathbf{T}^{-1} = \left(\begin{smallmatrix} 1 & -1 \\ 0 & 1 \end{smallmatrix}\right)$; for $\mathbf{A} = (1 \;\; 1)$, $\mathbf{A}^+ = \mathbf{v}_1 \sigma_1^{-1} u_1 = (\tfrac{1}{2}, \tfrac{1}{2})^\top$, so $\mathbf{A}^+ \cdot 2 = (1, 1)$.

Proposition (minimum-norm least squares). *Among all minimizers of $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|$, the unique one of smallest norm is $\hat{\mathbf{x}} = \mathbf{A}^+\mathbf{b}$.*

Proof. Change variables to the singular bases by setting $\mathbf{y} = \mathbf{V}^\top \mathbf{x}$ and $\mathbf{c} = \mathbf{U}^\top \mathbf{b}$. Because $\mathbf{U}$ is orthogonal, it preserves Euclidean norms, so

$$\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2 = \|\mathbf{U}^\top(\mathbf{A}\mathbf{x} - \mathbf{b})\|^2 = \|\Sigma \mathbf{y} - \mathbf{c}\|^2 = \sum_{i \le r} (\sigma_i y_i - c_i)^2 + \sum_{i > r} c_i^2.$$

Rotating into the singular bases decouples the system into independent scalar equations. The first sum is minimized term by term by setting $y_i = c_i / \sigma_i$ for $i \le r$. The second sum is a fixed constant, the component of $\mathbf{b}$ outside the column space, which no choice of $\mathbf{x}$ can reduce. Meanwhile, the coordinates y_i for $i > r$ do not enter the residual at all, and since $\|\mathbf{x}\| = \|\mathbf{y}\|$, setting them to zero gives the unique minimizer of smallest norm. That choice is $\mathbf{y} = \Sigma^+ \mathbf{c}$, which translates back to $\hat{\mathbf{x}} = \mathbf{V}\Sigma^+\mathbf{U}^\top \mathbf{b} = \mathbf{A}^+\mathbf{b}$. ∎

In the singular bases, minimizing the residual and minimizing the norm govern completely disjoint coordinates ($i \le r$ versus $i > r$), so both goals are achieved simultaneously. When $\mathbf{A}$ is square and invertible, every σ_i is positive and $\mathbf{A}^+ = \mathbf{V}\Sigma^{-1}\mathbf{U}^\top = \mathbf{A}^{-1}$. Yet the same formula also exposes the main danger of least squares: dividing by a tiny σ_i multiplies any noise in $\mathbf{b}$ along $\mathbf{u}_i$ by $1/\sigma_i$.

Two standard remedies tame these unstable directions. *Ridge regression* minimizes $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2 + \lambda \|\mathbf{x}\|^2$ for $\lambda > 0$, giving $\mathbf{x}_\lambda = (\mathbf{A}^\top \mathbf{A} + \lambda \mathbf{I})^{-1} \mathbf{A}^\top \mathbf{b}$. The *truncated pseudoinverse* $\mathbf{x}_k$ instead keeps only the first k singular terms of $\mathbf{A}^+\mathbf{b}$. Substituting the SVD and noting that $\mathbf{A}^\top \mathbf{A} + \lambda \mathbf{I} = \mathbf{V}(\Sigma^\top \Sigma + \lambda \mathbf{I})\mathbf{V}^\top$, both solutions take a transparent filter form:

$$\mathbf{x}_\lambda = \sum_{i \le r} \frac{\sigma_i^2}{\sigma_i^2 + \lambda} \, \frac{\mathbf{u}_i^\top \mathbf{b}}{\sigma_i} \, \mathbf{v}_i, \qquad \mathbf{x}_k = \sum_{i \le k} \frac{\mathbf{u}_i^\top \mathbf{b}}{\sigma_i} \, \mathbf{v}_i. \tag{33.57}$$

Both start from the unregularized pseudoinverse terms $\mathbf{u}_i^\top \mathbf{b} / \sigma_i$. Ridge regression scales component i by the smooth filter factor $\sigma_i^2 / (\sigma_i^2 + \lambda)$, which stays near 1 when $\sigma_i^2 \gg \lambda$ and shrinks toward 0 when $\sigma_i^2 \ll \lambda$; truncation applies a sharp step function of 1 or 0. For $\lambda = 1$, singular values 3, 1, and 0.3 receive filter factors 0.9, 0.5, and 0.083. For a linear model trained with squared loss, weight decay (Section 2.7) is precisely ridge regression, and these filter factors show exactly which directions it damps.

The normal equations. The classical textbook route to least squares solves the normal equations $\mathbf{A}^\top \mathbf{A}\mathbf{x} = \mathbf{A}^\top \mathbf{b}$. For any $\mathbf{A}$, its solutions are the least-squares minimizers (since $\mathbf{A}^\top(\mathbf{A}\mathbf{x} - \mathbf{b}) = \mathbf{0}$ states that the residual is orthogonal to the column space), and the solution is unique whenever $\mathbf{A}$ has full column rank. Numerically, however, forming $\mathbf{A}^\top \mathbf{A}$ is a bad idea because it squares the condition number (Section 33.5.3.2). Modern libraries therefore solve least-squares problems via the SVD or a QR factorization instead.

Let us test the pseudoinverse on one overdetermined and one underdetermined system. The first fits a line $b \approx x_1 + x_2 t$ to the four observations $\mathbf{b} = (6, 5, 7, 10)$ at $t = 1, 2, 3, 4$; the second is our single equation $x_1 + x_2 = 2$.

```
A = np.array([[1., 1.], [1., 2.], [1., 3.], [1., 4.]])     # 4 equations, 2 unknowns
b = np.array([6., 5., 7., 10.])
x_pinv = np.linalg.pinv(A) @ b
x_lstsq = np.linalg.lstsq(A, b, rcond=None)[0]
print('overdetermined: pinv', x_pinv.round(4), ' lstsq', x_lstsq.round(4),
      ' residual', np.linalg.norm(A @ x_pinv - b).round(4))
A1 = np.array([[1., 1.]])                                   # 1 equation: x1 + x2 = 2
x1 = np.linalg.pinv(A1) @ np.array([2.])
print('underdetermined: pinv gives', x1.round(4), ' norm', np.linalg.norm(x1).round(4))
```

```
overdetermined: pinv [3.5 1.4]  lstsq [3.5 1.4]  residual 2.0494
underdetermined: pinv gives [1. 1.]  norm 1.4142
```

The pseudoinverse and `np.linalg.lstsq` agree on the fitted line $3.5 + 1.4t$, with residual $\sqrt{4.2} \approx 2.049$, and for the single equation the pseudoinverse returns the foot of the perpendicular, $(1, 1)$.

33.5.3.2 The Condition Number

In practice, the entries of a linear system come from noisy measurements or finite-precision rounding. Before trusting a computed solution, we need to know how much a tiny change in the data can alter the answer. A simple 2×2 system reveals how dramatic the amplification can be. Consider $\mathbf{K}\mathbf{x} = \mathbf{b}$ with $\mathbf{K} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1.0001 \end{smallmatrix}\right)$ and $\mathbf{b} = (2, 2.0001)$. Its exact solution is $\mathbf{x} = (1, 1)$. Now nudge b_2 by just 10^{-4}, to 2.0002: the solution jumps all the way to $(0, 2)$. A perturbation of roughly three parts in 10^5 in the data has completely changed the answer. The singular values of $\mathbf{K}$, roughly 2.00005 and 5×10^{-5}, tell us why.

The *condition number* of a matrix $\mathbf{A}$ of rank r is the ratio of its largest to its smallest nonzero singular value,

$$\kappa(\mathbf{A}) = \frac{\sigma_1}{\sigma_r}. \tag{33.58}$$

Geometrically, $\kappa(\mathbf{A})$ measures how unevenly $\mathbf{A}$ stretches different directions: for $\mathbf{K}$ it is about 4×10^4, whereas for the shear it is only $\varphi^2 \approx 2.618$. When $\mathbf{A}$ is symmetric positive definite, its singular values coincide with its eigenvalues, so $\kappa = \lambda_{\max}/\lambda_{\min}$, recovering the condition number for quadratic bowls in Section 33.3.2.3. The next proposition shows that $\kappa(\mathbf{A})$ is the exact worst-case amplification factor for relative errors in a linear solve.

Proposition (error amplification). *Let $\mathbf{A}$ be square and invertible, $\mathbf{A}\mathbf{x} = \mathbf{b}$ with $\mathbf{b} \neq \mathbf{0}$, and let a perturbation $\delta\mathbf{b}$ shift the solution to $\mathbf{x} + \delta\mathbf{x}$. Then*

$$\frac{\|\delta\mathbf{x}\|}{\|\mathbf{x}\|} \le \kappa(\mathbf{A}) \, \frac{\|\delta\mathbf{b}\|}{\|\mathbf{b}\|}, \tag{33.59}$$

and for every $\mathbf{A}$ there exist $\mathbf{b}$ and $\delta\mathbf{b}$ that attain equality.

Proof. From $\mathbf{A}\,\delta\mathbf{x} = \delta\mathbf{b}$ we have $\delta\mathbf{x} = \mathbf{A}^{-1}\delta\mathbf{b}$. The largest singular value of $\mathbf{A}^{-1} = \mathbf{V}\Sigma^{-1}\mathbf{U}^{\top}$ is $1/\sigma_n$, so Equation 33.48 gives $\|\delta\mathbf{x}\| \le \sigma_n^{-1}\|\delta\mathbf{b}\|$. Likewise, $\mathbf{b} = \mathbf{A}\mathbf{x}$ gives $\|\mathbf{b}\| \le \sigma_1\|\mathbf{x}\|$. Combining the two inequalities yields

$$\frac{\|\delta\mathbf{x}\|}{\|\mathbf{x}\|} \le \frac{\sigma_1}{\sigma_n}\,\frac{\|\delta\mathbf{b}\|}{\|\mathbf{b}\|} = \kappa(\mathbf{A})\,\frac{\|\delta\mathbf{b}\|}{\|\mathbf{b}\|}.$$

Equality holds in both bounds simultaneously when $\mathbf{b} = \mathbf{u}_1$ (making $\mathbf{x} = \sigma_1^{-1}\mathbf{v}_1$ as short as possible for a unit right-hand side) and $\delta\mathbf{b} = \varepsilon\mathbf{u}_n$ (making $\delta\mathbf{x} = \varepsilon\sigma_n^{-1}\mathbf{v}_n$ as large as possible for a perturbation of size ε). ■

The relative error in the data is therefore amplified by at most κ. With $\kappa = 10^4$, a relative error of 10^{-8} in $\mathbf{b}$ can grow into 10^{-4} in $\mathbf{x}$, costing four digits of accuracy. In our 2×2 example, the relative change in $\mathbf{b}$ is $10^{-4}/\|\mathbf{b}\| \approx 3.5 \times 10^{-5}$, so the bound allows a relative change of 1.41 in $\mathbf{x}$, and the realized change is 1.0. The perturbation $(0, 10^{-4})$ places $1/\sqrt{2}$ of its length along the most amplified direction $\mathbf{u}_2 \approx (1, -1)/\sqrt{2}$, while $\mathbf{b}$ points almost directly along $\mathbf{u}_1$.

At the ideal extreme, an orthogonal matrix has all singular values equal to 1, so $\kappa = 1$: rotations and reflections never amplify error. That is why computing with the orthogonal factors $\mathbf{U}$ and $\mathbf{V}$ is numerically safe, and why an orthogonally initialized weight matrix preserves the norm of every input vector. At the opposite extreme, forming the Gram matrix squares the condition number,

$$\kappa(\mathbf{A}^\top\mathbf{A}) = \kappa(\mathbf{A})^2,$$

because Equation 33.49 is the SVD of $\mathbf{A}^\top\mathbf{A}$, with singular values σ_i^2 (for any matrix $\mathbf{A}$ of any rank). For the shear, κ jumps from $\varphi^2 \approx 2.62$ to $\varphi^4 \approx 6.85$. The cell below verifies our 2×2 example and compares $\kappa(\mathbf{A})$ with $\kappa(\mathbf{A}^\top\mathbf{A})$ for the line-fitting matrix above.

```
K = np.array([[1., 1.], [1., 1.0001]])
b = np.array([2., 2.0001])
x = np.linalg.solve(K, b)
x2 = np.linalg.solve(K, b + np.array([0., 1e-4]))
print('x =', x.round(4), '  after changing b_2 by 1e-4:', x2.round(4) + 0.)
kappa = np.linalg.cond(K)
print(f'kappa(K) = {kappa:.0f};  bound {kappa * 1e-4 / np.linalg.norm(b):.2f};  '
      f'realized {np.linalg.norm(x2 - x) / np.linalg.norm(x):.2f}')
A = np.array([[1., 1.], [1., 2.], [1., 3.], [1., 4.]])
print(f'kappa(A) = {np.linalg.cond(A):.3f};  kappa(A^T A) = {np.linalg.cond(A.T @ A):.2f};  '
      f'kappa(A)^2 = {np.linalg.cond(A)**2:.2f}')
```

```
x = [1. 1.]   after changing b_2 by 1e-4: [0. 2.]
kappa(K) = 40002;  bound 1.41;  realized 1.00
kappa(A) = 7.469;  kappa(A^T A) = 55.78;  kappa(A)^2 = 55.78
```

The output confirms our hand calculation: the solution jumps from $(1, 1)$ to $(0, 2)$, with $\kappa(\mathbf{K}) \approx 40{,}002$. Even for the modest 4×2 line-fitting matrix, $\kappa = 7.47$, so forming the normal equations would already inflate the condition number to $\kappa^2 = 55.8$.

Conditioning and the shape of a bowl. A large condition number also shows up directly in optimization as elongated level sets. For a full-column-rank least-squares objective $\frac{1}{2}\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2$, the Hessian is $\mathbf{H} = \mathbf{A}^\top\mathbf{A}$, whose level sets are ellipsoids with semi-axes proportional to $1/\sigma_i$ along the $\mathbf{v}_i$. The contours therefore have axis ratio $\kappa(\mathbf{A})$, while the Hessian itself has condition number $\kappa(\mathbf{A})^2$. On such a narrow valley, gradient descent zig-zags across the

steep walls and makes slow progress along the floor (Figure 33.31), at a convergence rate governed by $\kappa(\mathbf{H})$ that we derive in Section 35.1.

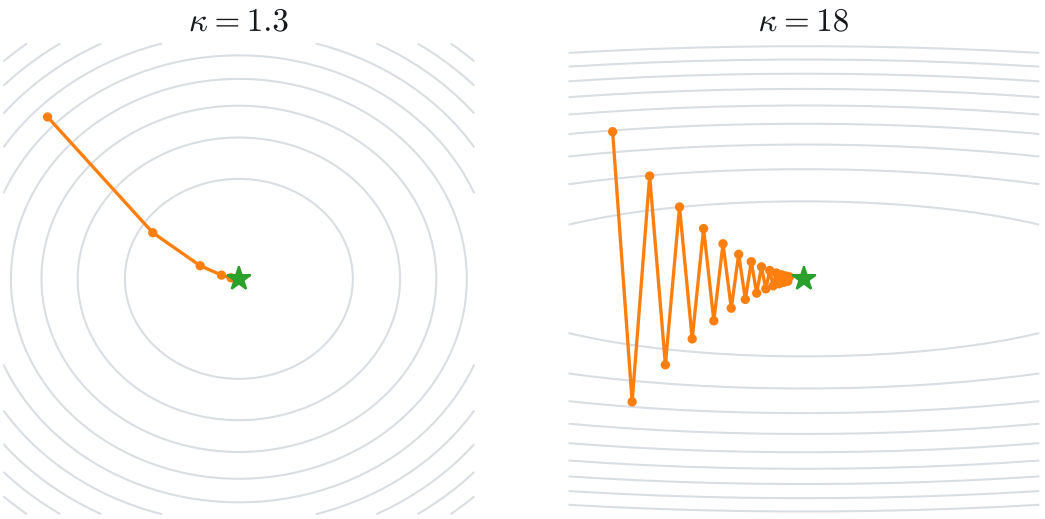

Figure 33.31: Gradient descent on a well-conditioned quadratic bowl ($\kappa(\mathbf{H}) = 1.3$, near-circular contours, an almost straight path) versus an ill-conditioned one ($\kappa(\mathbf{H}) = 18$, a zig-zag trajectory across the narrow valley). The panel titles give the condition number $\kappa(\mathbf{H})$ of the Hessian; the contours are elongated by its square root, a factor of about 4.2 in the second panel.

33.5.4 The SVD in Deep Learning

Three recurring questions in modern large-model training come down directly to the singular values of a weight matrix: how many parameters a fine-tuning adapter needs, how to construct an update that treats every direction of weight space equally, and how much a single layer can stretch its input.

33.5.4.1 Low-Rank Updates

Updating every parameter of a large pretrained model during fine-tuning is costly in both memory and compute. LoRA (Hu et al. 2021) avoids this by freezing each pretrained weight matrix $\mathbf{W} \in \mathbb{R}^{m\times n}$ and learning only a rank-k correction $\Delta\mathbf{W} = \mathbf{BA}$, where $\mathbf{B} \in \mathbb{R}^{m\times k}$ and $\mathbf{A} \in \mathbb{R}^{k\times n}$ (here $\mathbf{A}$ follows the paper's notation for the $k\times n$ down-projection, not the generic matrix of earlier subsections). The adapter uses $k(m+n)$ trainable parameters instead of mn. For a 4096×4096 layer with $k = 8$, that drops the parameter count from $16{,}777{,}216$ to $8 \cdot 8192 = 65{,}536$, or just 0.39%. As Figure 33.32 illustrates, the frozen weight and the low-rank bypass act in parallel on the same input and add their outputs.

What does Eckart–Young tell us here, and what does it *not* tell us? If full fine-tuning would produce an update with singular values $\sigma_1 \geq \sigma_2 \geq \cdots$, then Eckart–Young guarantees that no rank-k adapter can approximate that specific update closer than σ_{k+1} in the spectral norm or $(\sum_{i>k} \sigma_i^2)^{1/2}$ in the Frobenius norm. It does *not* dictate which adapter gradient descent actually learns. LoRA succeeds whenever *some* low-rank update achieves low loss—

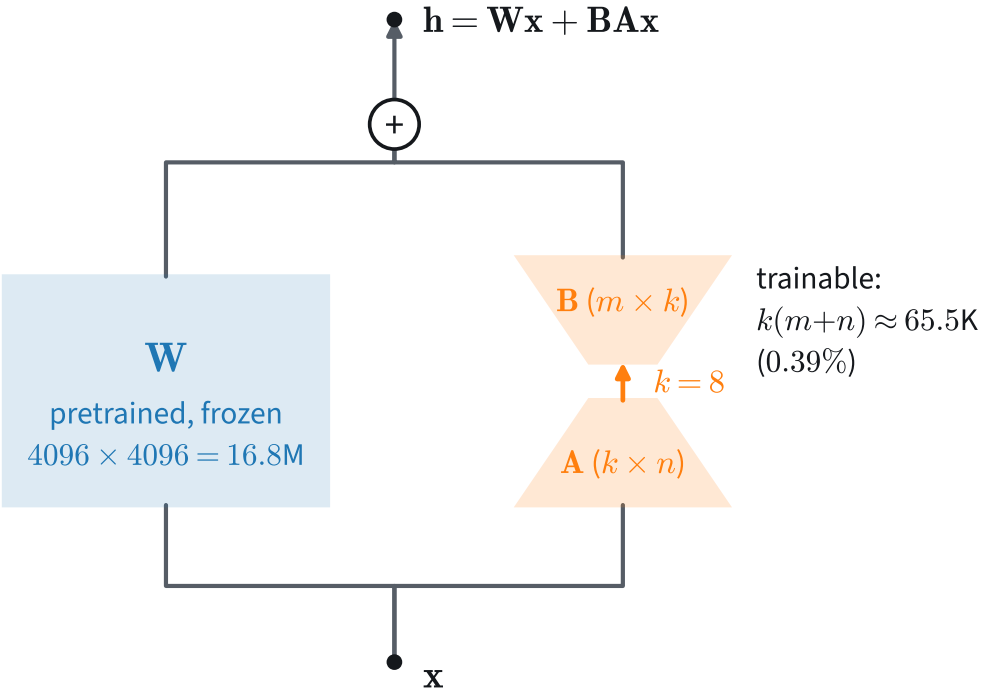

Figure 33.32: The LoRA architecture for one layer. The pretrained $\mathbf{W}$ (all $mn = 16.8\text{M}$ parameters for $m = n = 4096$) stays frozen; a parallel bypass first compresses the input to $k = 8$ dimensions with $\mathbf{A}$ and then expands back with $\mathbf{B}$, so only $k(m + n) \approx 65.5\text{K}$ parameters (about 0.39%) are trained. The two branches add: $\mathbf{h} = \mathbf{W}\mathbf{x} + \mathbf{B}\mathbf{A}\mathbf{x}$. After training, $\mathbf{B}\mathbf{A}$ can be merged into $\mathbf{W}$, so deployment costs nothing extra.

even if it is not the closest rank-k approximation to the full fine-tuning update. That such low-rank solutions exist for many downstream tasks is the empirical discovery behind LoRA. Exercise 2 bounds how much a rank-k adapter can perturb the singular values of $\mathbf{W}$.

33.5.4.2 Orthogonalized Updates

The Muon optimizer (Jordan et al. 2024) updates a weight matrix not along its raw momentum matrix $\mathbf{M}$, but along the *polar factor* of $\mathbf{M}$, the matrix that keeps the singular vectors of $\mathbf{M}$ while setting every nonzero singular value to 1. Section 9.6 motivates and develops the full optimizer; here we supply the two linear-algebraic tools it relies on: what the polar factor is, and how to compute it using only matrix multiplications.

The polar decomposition. For a square matrix $\mathbf{A}$, inserting $\mathbf{V}^\top\mathbf{V} = \mathbf{I}$ into the SVD splits it into an orthogonal factor times a symmetric stretch:

$$\mathbf{A} = \mathbf{U}\Sigma\mathbf{V}^\top = (\mathbf{U}\mathbf{V}^\top)\,(\mathbf{V}\Sigma\mathbf{V}^\top) = \mathbf{Q}\,\mathbf{P}. \tag{33.60}$$

Here $\mathbf{Q} = \mathbf{U}\mathbf{V}^\top$ is orthogonal (as a product of orthogonal matrices) and $\mathbf{P} = \mathbf{V}\Sigma\mathbf{V}^\top$ is symmetric positive semidefinite with eigenvalues σ_i. Every square matrix thus decomposes into a symmetric stretch followed by an orthogonal map, the matrix analogue of writing a complex number in polar form as $z = e^{i\theta}|z|$. Note that $\mathbf{Q}$ need not be a pure rotation: when $\mathbf{A}$ is invertible, $\det\mathbf{Q} = \operatorname{sign}\det\mathbf{A}$, so $\mathbf{Q}$ includes a reflection whenever $\det\mathbf{A} < 0$. For the shear $\mathbf{T}$, Equation 33.47 yields $\mathbf{Q} = \mathbf{R}_{31.7^\circ}\mathbf{R}_{58.3^\circ}^\top = \mathbf{R}_{-26.6^\circ} = \frac{1}{\sqrt{5}}\left(\begin{smallmatrix} 2 & 1 \\ -1 & 2 \end{smallmatrix}\right)$ (since $\tan 26.6^\circ = \frac{1}{2}$) and $\mathbf{P} = \frac{1}{\sqrt{5}}\left(\begin{smallmatrix} 2 & 1 \\ 1 & 3 \end{smallmatrix}\right)$. Checking the product confirms $\mathbf{Q}\mathbf{P} = \frac{1}{5}\left(\begin{smallmatrix} 5 & 5 \\ 0 & 5 \end{smallmatrix}\right) = \mathbf{T}$ and $\mathbf{P}^2 = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 2 \end{smallmatrix}\right) = \mathbf{T}^\top\mathbf{T}$.

For a rectangular matrix $\mathbf{M}$ with thin SVD $\mathbf{M} = \mathbf{U}\Sigma\mathbf{V}^\top$, the polar factor is still $\mathbf{U}\mathbf{V}^\top$: it shares the singular vectors of $\mathbf{M}$ and has all singular values equal to 1, so its columns (when $m \geq n$) or its rows (when $m \leq n$) are orthonormal. When $\mathbf{M}$ is rank-deficient ($r < \min(m, n)$), the polar factor is not unique, and the natural canonical choice is $\mathbf{U}_r\mathbf{V}_r^\top$ from the compact SVD. Exercise 6 shows that for a square matrix, $\mathbf{U}\mathbf{V}^\top$ is also the closest orthogonal matrix to $\mathbf{A}$ in the Frobenius norm.

Odd polynomials of a matrix. Computing a full SVD of every weight matrix at every training step would be prohibitively slow. Fortunately, we can transform the singular values without touching the singular vectors using nothing more than matrix multiplications.

Proposition (odd polynomials act on singular values). *Let $\mathbf{X} = \mathbf{U}\Sigma\mathbf{V}^\top$ be a thin SVD and let $p(\sigma) = \sum_j c_j\sigma^{2j+1}$ be an odd polynomial. Then*

$$p(\mathbf{X}) := \sum_j c_j\,\mathbf{X}(\mathbf{X}^\top\mathbf{X})^j = \mathbf{U}\,p(\Sigma)\,\mathbf{V}^\top. \tag{33.61}$$

Proof. Since $\mathbf{X}^\top\mathbf{X} = \mathbf{V}\Sigma^2\mathbf{V}^\top$, taking powers gives $(\mathbf{X}^\top\mathbf{X})^j = \mathbf{V}\Sigma^{2j}\mathbf{V}^\top$, and left-multiplying by $\mathbf{X} = \mathbf{U}\Sigma\mathbf{V}^\top$ gives $\mathbf{X}(\mathbf{X}^\top\mathbf{X})^j = \mathbf{U}\Sigma^{2j+1}\mathbf{V}^\top$. Summing over j completes the proof. ■

Any odd matrix polynomial therefore leaves $\mathbf{U}$ and $\mathbf{V}$ untouched while applying the scalar function p independently to each singular value. To reach the polar factor $\mathbf{U}\mathbf{V}^\top$, we simply need an odd polynomial p whose repeated application drives every positive singular value to 1.

Newton–Schulz. The classic *Newton–Schulz iteration* $\mathbf{X} \leftarrow \frac{1}{2}(3\mathbf{X} - \mathbf{X}\mathbf{X}^\top\mathbf{X})$ applies the cubic polynomial $p(\sigma) = \frac{1}{2}(3\sigma - \sigma^3)$ to every singular value. Its fixed points are 0 and ± 1. On $(0, 1]$, p pushes every value upward without ever overshooting 1, since $p(\sigma) - \sigma = \frac{1}{2}\sigma(1 - \sigma^2) \geq 0$ and p reaches its maximum $p(1) = 1$. In fact, p maps the entire interval $(0, \sqrt{3})$ into $(0, 1]$, so every starting value in this *immediate basin* of 1 converges to 1, whereas larger starting values can behave erratically (Exercise 5). Scaling the initial matrix as $\mathbf{X}_0 = \mathbf{M}/\|\mathbf{M}\|_F$ guarantees that every singular value starts inside $(0, 1]$, because $\|\mathbf{M}\|_F \geq \sigma_1(\mathbf{M})$. Any zero singular value stays zero (since $p(0) = 0$), so a rank-deficient $\mathbf{M}$ converges cleanly to $\mathbf{U}_r\mathbf{V}_r^\top$.

How many iterations does this take? Near 0, $p(\sigma) \approx \frac{3}{2}\sigma$, so a small singular value s grows by a factor of $3/2$ per step and needs roughly $\log_{3/2}(1/s)$ steps to reach order one. Near 1, expanding gives $p(1 - e) = 1 - \frac{3}{2}e^2 + \frac{1}{2}e^3$: the error roughly squares at every step, shrinking from order one to 10^{-6} in about four additional steps. Gluing the two phases together predicts roughly $\log_{3/2}(1/s_{\min}) + 4$ steps, governed by the smallest normalized singular value $s_{\min} = \sigma_{\min}(\mathbf{M})/\|\mathbf{M}\|_F$. Let us test this rough estimate on a random 6×4 matrix standing in for the momentum.

```
M = np.random.standard_normal((6, 4))                # a stand-in momentum matrix
X = M / np.linalg.norm(M)                           # Frobenius normalization: sigma in (0, 1]
s_min = np.linalg.svd(X, compute_uv=False)[-1]
for k in range(1, 41):
    X = 1.5 * X - 0.5 * X @ X.T @ X                  # p(sigma) = (3 sigma - sigma^3) / 2
    if np.abs(np.linalg.svd(X, compute_uv=False) - 1).max() < 1e-6:
        break
U, s, Vt = np.linalg.svd(M, full_matrices=False)
print(f'smallest scaled sigma {s_min:.3f};  predicted steps '
      f'{np.log(1 / s_min) / np.log(1.5) + 4:.1f}')
print(f'steps until max|sigma_i - 1| < 1e-6: {k};  distance to U V^T: '
      f'{np.linalg.norm(X - U @ Vt):.1e}')
```

```
smallest scaled sigma 0.223;  predicted steps 7.7
steps until max|sigma_i - 1| < 1e-6: 8;  distance to U V^T: 2.5e-11
```

The actual step count matches the prediction to within a single iteration, and the iterate lands within 10^{-5} of the exact polar factor from a full SVD. Because $s_{\min}$ varies across random draws, so does the step count; a nearly rank-deficient $\mathbf{M}$ takes longer. In practice, Muon replaces the cubic with a tuned quintic polynomial that trades exact convergence to 1 for speed (Section 9.6.2).

33.5.4.3 Measuring and Controlling the Spectrum

Our third question asks how much a linear layer can stretch its input, and the largest singular value answers it directly. More broadly, the full singular spectrum tells us whether a matrix is truly close to low rank. Modern training recipes therefore bound, inspect, and approximate singular values without ever paying for a full SVD.

Spectral normalization. By Equation 33.48, a linear layer $\mathbf{x} \mapsto \mathbf{W}\mathbf{x}$ satisfies $\|\mathbf{W}\mathbf{x} - \mathbf{W}\mathbf{x}'\| \leq \sigma_1\|\mathbf{x} - \mathbf{x}'\|$, with equality whenever $\mathbf{x} - \mathbf{x}'$ aligns with $\mathbf{v}_1$. The smallest constant bounding how much a map can amplify input differences is its *Lipschitz constant*, so here the Lipschitz constant is simply $\sigma_1 = \|\mathbf{W}\|_2$. Dividing $\mathbf{W}$ by σ_1 caps the layer's stretch at 1, a technique that

stabilizes the training of GAN discriminators (Miyato et al. 2018). Rather than computing a full SVD, σ_1 is estimated via power iteration on $\mathbf{W}^\top\mathbf{W}$ (Section 33.4.1.2). In practice, one alternates $\mathbf{u} \leftarrow \mathbf{W}\mathbf{v}$ and $\mathbf{v} \leftarrow \mathbf{W}^\top\mathbf{u}$, normalizing at each half-step; together they perform one multiplication by $\mathbf{W}^\top\mathbf{W}$, with $\|\mathbf{W}\mathbf{v}\|$ as the estimate of σ_1. Each round pulls $\mathbf{v}$ closer to $\mathbf{v}_1$, shrinking the error by roughly $(\sigma_2/\sigma_1)^2$. Miyato et al. (2018) found empirically that a single round per training step suffices when warm-started from the previous step's vector. (For a convolutional layer, reshaping the kernel into a 2D matrix gives an approximation to the convolution's spectral norm, though not its exact value.)

Measuring the spectrum. Our earlier 0.39% LoRA figure assumed that rank 8 suffices. Whether a matrix is truly close to low rank depends entirely on how fast its singular values decay, so one should measure before truncating. The cell below compares two 400×500 matrices: a random Gaussian matrix with no structure at all, and our cat photograph with its mean pixel value subtracted.

```
G = np.random.standard_normal(img.shape)                        # no structure
for name, W in [('Gaussian', G), ('photograph', img - img.mean())]:
    s = np.linalg.svd(W, compute_uv=False)
    r95 = int(np.searchsorted(np.cumsum(s**2) / (s**2).sum(), 0.95)) + 1
    print(f'{name:10s}: sigma from {s[0]:.3g} to {s[-1]:.2g};  95% energy at rank {r95:3d};  '
          f'adapter {r95 * (m + n) / (m * n):.1%} of W')
```

```
Gaussian  : sigma from 42 to 2.5;  95% energy at rank 269;  adapter 121.0% of W
photograph: sigma from 2.65e+04 to 2.4;  95% energy at rank   8;  adapter 3.6% of W
```

The contrast is stark. The singular values of the Gaussian matrix spread across the Marchenko–Pastur interval $[\sqrt{n} - \sqrt{m}, \sqrt{n} + \sqrt{m}] \approx [2.4, 42.4]$ from Section 33.5.2.1, with no drop-off: capturing 95% of its energy takes rank roughly 270 out of 400, so a low-rank adapter would actually use *more* parameters than the original matrix. The centered photograph, by contrast, reaches 95% of its energy at rank 8, corresponding to an adapter with under 4% of the parameters. Neither matrix is a trained neural-network weight, so this pair only illustrates the two extremes; for LoRA, the matrix that matters is the task-specific update, whose spectrum must be measured rather than assumed.

Randomized SVD. When a matrix is too large to factor directly, *randomized SVD* (Halko et al. 2011) computes an accurate rank-k approximation using only a handful of matrix–vector products with $\mathbf{A}$. Its core ingredient is a *range finder*: multiply $\mathbf{A}$ by a random Gaussian matrix Ω with slightly more than k columns, orthonormalize the columns of $\mathbf{A}\Omega$ into $\mathbf{Q}$, and compute the SVD of the much smaller matrix $\mathbf{Q}^\top\mathbf{A}$. Whenever the singular values decay, the top singular directions dominate every random linear combination of the columns of $\mathbf{A}$, so $\mathbf{Q}$ captures them with high probability. Exercise 7 implements this algorithm along with a power-iteration refinement for slowly decaying spectra, and Section 33.6 places it in the broader context of randomized sketching.

Finally, keep three limits of the SVD in mind. First, a full SVD costs $O(mn\min(m,n))$ operations (roughly $4096^3 \approx 7 \times 10^{10}$ for a single 4096×4096 weight matrix), which is why practical algorithms like Newton–Schulz and randomized range finders rely solely on matrix products. Second, low rank is a property of the data, never a free guarantee, as the Gaussian matrix just demonstrated. Third, the SVD captures only *linear* structure: points lying on a circle in the plane form a rank-2 data matrix even though the circle is inherently one-dimensional. Understanding curved functions and nonlinear structure requires derivatives, which is where we turn in the next chapter.

33.5.5 Summary

Every real matrix $\mathbf{A}$, regardless of its shape, admits an orthonormal input basis $\{\mathbf{v}_i\}$ and an orthonormal output basis $\{\mathbf{u}_i\}$ between which it acts as a simple list of non-negative stretches, $\mathbf{A}\mathbf{v}_i = \sigma_i \mathbf{u}_i$ with $\sigma_1 \geq \sigma_2 \geq \cdots \geq 0$. The factorization follows from applying the spectral theorem to the Gram matrix $\mathbf{A}^\top \mathbf{A}$, with $\sigma_i = \sqrt{\lambda_i(\mathbf{A}^\top \mathbf{A})}$.

From that single ordered list of singular values, five core quantities fall out at once: the rank (the number of positive σ_i), the spectral and Frobenius norms ($\|\mathbf{A}\|_2 = \sigma_1$ and $\|\mathbf{A}\|_F^2 = \sum_i \sigma_i^2$), the optimal rank-$k$ approximation given by the truncated SVD $\mathbf{A}_k$ (Eckart–Young, which becomes principal component analysis on centered data), the Moore–Penrose pseudoinverse $\mathbf{A}^+$ that returns the minimum-norm least-squares solution, and the condition number $\kappa = \sigma_1/\sigma_r$ that bounds relative error amplification. In deep learning, the same singular spectrum sizes low-rank fine-tuning adapters, defines the polar factor used by Muon, and gives the Lipschitz constant controlled by spectral normalization.

33.5.6 Exercises

1. **Norms and the maximum stretch.** The text obtained Equation 33.48 from the spectral theorem. The maximum stretch can also build the SVD on its own.
    1. Let $\sigma_1 = \max_{\|\mathbf{x}\|=1} \|\mathbf{A}\mathbf{x}\|$, assume $\sigma_1 > 0$, and build an SVD without the spectral theorem. (i) Show that the maximum is attained at some unit $\mathbf{v}_1$, and set $\mathbf{u}_1 = \mathbf{A}\mathbf{v}_1/\sigma_1$. (ii) For a unit $\mathbf{w} \perp \mathbf{v}_1$, the function $t \mapsto \|\mathbf{A}(\mathbf{v}_1 + t\mathbf{w})\|^2/(1+t^2)$ has a maximum at $t = 0$, so its derivative there vanishes. Deduce $\mathbf{u}_1^\top \mathbf{A}\mathbf{w} = 0$: $\mathbf{A}$ maps $\mathbf{v}_1^\perp$ into $\mathbf{u}_1^\perp$. (iii) Recurse on the restriction of $\mathbf{A}$ to $\mathbf{v}_1^\perp$. Where did compactness of the unit sphere enter?
    2. Show that $\|\mathbf{A}\|_2 \leq \|\mathbf{A}\|_F \leq \sqrt{r}\,\|\mathbf{A}\|_2$ with $r = \operatorname{rank}\mathbf{A}$. Which matrices attain equality on each side?
    3. The ratio $\|\mathbf{A}\|_F^2/\|\mathbf{A}\|_2^2$ is called the *stable rank* of $\mathbf{A}$; by (b) it lies between 1 and $\operatorname{rank}\mathbf{A}$. Compute it in closed form for the decaying spectrum $\sigma_i = e^{-i/12}$, $i = 0, \ldots, 255$ (a geometric series), and show that rank 18 is needed to hold 95% of the energy of this spectrum. Then estimate the stable rank of the 400×500 Gaussian matrix of Section 33.5.4.3 from $\|\mathbf{G}\|_F^2 \approx mn$ and $\sigma_1 \approx \sqrt{m} + \sqrt{n}$, and compare it with the rank of about 270 that holds 95% of its energy. Why can the stable rank be far below the rank?
2. **Weyl perturbation bound.** An update Δ, for instance a rank-k LoRA update $\mathbf{BA}$ (the paper's letters), changes the singular values of a weight matrix $\mathbf{W}$. The Weyl inequality Equation 33.54, proved in Section 33.5.2.1, limits how far they move.
    1. Set $j = 1$ in Equation 33.54 and apply the inequality in both directions to derive $|\sigma_i(\mathbf{W}+\Delta) - \sigma_i(\mathbf{W})| \leq \sigma_1(\Delta)$ for every i.
    2. Take $\mathbf{W} = \operatorname{diag}(1, 2)$ and $\Delta = 0.1\,\mathbf{1}\mathbf{1}^\top$. Compute the singular values of $\mathbf{W} + \Delta$ and compare each change with $\sigma_1(\Delta)$.
    3. Now let $\operatorname{rank}\Delta \leq k$. The Frobenius proof in Section 33.5.2.1 applies Equation 33.54 with $j = k + 1$ to a matrix of rank at most k. Apply the same step to Δ to obtain the interlacing inequalities $\sigma_{i+k}(\mathbf{W}) \leq \sigma_i(\mathbf{W}+\Delta)$ and $\sigma_{i+k}(\mathbf{W}+\Delta) \leq \sigma_i(\mathbf{W})$. Use them to show that the ranks of $\mathbf{W}+\Delta$ and $\mathbf{W}$ differ by at most k, and that at most k singular values of $\mathbf{W}+\Delta$ exceed $\sigma_1(\mathbf{W})$, however large $\sigma_1(\Delta)$ is. Why does the bound of
    (a) not give these conclusions?

3. code **Centering in PCA, and Fashion-MNIST.** Let the rows of $\mathbf{X} \in \mathbb{R}^{n\times d}$ be data points with mean row $\bar{\mathbf{x}}$ and covariance $\mathbf{C}$ as in the principal component analysis of Section 33.5.2.2.

   1. Show that $\frac{1}{n}\mathbf{X}^\top\mathbf{X} = \mathbf{C} + \bar{\mathbf{x}}\bar{\mathbf{x}}^\top$.
   2. Generate a cloud like the one of Section 33.5.2.2 (300 points with standard deviations 3 and 0.8 along axes rotated by $\pi/5$) and shift every point by $c\,(1,-1)/\sqrt{2}$ for $c \in \{0, 1, 3, 10, 30\}$. For each c, compute the top right singular vector of the *uncentered* data, its angle to the principal axis $(\cos\frac{\pi}{5}, \sin\frac{\pi}{5})$, and the ratio $\sigma_1^2/\sum_i \sigma_i^2$.
   3. Use (a) to predict, from the eigenvalues of $\mathbf{C}$, the offset at which the top singular vector turns from the principal axis toward the mean.
   4. Use (a) again to approximate the ratio $\sigma_1^2/\sum_i \sigma_i^2$ for large c, and find its limit as $c \to \infty$. At $c = 10$ the ratio is close to the centered explained-variance ratio. Does this agreement reflect the data or the chosen offset?
   5. Load the Fashion-MNIST test images of t-shirts and trousers through `d2l.FashionMNIST`, as in Section 33.1, flatten them to vectors of length 784, center them, and compute the top two right singular vectors. Plot the two classes in the plane of the first two principal components. What fraction of the variance do these two directions hold? Compute the angle between $\mathbf{v}_1$ and the difference of the class means $\bar{\mathbf{x}}_{\text{trouser}} - \bar{\mathbf{x}}_{\text{t-shirt}}$, and explain why the two directions are close but not equal. Finally, reconstruct one t-shirt from its first 5, 20 and 50 components and report the relative error of each.

4. code **Ridgeless limit and gradient descent.** An overparameterized linear model has more parameters than equations, so least squares has infinitely many minimizers. Part (a) holds for every shape and rank;

   (b) and (c) use $\mathbf{A} \in \mathbb{R}^{m\times n}$ with $m < n$.

   1. Use the filter form Equation 33.57 to show that $(\mathbf{A}^\top\mathbf{A} + \lambda\mathbf{I})^{-1}\mathbf{A}^\top \to \mathbf{A}^+$ as $\lambda \to 0^+$, for a matrix $\mathbf{A}$ of any shape and rank. Why does $(\mathbf{A}^\top\mathbf{A})^{-1}\mathbf{A}^\top$ not exist when $m < n$?
   2. Gradient descent on $\frac{1}{2}\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2$ with step size $0 < \eta < 2/\sigma_1^2$ updates $\mathbf{x}_{t+1} = \mathbf{x}_t - \eta\,\mathbf{A}^\top(\mathbf{A}\mathbf{x}_t - \mathbf{b})$. Show that $\mathbf{x}_t - \mathbf{x}_0$ stays in the row space of $\mathbf{A}$ and that $\mathbf{x}_t$ converges to $\mathbf{A}^+\mathbf{b} + (\mathbf{I} - \mathbf{A}^+\mathbf{A})\mathbf{x}_0$. Which solution does the initialization $\mathbf{x}_0 = \mathbf{0}$ select?
   3. Check (a) and (b) for a 20×50 Gaussian $\mathbf{A}$ and a Gaussian $\mathbf{b}$: run gradient descent from $\mathbf{x}_0 = \mathbf{0}$ and from a random $\mathbf{x}_0$, and compare both limits and their norms with $\mathbf{A}^+\mathbf{b}$.

5. code **Newton–Schulz basin.** The Newton–Schulz iteration $\mathbf{X} \leftarrow \frac{1}{2}(3\mathbf{X} - \mathbf{X}\mathbf{X}^\top\mathbf{X})$ of Section 33.5.4.2 starts from $\mathbf{X} = \mathbf{M}/\|\mathbf{M}\|_F$.

   1. Let $\mathbf{X} = \mathbf{U}\Sigma\mathbf{V}^\top$ be a thin SVD. Show directly, without Equation 33.61, that one step produces $\mathbf{U}\,p(\Sigma)\,\mathbf{V}^\top$ with $p(\sigma) = \frac{1}{2}(3\sigma - \sigma^3)$ applied to every diagonal entry.
   2. Show that $(0, \sqrt{3})$ is the immediate basin of 1: p maps it into $(0, 1]$, and the iterates $p(p(\cdots p(\sigma_0)))$ converge to 1 for every $\sigma_0 \in (0, \sqrt{3})$. Show that some starting values beyond $\sqrt{3}$ also reach 1 (try 2.15) and others do not (try 2). Expand $p(1 - e)$ in powers of e. How fast does the distance to 1 shrink once it is small?
   3. For a 6×4 Gaussian $\mathbf{M}$, count the steps until $\|\mathbf{X} - \mathbf{U}\mathbf{V}^\top\|_F < 10^{-6}$ when the iteration starts from $\mathbf{M}/c$ with $c = \|\mathbf{M}\|_F$ and with $c = \sigma_1(\mathbf{M})$. Compare both

counts with $\log_{3/2}(1/s_{\min}) + 4$, where $s_{\min}$ is the smallest singular value after scaling. Why does Muon divide by $\|\mathbf{M}\|_F$ although $\sigma_1(\mathbf{M})$ saves a step?

4. Start the iteration from $\mathbf{M}/c$ with $c = \sigma_1(\mathbf{M})/2$ and with $c = \sigma_1(\mathbf{M})/2.5$. What does it converge to in each case? Explain both outcomes with the polynomial p of (b).

6. code **Polar factor and Procrustes.** ● The polar decomposition Equation 33.60 writes a square matrix as $\mathbf{A} = \mathbf{QP}$ with $\mathbf{Q}$ orthogonal and $\mathbf{P}$ symmetric positive semidefinite.

   1. Show that $\mathbf{P} = (\mathbf{A}^\top\mathbf{A})^{1/2}$ is determined by $\mathbf{A}$, and that $\mathbf{Q}$ is determined by $\mathbf{A}$ when $\mathbf{A}$ is invertible. Give two different polar decompositions of $\operatorname{diag}(1, 0)$.
   2. Show that $\mathbf{Q} = \mathbf{UV}^\top$ is an orthogonal matrix closest to $\mathbf{A}$ in the Frobenius norm. Reduce the problem to maximizing $\operatorname{tr}(\mathbf{R}^\top\mathbf{A})$ over orthogonal $\mathbf{R}$.
   3. Two embedding spaces that differ by a rotation can be aligned from paired points $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{d\times N}$ by minimizing $\|\mathbf{RX} - \mathbf{Y}\|_F$ over orthogonal $\mathbf{R}$. Use (b) to show that the minimizer is the polar factor of $\mathbf{YX}^\top$. Test it with $d = 50$, $N = 1000$, a random orthogonal $\mathbf{R}$ (the $\mathbf{Q}$ factor of a QR decomposition of a Gaussian matrix), Gaussian $\mathbf{X}$, and $\mathbf{Y} = \mathbf{RX} + \mathbf{E}$, where $\mathbf{E}$ has i.i.d. $\mathcal{N}(0, s^2)$ entries for $s \in \{0, 0.1, 1, 3\}$. Compare $\|\hat{\mathbf{R}} - \mathbf{R}\|_F/\sqrt{d}$ for this estimate and for the unconstrained least-squares estimate $\mathbf{YX}^+$.

7. code **Randomized range finder.** ● The randomized SVD of Section 33.5.4.3 multiplies $\mathbf{A}$ by a Gaussian $\Omega \in \mathbb{R}^{n\times(k+p)}$, orthonormalizes $\mathbf{Y} = \mathbf{A}\Omega$ into $\mathbf{Q}$, and truncates the SVD of $\mathbf{Q}^\top\mathbf{A}$ to rank k.

   1. Implement it. Build $\mathbf{A} \in \mathbb{R}^{1000\times 500}$ as $\mathbf{U}\operatorname{diag}(\sigma_1, \dots, \sigma_{500})\mathbf{V}^\top$ with random orthonormal $\mathbf{U}$ and $\mathbf{V}$, once with the fast decay $\sigma_i = e^{-i/5}$ and once with the slow decay $\sigma_i = 1/i$. For $k = 20$ and $p \in \{0, 5, 10\}$, divide the spectral-norm error of the rank-k result by σ_{k+1}, the minimum of Equation 33.53, and average over 10 draws of Ω. Why does oversampling alone suffice for one spectrum but not for the other?
   2. Replace $\mathbf{Y}$ by $(\mathbf{AA}^\top)^q\mathbf{A}\Omega$ for $q \in \{1, 2\}$. How do the ratios change for each spectrum? Explain the effect of q with the singular values of $(\mathbf{AA}^\top)^q\mathbf{A}$. How many products with $\mathbf{A}$ or $\mathbf{A}^\top$ does each variant cost?

8. code **Optimal hard threshold.** ●● The threshold $\frac{4}{\sqrt{3}}\sqrt{n}\,\sigma_{\text{noise}}$ of Gavish and Donoho (2014) follows from the behavior of a single signal component. Let $\mathbf{A} = \theta\,\mathbf{uv}^\top + \mathbf{N}$ be $n \times n$, with unit vectors $\mathbf{u}, \mathbf{v}$, $\theta > 0$, and $\mathbf{N}$ with i.i.d. Gaussian entries $\mathcal{N}(0, \sigma^2_{\text{noise}})$. Write $x = \theta/(\sqrt{n}\,\sigma_{\text{noise}})$ and let $(\sigma_1, \hat{\mathbf{u}}, \hat{\mathbf{v}})$ be the top singular triple of $\mathbf{A}$, with the sign of the pair chosen so that $\mathbf{u}^\top\hat{\mathbf{u}} \geq 0$. As $n \to \infty$, Benaych-Georges and Nadakuditi (2012) show that σ_1 tends to the bulk edge $2\sqrt{n}\,\sigma_{\text{noise}}$ and the singular vectors become orthogonal to $\mathbf{u}$ and $\mathbf{v}$ when $x \leq 1$, and that for $x > 1$

$$\frac{\sigma_1}{\sqrt{n}\,\sigma_{\text{noise}}} \to x + \frac{1}{x}, \qquad (\mathbf{u}^\top\hat{\mathbf{u}})^2 \to 1 - \frac{1}{x^2}, \qquad (\mathbf{v}^\top\hat{\mathbf{v}})^2 \to 1 - \frac{1}{x^2}.$$

   The transition at $x = 1$ is the singular-value counterpart of the eigenvalue transition at $\beta = \sqrt{c}$ in exercise 5 of Section 33.3.

   1. Two estimates of the signal $\theta\,\mathbf{uv}^\top$ are the rank-one truncation $\sigma_1\hat{\mathbf{u}}\hat{\mathbf{v}}^\top$ and the zero matrix. Express the squared Frobenius error of each in terms of θ, σ_1, $\mathbf{u}^\top\hat{\mathbf{u}}$ and $\mathbf{v}^\top\hat{\mathbf{v}}$.

2. Use the limits to show that the truncation has the smaller asymptotic error exactly when $x > \sqrt{3}$, and that the singular value at $x = \sqrt{3}$ is $\frac{4}{\sqrt{3}}\sqrt{n}\,\sigma_{\text{noise}}$. Which signal strengths produce a singular value above the noise edge that should nevertheless be discarded?
3. Check (a) and (b) for $n = 500$ and $\sigma_{\text{noise}} = 1/\sqrt{n}$, with $x \in \{0.5, 1.2, 1.5, \sqrt{3}, 2, 3\}$ and 10 draws each: compare σ_1, the squared cosines, and both errors with their limits.

33.6 Further Reading

This section connects the linear algebra developed in this chapter to numerical analysis, random matrix theory, and deep-learning applications, followed by a curated list of textbooks and courses covering the chapter's core material. If your main interest is deep learning, start with random projections, iterative solvers, random matrices and trainable depth, and sketching, then jump to the final two entries on low-rank attention and spectral-norm optimizers. Nothing elsewhere in the book depends on this section.

33.6.1 Geometry and Linear Maps

33.6.1.1 Other Inner Products: Kernel Methods

The nearest-mean rule of Section 33.1.4.2 classifies a test image by comparing it with two class averages through a single dot product, which forces the decision boundary to be a flat hyperplane. That simplicity breaks down whenever a class is curved or split into clusters, as happens when distinguishing t-shirts from shirts. Kernel methods keep the exact same geometric rule and change only the inner product: we replace $\mathbf{x} \cdot \mathbf{x}_i$ by a similarity function $k(\mathbf{x}, \mathbf{x}_i)$ that corresponds to a genuine inner product in some other, possibly infinite-dimensional, feature space. The class average becomes a mean in that hidden space, every training example votes with weight $k(\mathbf{x}, \mathbf{x}_i)$, and the resulting boundary can bend freely in the original input space. Asking which training points actually need nonzero weights leads directly to the support vector machine. Schölkopf and Smola (2002) open their book with this very classifier and build the full theory of kernel methods from it.

33.6.1.2 Random Projections

In Section 33.1, we saw that random directions in high-dimensional space $\mathbb{R}^d$ are almost orthogonal to one another. Surprisingly, that geometric quirk lets us shrink the dimension of a dataset without looking at the data at all. The Johnson–Lindenstrauss lemma (Johnson and Lindenstrauss 1984) guarantees that for any collection of n points, multiplying by a suitably scaled random Gaussian matrix into k dimensions of order $\varepsilon^{-2} \log n$ preserves all $\binom{n}{2}$ pairwise distances within a factor of $1 \pm \varepsilon$, with high probability. Unlike principal component analysis (Section 33.5.2.2), a random projection is completely data-independent, and its target dimension k does not even depend on the ambient dimension d. The trick therefore pays off most when d is vastly larger than $\varepsilon^{-2} \log n$. Dasgupta and Gupta (2003) give a remarkably short proof with explicit constants, while Vershynin (2018) situates the lemma inside the broader theory of concentration for random vectors.

33.6.1.3 Solving Linear Systems at Scale

In Section 33.2.2.4, we solved linear systems via LU factorization and noted that the inverse of a large sparse matrix is typically dense. Why does Gaussian elimination with partial pivoting work so reliably in floating-point arithmetic, even though pathological worst-case matrices exist? Trefethen and Bau (1997) give an illuminating explanation of this gap between worst-case and practical stability, and Higham (2002) provides the definitive rounding-error analysis.

At large scale, sparse solvers never form $\mathbf{A}^{-1}$, and often avoid forming dense LU factors altogether. Sparse direct methods carefully reorder the unknowns so that elimination introduces as few new nonzeros as possible. Iterative methods go a step further and access the matrix solely through matrix–vector products $\mathbf{A}\mathbf{x}$, much like power iteration (Section 33.4.1.2). When $\mathbf{A}$ is symmetric positive definite, the conjugate gradient method of Hestenes and Stiefel (1952) shrinks the error after k steps by at least a factor of $2\big((\sqrt{\kappa}-1)/(\sqrt{\kappa}+1)\big)^{k}$ in the norm induced by $\mathbf{A}$, where κ is the condition number from Section 33.5.3.2. Golub and Van Loan (1996) treat conjugate gradient and its relatives in full detail.

33.6.1.4 Contraction Order and Tensor Decompositions

The `einsum` notation of Section 33.2.1.4 specifies the mathematical result of contracting several tensors, but it leaves open the order in which pairwise contractions are carried out. That choice can make a dramatic difference: for $n \times n$ matrices, computing $(\mathbf{A}\mathbf{B})\mathbf{x}$ takes roughly n^3 multiplications, whereas $\mathbf{A}(\mathbf{B}\mathbf{x})$ takes only $2n^2$. When many factors are involved, choosing the cheapest order becomes a search over parenthesizations, which `np.einsum(..., optimize=True)` and the `opt_einsum` package (Smith and Gray 2018) automate.

The idea of low-rank approximation also extends beyond matrices to higher-order tensors, though with a sobering catch. A three-way tensor can be written as a sum of rank-one outer products $\mathbf{a}_i \otimes \mathbf{b}_i \otimes \mathbf{c}_i$ (the CP decomposition), as a small core tensor multiplied by a factor matrix along each mode (the Tucker decomposition), or as a chain of three-way cores (the tensor train of Oseledets (2011)). Unfortunately, nothing as clean as the Eckart–Young theorem holds in general for tensors: determining the CP rank is NP-hard, and a best approximation of a given CP rank may not even exist. The survey by Kolda and Bader (2009) is the standard guide to CP and Tucker decompositions and their algorithms.

33.6.2 Eigenvalues and Spectra

33.6.2.1 Computing Eigenvalues in Practice

There is no formula in radicals for the roots of a general polynomial of degree five or higher, so every practical eigensolver must iterate. Worse still, no production library forms the characteristic polynomial of Section 33.3.1.2, because the roots of a polynomial can be extraordinarily sensitive to tiny rounding errors in its coefficients. Instead, `eig` first applies orthogonal similarity transformations to reduce the matrix to Hessenberg form (zero everywhere below the first subdiagonal), which takes $O(n^3)$ operations. It then runs the shifted QR algorithm: factor $\mathbf{H} - \mu\mathbf{I} = \mathbf{Q}\mathbf{R}$, form $\mathbf{R}\mathbf{Q} + \mu\mathbf{I}$, and repeat. Every step is a similarity transformation, so the eigenvalues never change, while the subdiagonal entries shrink toward zero and the diagonal reveals the spectrum (complex conjugate pairs of a real matrix settle into 2×2 diagonal blocks). For symmetric matrices, the Hessenberg form is tridiagonal, and `eigh` exploits that structure for major speedups. Trefethen and Bau (1997) derive the

QR algorithm cleanly from power iteration on subspaces, and Golub and Van Loan (1996) supply the production engineering details.

33.6.2.2 Pseudospectra and the Kreiss Matrix Theorem

In Section 33.4.2.4, we saw that for a non-normal matrix, eigenvalues inside the unit disc do not prevent large transient growth in $\|\mathbf{A}^k\|_2$. The Kreiss matrix theorem turns the visual intuition of pseudospectra into a quantitative bound. Defining the Kreiss constant as $K(\mathbf{A}) = \sup_{|z|>1} (|z|-1)\|(z\mathbf{I}-\mathbf{A})^{-1}\|_2$, the theorem brackets the worst-case power norm for any $n \times n$ matrix: $K(\mathbf{A}) \le \sup_k \|\mathbf{A}^k\|_2 \le e\, n\, K(\mathbf{A})$. You can prove the lower bound in an exercise in Section 33.4; the upper bound guarantees that a matrix whose pseudospectra hug the unit disc closely cannot experience unbounded transient growth. Trefethen and Embree (2005) develop this theory thoroughly, including its classic application to fluid flows that transition to turbulence even when every linearized eigenvalue is strictly stable.

33.6.2.3 Mixing Times and the Spectral Gap

In the two-page Markov chain of Section 33.3, the distance to the stationary distribution shrinks by a factor of 4 at every click because the second eigenvalue is $1/4$. How many steps does a general Markov chain need to mix? For a reversible chain, let $\lambda_\star$ be the largest modulus among all eigenvalues other than 1. The number of steps required to come within total variation distance ε of the stationary distribution is bounded both above and below by multiples of $1/(1-\lambda_\star)$, where the constants depend on ε and on the smallest stationary probability. For a lazy chain—one that stays at its current state with probability at least $1/2$—all eigenvalues are nonnegative, so $\lambda_\star$ is simply the second eigenvalue λ_2. Cheeger's inequality then links the spectral gap $1-\lambda_2$ from both sides to the chain's *conductance*, the smallest probability flow leaving any subset relative to its stationary mass. In other words, you can read the convergence rate directly from the bottlenecks of the graph. Levin and Peres (2017) present this theory with great clarity, alongside the convergence results that Section 33.4.1.3 cites from Horn and Johnson (2012) .

33.6.2.4 Random Matrices and Trainable Depth

In Section 33.4.2.5, we observed that the spectral radii of individual layer Jacobians do not control the behavior of a long product of Jacobians. What, then, determines whether a very deep network can be trained from initialization? Saxe et al. (2014) solve the learning dynamics of deep linear networks exactly and show that orthogonal initial weights keep the training time independent of depth, whereas scaled Gaussian weights cause learning to slow down as depth grows. Extending the analysis to nonlinear networks, Pennington et al. (2017) use free probability to compute the full singular value distribution of the input–output Jacobian. They show that *dynamical isometry*, the regime in which all singular values cluster tightly near 1, is achievable with orthogonal weights and tanh activations but not with ReLU, and that networks initialized in this regime train substantially faster at large depth.

33.6.2.5 Spectra of Trained Weights

The Marchenko–Pastur law of Section 33.3.2.4 describes the singular value spectrum of a matrix of pure independent noise, which is what the weight matrices of a freshly initialized network look like. Martin and Mahoney (2021) compare the spectra of trained neural network weights against this random-matrix baseline and observe that training produces both

sharp outliers and a heavy, power-law tail. They interpret the tail exponent as a signature of implicit self-regularization. While this departure from Marchenko–Pastur appears consistently across many architectures, using the tail exponent to rank model quality without evaluating on test data remains an empirical correlation rather than a proven theorem.

33.6.3 Low Rank Beyond the Truncated SVD

33.6.3.1 Matrix Completion and the Nuclear Norm

A movie-ratings matrix might have only a few percent of its entries observed, whereas the Eckart–Young theorem (Section 33.5.2.1) requires knowing the entire matrix up front. Matrix completion bridges this gap by minimizing the *nuclear norm* $\|\mathbf{Z}\|_* = \sum_i \sigma_i$, which serves as a convex stand-in for matrix rank in the same way that the ℓ_1 norm stands in for vector sparsity, subject to matching all observed entries. Candès and Recht (2009) prove that this convex optimization problem recovers an underlying low-rank matrix exactly, with high probability, from far fewer than n^2 randomly observed entries, provided its singular vectors are spread out across the coordinates rather than concentrated on a few spikes. Soft-Impute (Mazumder et al. 2010) solves the penalized version of this problem by alternating a fill-in step with soft-thresholding of the singular values.

33.6.3.2 CUR Decompositions and Sketching

Although the truncated SVD is optimal in approximation error, its singular vectors mix together all rows and columns, making them difficult to interpret, and computing a full SVD of an $m \times n$ matrix costs $O(mn \min(m, n))$ operations. A CUR decomposition instead builds an approximation from actual columns $\mathbf{C}$ and actual rows $\mathbf{R}$ of the data matrix, linked by a small core matrix $\mathbf{U}$. In Section 33.5.2.1, we saw that the naive strategy of picking the columns with the largest norms loses badly to the truncated SVD. Mahoney and Drineas (2009) show how to fix this: sampling columns and rows according to their *leverage scores*, the squared lengths of their projections onto the top singular vectors, gets within a small constant factor of the Eckart–Young error with high probability.

More broadly, the randomized range finder of Section 33.5.4.3 (Halko et al. 2011) is one example of *sketching*: multiply a large matrix by a thin random matrix and solve the problem on the much smaller sketch. Woodruff (2014) surveys how this same idea accelerates least squares and regression, returning a solution within a $1 + \varepsilon$ factor of optimal from a sketch with far fewer rows than the original dataset.

33.6.3.3 Adapter Variants

LoRA (Section 33.5.4.1) initializes its low-rank update $\mathbf{BA}$ with $\mathbf{B} = \mathbf{0}$ and a random $\mathbf{A}$, which means the earliest gradient steps see the input only through a random k-dimensional subspace unrelated to the pretrained weight. Several variants change this initialization or parameterization in simple ways. PiSSA (Meng et al. 2024) initializes $\mathbf{BA}$ to the rank-k truncated SVD of the pretrained weight and freezes the residual, so fine-tuning immediately adapts the principal directions of the original matrix. DoRA (S.-Y. Liu et al. 2024) decomposes each weight column into a scalar magnitude and a unit direction, trains the magnitudes directly, and applies the low-rank update only to the directions.

33.6.3.4 Low Rank in Attention

Self-attention over a sequence of n tokens forms an $n \times n$ score matrix, and several efficient architectures in the attention chapters replace either that matrix or its key–value cache with a low-rank factorization. Linear attention (Section 10.6) expresses the attention scores as feature dot products $\phi(\mathbf{q}) \cdot \phi(\mathbf{k})$, capping the rank of the score matrix at the feature dimension. Multi-head latent attention (Section 11.3.3.2) (DeepSeek-AI 2024) compresses the cache by storing a single low-dimensional latent vector per token instead of separate keys and values for every head. Linformer (Wang et al. 2020) starts from the empirical observation that trained attention matrices have rapidly decaying singular values, and projects the keys and values along the sequence dimension down to a fixed length.

33.6.3.5 Steepest Descent under Other Norms

In Section 33.5.4.2, we computed the polar factor $\mathbf{U}\mathbf{V}^\top$ of a gradient matrix. Geometrically, this matrix is the steepest-descent direction when step sizes are measured in the spectral norm rather than the Euclidean norm. Bernstein and Newhouse (2024) turn that observation into a unifying lens for deep-learning optimizers: with their moving averages turned off, Adam reduces to sign descent (steepest descent under the ℓ_∞ norm), while Shampoo reduces to steepest descent under the spectral norm. From this viewpoint, choosing the right norm for each layer is the core design decision, and the update rule follows automatically. The spectral-norm optimizer built on this idea is developed in Section 9.6.

33.6.4 Books, Courses, and Notes

Books

- Mathematics for Machine Learning by Deisenroth, Faisal, and Ong: a free textbook whose Chapters 2 (Linear Algebra), 3 (Analytic Geometry), and 4 (Matrix Decompositions) cover the material of this chapter from a machine-learning perspective.
- Introduction to Applied Linear Algebra: Vectors, Matrices, and Least Squares by Boyd and Vandenberghe: a free book with slides and code organized around least squares and data, pairing well with Section 33.1 and Section 33.5.
- Introduction to Linear Algebra, 6th ed. and Linear Algebra and Learning from Data by Gilbert Strang: the classic introduction built around the column picture and the four fundamental subspaces, and its SVD-centered companion for data analysis and optimization.
- Linear Algebra Done Right, 4th ed. by Sheldon Axler: a free, determinant-free treatment of eigenvalues, operators, and the spectral theorem (Section 33.3).
- Numerical Linear Algebra by Trefethen and Bau: an accessible treatment of conditioning, stability, QR, and the floating-point algorithms behind `solve`, `eig`, and `svd`.

Courses and Tutorials

- MIT 18.06 Linear Algebra and MIT 18.065 Matrix Methods in Data Analysis, Signal Processing, and Machine Learning by Gilbert Strang: complete lecture courses with notes and problem sets.
- Essence of Linear Algebra by 3Blue1Brown and Singular Value Decomposition by Steve Brunton: visual lectures on linear maps, determinants, eigenvectors, and the SVD.
- Linear Algebra Review and Reference by Kolter and Do (Stanford CS229) and Immersive Linear Algebra by Ström, Åström, and Akenine-Möller.

Chapter 34

Calculus and Automatic Differentiation

Throughout this book, training a neural network follows the same rhythm: evaluate a loss, ask the framework for its gradient, and nudge every weight a small step downhill. We have relied on that loop without pausing to ask two natural questions about how it works. First, suppose a training run suddenly diverges after we double the learning rate. The gradient itself is still correct, yet the step has carried us past the small neighborhood where a local slope reliably predicts the loss. How far can that linear approximation be trusted? Second, notice how remarkably cheap the gradient is. Estimating every slope by perturbing a hundred million weights one at a time would require a hundred million forward passes, yet a single backward call returns all of them for roughly the cost of a few forward passes. How is that possible?

Both questions belong to calculus, a subject born in the seventeenth century when Newton and Leibniz asked how to measure continuous change and how to add up infinitely many tiny pieces. Their two tools, the derivative and the integral, turn out to be inverses of each other. In deep learning, the derivative supplies the best linear model of a loss surface near our current weights, and aside from the loss value itself, it is the only information an optimizer ever sees. The integral enters as soon as data or weights are random: a probability or an expected loss is an area under a curve, and methods such as policy gradients (Section 14.7) must differentiate that integral with respect to the very distribution they sample from.

Earlier in the book, we stated the basic rules of differentiation (Section 1.4) and treated automatic differentiation as a ready-made tool (Section 1.5). The main chapters require nothing more, so this appendix chapter is optional reading for readers who want to see why the machinery works and where its guarantees come from. Three results do most of the heavy lifting: the descent lemma, which converts a bound on curvature into the safe step-size rule quoted in Section 9.1; the chain rule written as a product of Jacobians, which becomes far cheaper when multiplied from the loss backward to give backpropagation (Section 4.3); and the two complementary estimators for the gradient of an expectation, which trade generality against variance.

The chapter unfolds in three parts. We first build linear and quadratic approximations of a function, in one variable (Section 34.1) and then in many (Section 34.2), so we can bound

safe step sizes and tell a minimum from a saddle point. Next, we follow the chain rule from a sum over paths in a computation graph (Section 34.3) to products of layer Jacobians (Section 34.4), and finally to the algorithms that multiply them automatically (Section 34.5). The closing part introduces integration (Section 34.6) and brings sampling and differentiation together to estimate gradients of expectations (Section 34.7).

If you are already comfortable with introductory calculus, feel free to skim the warm-up pages that open several sections. We omit vector calculus beyond the gradient (such as divergence and Stokes' theorem) as well as measure theory; for differential equations, see Chapter 38.

34.1 Single Variable Calculus

Every model in the Basics part was trained by gradient descent. At each step, the optimizer evaluates the loss and its slope at the current weights, nudges the weights a little downhill, and repeats. Because it never inspects the loss anywhere else, every step rests on a local prediction: the slope at the current point is assumed to describe the loss a short distance away. How accurate is that prediction, and how large a step can it safely support?

A single weight already shows what the answer looks like. Consider one training example, one scalar weight w, and the logistic loss $\ell(w) = \log(1 + e^{-w})$. At $w = 0$, the loss is 0.693147 and its slope is $-\frac{1}{2}$. If we move the weight to $w = 0.1$, a straight line through $w = 0$ with that slope predicts a loss of $0.693147 - 0.05 = 0.643147$. The actual loss is 0.644397, so the linear prediction is off by only 0.00125. Remarkably, that small gap has a simple structure: to the digits shown, it equals $\frac{1}{2} \cdot \frac{1}{4} \cdot 0.1^2$, where the factor $\frac{1}{4}$ measures how sharply the graph of ℓ bends at $w = 0$. The slope makes the prediction, and the bend tells us how quickly that prediction drifts off as the step grows. We will derive both constants shortly, once we have the rules of differentiation in hand.

This section develops the local straight-line model from the first derivative and extends it, using the second derivative, to a parabola that also captures the bend. Three results anchor the development: the Mean Value Theorem, which connects slopes at points to changes over intervals; the Lagrange remainder, which bounds the error of both the line and the parabola; and the descent lemma, which turns a bound on curvature into a guaranteed safe step size for gradient descent. We also meet Newton's method and the corner of ReLU, where no tangent line exists yet backpropagation must still return a number. Here we study all of these ideas in one variable; their multivariable optimization theory belongs to Chapter 35.

Earlier, Section 1.4 introduced the derivative, listed the rules of differentiation, and used automatic differentiation as a practical tool. Here we review those rules briefly and focus on the proofs, geometric intuition, and error bounds. If you are already comfortable with the differentiation rules, you can jump straight to Section 34.1.3. One variable is the natural starting point because every multivariable loss contains it: holding all weights of $\ell(w_1, \dots, w_n)$ fixed except w_i yields a one-dimensional slice, and single-variable calculus is the study of such slices.

Our running example throughout this section is the *softplus* function, $s(x) = \log(1 + e^x)$. It is the one-variable slice $\log(e^0 + e^x)$ of the log-sum-exp function used across this chapter, and the logistic loss above is simply $\ell(w) = s(-w)$.

34.1.1 The Derivative

34.1.1.1 The Difference Quotient

Zoom in far enough on the graph of a smooth function f near a point x, and the curve becomes indistinguishable from a straight line (Figure 34.1). The slope of that line is the derivative.

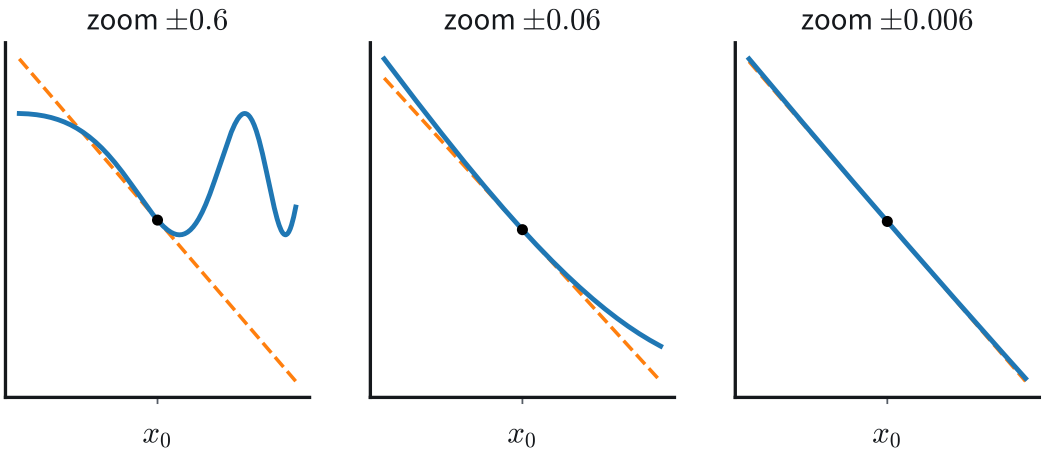

Figure 34.1: The curve $\sin(x^x)$ near $x_0 = 2$, shown in windows of half-width 0.6, 0.06, and 0.006. As the window shrinks, the curve (solid) becomes indistinguishable from its tangent line (dashed).

To capture that slope algebraically, we follow Section 1.4 and start with the *secant* line through $(x, f(x))$ and $(x+\epsilon, f(x+\epsilon))$. Its slope is the *difference quotient* $(f(x+\epsilon)-f(x))/\epsilon$. As ϵ shrinks toward zero, the secant rotates toward the tangent line (Figure 34.2).

How small must ϵ be before the secant slope is a trustworthy stand-in for the tangent slope? Unfortunately, there is no universal threshold: it depends entirely on the function. Consider the polynomial $f(x) = x^2 + 1701(x-4)^3$, whose true slope at $x = 4$ is 8, and observe how slowly the secant slope settles as ϵ shrinks.

```
def f(x):
    return x**2 + 1701*(x-4)**3

# Slope of the secant through x=4, for shrinking epsilon
for epsilon in [0.1, 0.001, 0.0001, 0.00001]:
    print(f'epsilon = {epsilon:.5f} -> {(f(4+epsilon) - f(4)) / epsilon:.5f}')
```

```
epsilon = 0.10000 -> 25.11000
epsilon = 0.00100 -> 8.00270
epsilon = 0.00010 -> 8.00012
epsilon = 0.00001 -> 8.00001
```

At $\epsilon = 0.1$, the secant slope is 25.11, more than three times the true limit, and the printed values only settle near 8 once ϵ reaches 0.001. Expanding $f(4+\epsilon)-f(4) = 8\epsilon+\epsilon^2+1701\epsilon^3$ shows why: the difference quotient equals $8 + \epsilon + 1701\epsilon^2$, so the cubic term adds 17 at

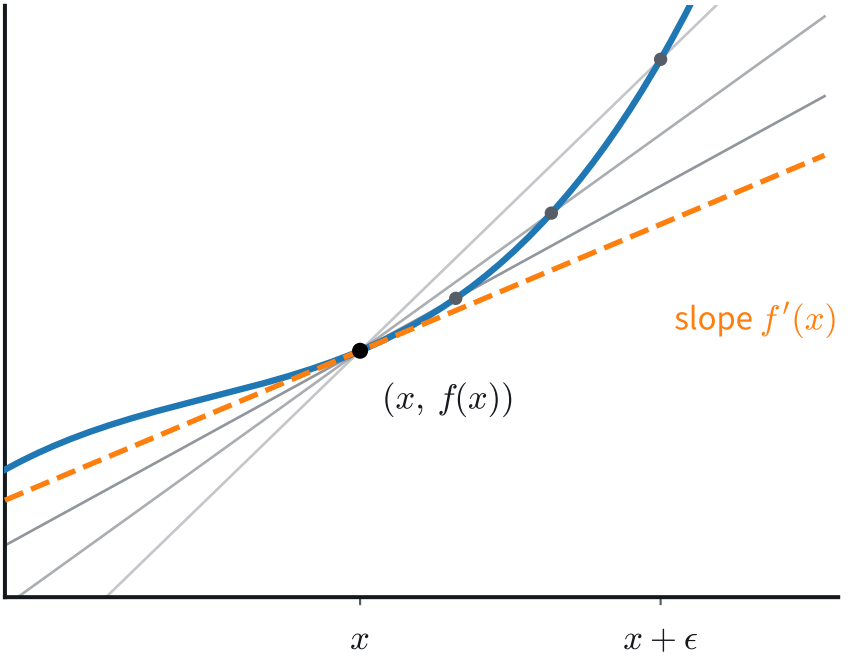

Figure 34.2: The difference quotient is the slope of the secant through $(x, f(x))$ and $(x+\epsilon, f(x+\epsilon))$. As $\epsilon \to 0$, this slope approaches the tangent slope $f'(x)$.

$\epsilon = 0.1$ but only 1.7×10^{-7} at $\epsilon = 10^{-5}$. The large coefficient delays the approach to the limit without changing it. Automatic differentiation sidesteps this problem altogether: it never chooses an ϵ, instead applying the rules of differentiation directly (Section 34.5).

34.1.1.2 The Derivative and the Linear Approximation

The **derivative** of f at x is the limit of the secant slopes,

$$f'(x) = \frac{df}{dx}(x) = \lim_{\epsilon \to 0} \frac{f(x+\epsilon) - f(x)}{\epsilon}, \tag{34.1}$$

whenever this limit exists, in which case we say f is *differentiable* at x. For the cubic above, $f'(4) = 8$. We write f' or $\frac{df}{dx}$, and $\frac{d}{dx}[\ldots]$ when differentiating a bulky expression. The limit can also fail to exist, as it does for $|x|$ at 0; we return to such corners in Section 34.1.6.

It is instructive to rearrange this definition. Let $r(\epsilon) = f(x+\epsilon) - f(x) - \epsilon f'(x)$ denote the error of the straight-line prediction; the limit Equation 34.1 says that $r(\epsilon)/\epsilon \to 0$. Writing $o(\epsilon)$ for any quantity $r(\epsilon)$ satisfying $r(\epsilon)/\epsilon \to 0$ as $\epsilon \to 0$, we obtain the **linear approximation**

$$f(x+\epsilon) = f(x) + \epsilon f'(x) + o(\epsilon). \tag{34.2}$$

In plain words, a small step ϵ changes the output by $\epsilon f'(x)$, up to an error that vanishes faster than ϵ. The converse holds too: if $f(x+\epsilon) = f(x) + a\epsilon + o(\epsilon)$ for some constant a,

then dividing by ϵ and letting $\epsilon \to 0$ proves that f is differentiable at x with $f'(x) = a$. The expansion Equation 34.2 and the limit Equation 34.1 therefore carry the same information, and our proofs of the sum and chain rules will lean on this equivalence.

Plotted as a function of $x+\epsilon$, the line $f(x)+\epsilon f'(x)$ is the *tangent* to the graph at x, the limit of the rotating secants. This is the line that predicted the logistic loss at $w = 0.1$, and the gap of 0.00125 was its $o(\epsilon)$ remainder. By itself, $o(\epsilon)$ promises very little: an error of order $o(\epsilon)$ could shrink only slightly faster than ϵ. Here, however, the gap shrank as ϵ^2, and as we will see in Section 34.1.5.2, quadratic error decay is the rule for every twice differentiable function.

34.1.2 Computing Derivatives

In practice, nobody computes derivatives by taking limits. Instead, as in Section 1.4, we combine a short table of elementary derivatives with rules for sums, products, and compositions. Here we prove each rule directly from the linear approximation. Among the table entries, we derive the exponential, the logarithm, and the power rule; we take the sine and cosine entries, along with the existence of a base whose exponential has slope 1 at 0, as known from a first calculus course.

34.1.2.1 A Table of Common Derivatives

The following formulas hold wherever the right-hand sides are defined: the power rule for every real n when $x > 0$ and for integer n wherever x^n is defined, and the logarithm for $x > 0$.

- **Derivative of constants.** $\frac{d}{dx} c = 0$.
- **Derivative of linear functions.** $\frac{d}{dx}(ax) = a$.
- **Power rule.** $\frac{d}{dx} x^n = n x^{n-1}$.
- **Derivative of exponentials.** $\frac{d}{dx} e^x = e^x$.
- **Derivative of the logarithm.** $\frac{d}{dx} \log(x) = \frac{1}{x}$.
- **Derivative of sine.** $\frac{d}{dx} \sin(x) = \cos(x)$.
- **Derivative of cosine.** $\frac{d}{dx} \cos(x) = -\sin(x)$.

The exponential entry rests on a one-line observation that also reveals what makes the base e special. For any $a > 0$, the difference quotient of a^x factors cleanly as

$$\frac{a^{x+\epsilon} - a^x}{\epsilon} = a^x \, \frac{a^\epsilon - 1}{\epsilon},$$

where the second factor is simply the difference quotient at 0. Thus, if a^x is differentiable at 0 with slope c_a, then $\frac{d}{dx} a^x = c_a \, a^x$ for every x: the slope of an exponential is always proportional to its height, with a single proportionality constant per base. Numerically, at $\epsilon = 10^{-6}$ we find $(2^\epsilon - 1)/\epsilon = 0.69315$ for base 2 and $(10^\epsilon - 1)/\epsilon = 2.30259$ for base 10. The number e is defined as the unique base whose constant is 1, which immediately yields $\frac{d}{dx} e^x = e^x$. Once we have the derivative of the logarithm, the chain rule will identify c_a for every other base.

34.1.2.2 Rules for Combining Derivatives

A loss function builds on the table above using sums, products, quotients, and compositions. Let g and h be differentiable at x (for the chain rule, assume h is differentiable at x and g is differentiable at $h(x)$). Then:

- **Sum rule.** $\frac{d}{dx}\big(g(x)+h(x)\big) = g'(x)+h'(x)$.
- **Product rule.** $\frac{d}{dx}\big(g(x)\,h(x)\big) = g(x)h'(x)+g'(x)h(x)$.
- **Quotient rule.** $\frac{d}{dx}\frac{g(x)}{h(x)} = \frac{g'(x)h(x)-g(x)h'(x)}{h(x)^2}$, where $h(x)\neq 0$.
- **Chain rule.** $\frac{d}{dx}g(h(x)) = g'(h(x))\,h'(x)$.

The sum and product rules are routine; only the chain rule requires real care, because the naive argument divides by $h(x+\epsilon)-h(x)$, which can vanish even when $\epsilon \neq 0$. The proofs all rely on one basic fact: **a function differentiable at x is continuous at x**, because $g(x+\epsilon)-g(x) = \epsilon\cdot\frac{g(x+\epsilon)-g(x)}{\epsilon}$ tends to $0\cdot g'(x)=0$ as $\epsilon\to 0$.

Sum rule. Adding the linear approximations for g and h gives

$$g(x+\epsilon)+h(x+\epsilon) = g(x)+h(x)+\epsilon\big(g'(x)+h'(x)\big)+o(\epsilon),$$

since the sum of two quantities that vanish faster than ϵ also vanishes faster than ϵ. By the converse of the linear approximation, the coefficient of ϵ is the derivative: first-order changes simply add. ■

Product rule. Adding and subtracting $g(x+\epsilon)h(x)$ in the numerator splits the difference quotient of the product into two quotients we already know:

$$\frac{g(x+\epsilon)h(x+\epsilon)-g(x)h(x)}{\epsilon} = g(x+\epsilon)\,\frac{h(x+\epsilon)-h(x)}{\epsilon} + h(x)\,\frac{g(x+\epsilon)-g(x)}{\epsilon}.$$

As $\epsilon\to 0$, continuity gives $g(x+\epsilon)\to g(x)$, so the right-hand side converges to $g(x)h'(x)+h(x)g'(x)$. ■

Chain rule. Rather than dividing by $h(x+\epsilon)-h(x)$, we feed the change of the inner function directly into the linear approximation of the outer function. Because g is differentiable at $h(x)$, the error ratio $\rho(t) = \frac{g(h(x)+t)-g(h(x))}{t} - g'(h(x))$ for $t\neq 0$, extended by $\rho(0)=0$, tends to 0 as $t\to 0$. For every t, including $t=0$, we can therefore write

$$g(h(x)+t) = g(h(x)) + \big(g'(h(x))+\rho(t)\big)\,t.$$

Now set $t = h(x+\epsilon)-h(x) = \epsilon h'(x)+o(\epsilon)$. By continuity of h, $t\to 0$ as $\epsilon\to 0$, so $\rho(t)\to 0$ as well. Substituting this t yields

$$\begin{aligned} g(h(x+\epsilon))-g(h(x)) &= \big(g'(h(x))+\rho(t)\big)\big(\epsilon h'(x)+o(\epsilon)\big)\\ &= \epsilon\,g'(h(x))\,h'(x)+o(\epsilon), \end{aligned}$$

because every term other than $g'(h(x))\,\epsilon h'(x)$ contains a factor that vanishes faster than ϵ. Applying the converse of the linear approximation finishes the proof. ■

Rates multiply along a composition. Applied layer by layer to a neural network, the chain rule produces a product of local slopes, and evaluating that product efficiently is precisely what backpropagation does. The quotient rule follows immediately by applying the product and chain rules to $g \cdot h^{-1}$.

34.1.2.3 Inverse Functions

The chain rule also differentiates a function that undoes another. A function g satisfying $g(f(x)) = x$ for all x near a point is an *inverse* of f there. Suppose such a g exists and is differentiable at $f(x)$; by the inverse function theorem (Rudin 1976), which we use without proof, both hold whenever f' is continuous and nonzero near x. Differentiating both sides of $g(f(x)) = x$ with the chain rule gives

$$g'(f(x))\, f'(x) = 1, \qquad \text{so} \qquad g'(y) = \frac{1}{f'(g(y))} \quad \text{at } y = f(x).$$

In other words, the slope of the inverse is the reciprocal of the slope of f, evaluated at the matching point. Geometrically, the graph of g is the graph of f reflected across the diagonal, and reflecting a line across the diagonal turns rise over run upside down.

Since the logarithm undoes e^x, this rule gives $\log'(y) = 1/e^{\log y} = 1/y$, the fifth entry in our table. Notice that the condition $f'(x) \neq 0$ is strictly necessary. For $f(x) = x^3$ we have $f'(0) = 0$, so the formula breaks down at $y = 0$; indeed, its inverse $x^{1/3}$ is not differentiable at 0, because the difference quotient $\epsilon^{1/3}/\epsilon = \epsilon^{-2/3}$ grows without bound and the graph has a vertical tangent there.

With the logarithm in hand, the chain rule settles the remaining two entries of the table. Writing $a^x = e^{x \log a}$ gives $\frac{d}{dx} a^x = (\log a)\, a^x$, identifying the constant $c_a = \log a$; indeed, $\log 2 = 0.69315$ and $\log 10 = 2.30259$ are the constants we measured numerically above. Similarly, writing $x^n = e^{n \log x}$ for $x > 0$ yields $\frac{d}{dx} x^n = e^{n \log x} \cdot \frac{n}{x} = n x^{n-1}$ for every real n.

34.1.2.4 The Softplus, the Sigmoid, and the Logit

We can now apply these rules to our running function, $s(x) = \log(1 + e^x)$. Using the chain rule with outer function log and inner function $1 + e^x$ gives

$$s'(x) = \frac{e^x}{1 + e^x} = \frac{1}{1 + e^{-x}} = \sigma(x),$$

so the derivative of the softplus is the *sigmoid* σ. Applying the chain rule a second time to $\sigma(x) = (1 + e^{-x})^{-1}$, with outer function u^{-1} and inner function $1 + e^{-x}$ of slope $-e^{-x}$, yields

$$\sigma'(x) = \frac{e^{-x}}{(1 + e^{-x})^2} = \sigma(x)(1 - \sigma(x)),$$

since $1 - \sigma(x) = e^{-x}/(1 + e^{-x})$. Because a product $p(1 - p)$ is maximized at $p = \frac{1}{2}$, the sigmoid is steepest at the origin, where $\sigma(0) = \frac{1}{2}$ and $\sigma'(0) = \frac{1}{4}$. The inverse of σ

is the *logit* function $\operatorname{logit}(p) = \log \frac{p}{1-p}$, and the inverse-function rule immediately gives $\operatorname{logit}'(p) = 1/\sigma'(\operatorname{logit} p) = \frac{1}{p(1-p)}$. At $p = \frac{1}{2}$, this equals $4 = 1/\frac{1}{4}$, matching the reciprocal of the sigmoid's slope.

We can now verify the two constants from the opening logistic-loss example. Since $\ell(w) = s(-w)$, the chain rule gives $\ell'(w) = -\sigma(-w)$, so $\ell'(0) = -\frac{1}{2}$. Differentiating once more gives $\ell''(w) = \sigma(-w)(1 - \sigma(-w))$ and thus $\ell''(0) = \frac{1}{4}$, the curvature at the origin. Let us check numerically whether the gap between $\ell(\epsilon)$ and its linear approximation $\ell(0) - \frac{1}{2}\epsilon$ indeed shrinks like ϵ^2 with leading constant $\frac{1}{2}\ell''(0) = \frac{1}{8}$.

```
# The logistic loss l(w) = log(1 + e^{-w}) near w = 0, where l'(0) = -1/2
def ell(w):
    return np.log(1 + np.exp(-w))

for eps in [0.1, 0.01, 0.001]:
    line = ell(0) - 0.5 * eps          # the linear approximation
    gap = ell(eps) - line
    print(f'eps = {eps:<5}: l = {ell(eps):.6f}, line = {line:.6f}, '
          f'gap = {gap:.2e}, gap / eps^2 = {gap / eps**2:.4f}')
```

```
eps = 0.1  : l = 0.644397, line = 0.643147, gap = 1.25e-03, gap / eps^2 = 0.1249
eps = 0.01 : l = 0.688160, line = 0.688147, gap = 1.25e-05, gap / eps^2 = 0.1250
eps = 0.001: l = 0.692647, line = 0.692647, gap = 1.25e-07, gap / eps^2 = 0.1250
```

Sure enough, the gap drops a hundredfold every time we cut ϵ by a factor of ten, and gap/ϵ^2 settles to $0.125 = \frac{1}{2}\ell''(0)$. The error of the linear approximation is indeed of second order, with a leading constant governed by the curvature. Notice also that the first line prints 0.1249 rather than 0.1250: the gap is not quite $\epsilon^2/8$, and Section 34.1.5.2 will identify the higher-order term responsible for that small difference.

So far, every calculation has lived in an infinitesimal neighborhood of a single point. Asking what the slope tells us about a function across an entire interval is a different kind of question.

34.1.3 The Mean Value Theorem

In optimization, we routinely act on two intuitions: a positive slope means the function is climbing, and a point where the slope vanishes is a candidate minimum. Gradient descent relies on both. Yet each claim infers the behavior of f over an interval from its derivative at individual points, and neither is built into the definition of the derivative. We prove the second claim first, as it is the simpler one.

Lemma (Fermat). *If f attains a local maximum or a local minimum at an interior point ξ of an interval and is differentiable at ξ, then $f'(\xi) = 0$.*

Proof. At a local maximum, $f(\xi+\epsilon) - f(\xi) \le 0$ for all sufficiently small ϵ of either sign. The difference quotient is therefore ≤ 0 for $\epsilon > 0$ and ≥ 0 for $\epsilon < 0$. Because f is differentiable at ξ, both one-sided limits must equal $f'(\xi)$, and the only number that is simultaneously ≤ 0 and ≥ 0 is zero. A local minimum follows by the same argument with inequalities reversed. ■

The first intuition requires a deeper tool: the Mean Value Theorem. Every error bound in

the remainder of this section is obtained by applying this theorem to a well-chosen auxiliary function. Geometrically (Figure 34.3), it states that the chord joining the endpoints of the graph over $[a, b]$ is parallel to the tangent line at some interior point.

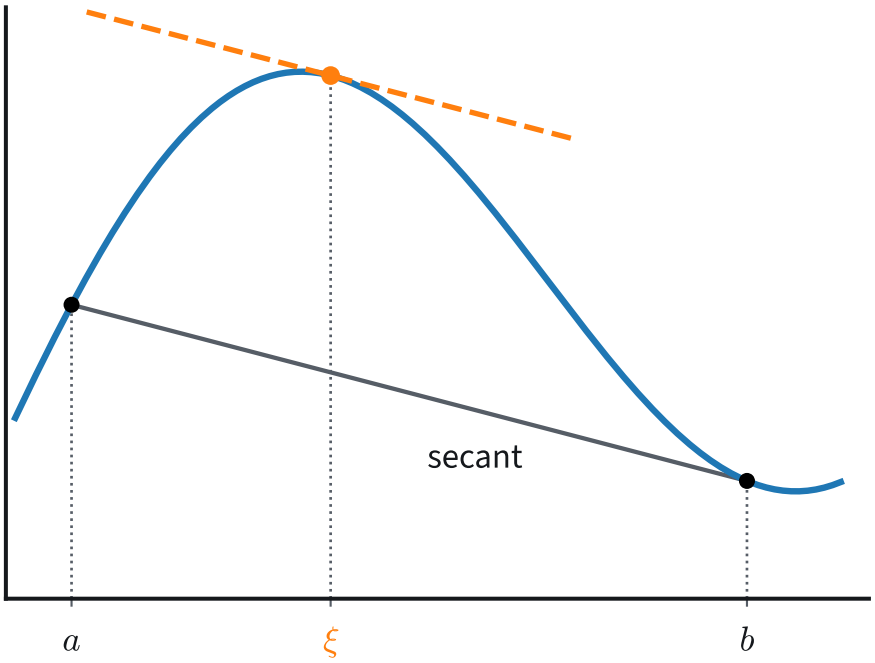

Figure 34.3: Over the interval from a to b, the secant chord through the endpoints has slope equal to the average rate of change; the Mean Value Theorem guarantees that some interior point ξ has a tangent of that same slope, parallel to the chord.

On a simple example like $f(x) = x^2$ over $[0, 2]$, the chord has slope $(4 - 0)/2 = 2$, and the tangent slope $f'(\xi) = 2\xi$ matches it at the midpoint $\xi = 1$. Notice, however, that the theorem truly requires differentiability at every interior point. The absolute value $|x|$ on $[-1, 1]$ satisfies $f(-1) = f(1)$, so its chord is horizontal, yet no interior point has slope 0: the slope is -1 on the left, $+1$ on the right, and undefined at 0.

Proposition (Mean Value Theorem). *If f is continuous on $[a, b]$ and differentiable on (a, b), then there exists a point $\xi \in (a, b)$ such that*

$$f'(\xi) = \frac{f(b) - f(a)}{b - a}. \tag{34.3}$$

Proof. Consider first the flat case $f(a) = f(b)$, known as Rolle's theorem. We invoke one foundational result from real analysis, the **extreme value theorem**: a continuous function on a closed interval attains both a maximum and a minimum (Rudin 1976). If both extrema occur at the endpoints, then f is constant and $f' \equiv 0$ everywhere inside. Otherwise, at least one extremum occurs at an interior point ξ, where $f'(\xi) = 0$ by Fermat's lemma.

For the general case, we subtract the chord to flatten the endpoints. Define the tilted function $\tilde{f}(x) = f(x) - \frac{f(b)-f(a)}{b-a}(x - a)$. Since $\tilde{f}(a) = \tilde{f}(b) = f(a)$, Rolle's theorem provides

an interior point ξ with $\tilde{f}'(\xi) = 0$, which rearranges directly to Equation 34.3. ■

In words, the average rate of change over an interval is always realized as an instantaneous rate of change at some point inside it. Two consequences will appear repeatedly throughout the chapter:

1. *If $f' > 0$ on an interval, then f is strictly increasing there.* For any $x_1 < x_2$ in the interval, Equation 34.3 gives $f(x_2) - f(x_1) = f'(\xi)(x_2 - x_1) > 0$ for some ξ between them. By the same token, $f' < 0$ implies f is strictly decreasing, and $f' = 0$ implies f is constant.
2. *If $f' < 0$ on $(x_0 - \delta, x_0)$ and $f' > 0$ on $(x_0, x_0 + \delta)$ for some $\delta > 0$, and f is continuous at x_0, then x_0 is a strict local minimum.* Applying the first consequence on each side shows that f falls into x_0 from the left and rises out of it to the right.

Returning to our running function, $s' = \sigma > 0$ everywhere, so the softplus is strictly increasing on all of $\mathbb{R}$.

34.1.4 Gradient Descent in One Variable

34.1.4.1 The Gradient-Descent Step

The linear approximation predicts how f responds to any small step ϵ: $f(x + \epsilon) \approx f(x) + \epsilon f'(x)$. To decrease f, we should choose ϵ with the sign opposite to the slope. Setting $\epsilon = -\eta f'(x)$ for a positive *step size* $\eta > 0$, the linear model predicts the change

$$f(x - \eta f'(x)) - f(x) \approx -\eta\, f'(x)^2,$$

which is strictly negative whenever $f'(x) \neq 0$. Regardless of whether the slope is positive or negative, stepping opposite to it lowers the linear model by an amount proportional to the squared slope (Figure 34.4).

Iterating this update gives one-dimensional **gradient descent**:

$$x_{t+1} = x_t - \eta\, f'(x_t). \tag{34.4}$$

Each step moves against the local slope, and the iteration comes to rest at a *stationary point*, where $f'(x_t) = 0$. In a neural network, every coordinate of the weight update $w_i \leftarrow w_i - \eta\, \partial \ell / \partial w_i$ takes this form, with all coordinates updated simultaneously. On our logistic loss starting at $w = 0$, the slope is $\ell'(0) = -\frac{1}{2}$, so a step of size η moves the weight by $\epsilon = \eta/2$ and predicts a loss drop of $\eta/4$.

Notice a glaring limitation of the linear model: its predicted change $-\eta f'(x)^2$ is negative for every $\eta > 0$, no matter how huge. In reality, too large a step can overshoot the minimum and land higher than where it began. The tangent line cannot warn us of this danger because it knows nothing about how the curve bends. The simplest bowl, $f(x) = x^2$, already reveals where the linear prediction breaks down.

34.1.4.2 The Quadratic Case

For $f(x) = x^2$, the slope is $f'(x) = 2x$, so the gradient-descent update simplifies to

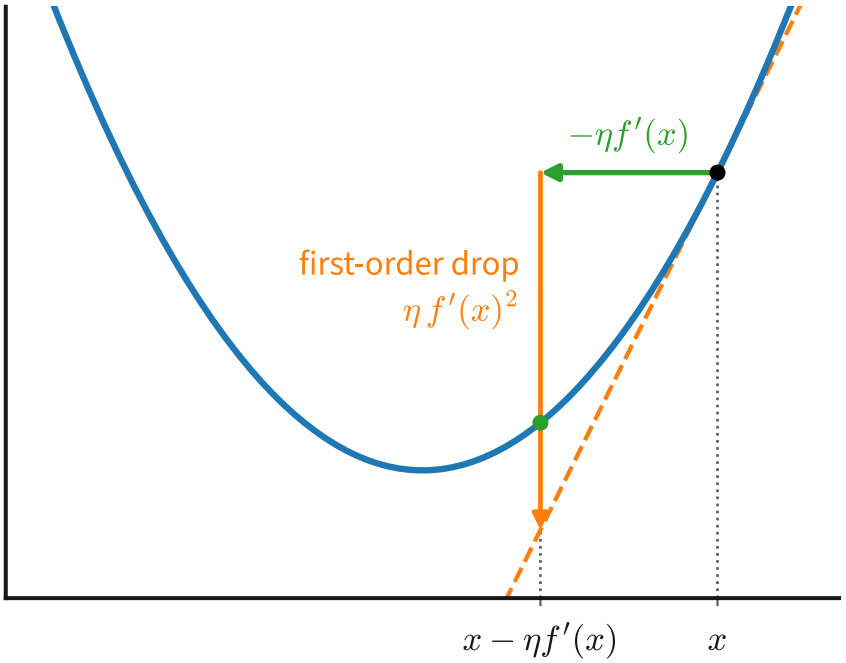

Figure 34.4: One gradient-descent step on a 1-D bowl. At x the tangent line has slope $f'(x)$; the step $-\eta f'(x)$ moves opposite the slope and lands at $x - \eta f'(x)$, lower on the curve, with the drop equal to $\eta f'(x)^2$ to first order.

$$x_{t+1} = x_t - \eta\,(2x_t) = (1 - 2\eta)\,x_t.$$

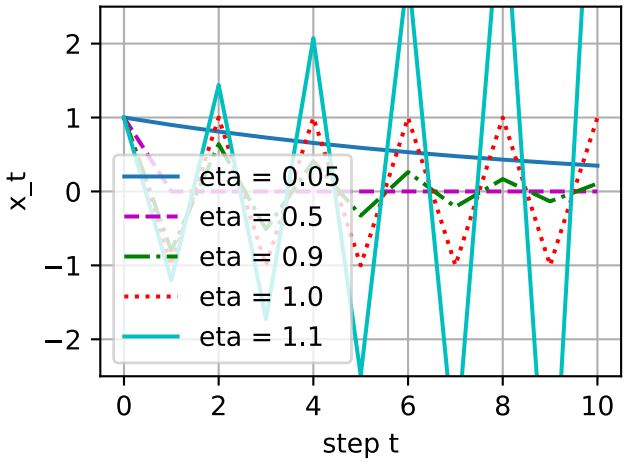
Every step multiplies the current iterate by the same factor $1 - 2\eta$, giving the closed form $x_t = (1 - 2\eta)^t x_0$. The iterates therefore converge to the minimum $x = 0$ if and only if $|1 - 2\eta| < 1$, which is $0 < \eta < 1$. Within this convergent range, a small η creeps monotonically toward 0, $\eta = \frac{1}{2}$ lands on the minimum in a single step, and $\frac{1}{2} < \eta < 1$ overshoots and oscillates inward. Right at the boundary $\eta = 1$, the iterates bounce forever between $+x_0$ and $-x_0$, and for $\eta > 1$ they blow up.

Let us run ten steps from $x_0 = 1$ across five step sizes, one from each regime, to see these trajectories side by side.

```
# Gradient descent on f(x) = x^2 from x0 = 1, for several step sizes
def gd(eta, steps=10, x0=1.0):
    xs = [x0]
    for _ in range(steps):
        xs.append(xs[-1] - eta * (2 * xs[-1]))  # x <- x - eta * f'(x)
    return xs

etas = [0.05, 0.5, 0.9, 1.0, 1.1]
trajectories = [gd(eta) for eta in etas]
for eta, xs in zip(etas, trajectories):
    print(f'eta = {eta:.2f} -> x_10 = {xs[-1]:+.5f}')
d2l.plot(list(range(11)), trajectories, 'step t', 'x_t', ylim=[-2.5, 2.5],
         legend=[f'eta = {eta}' for eta in etas],
         fmts=('-', 'm--', 'g-.', 'r:', 'c-'))
```

```
eta = 0.05 -> x_10 = +0.34868
eta = 0.50 -> x_10 = +0.00000
eta = 0.90 -> x_10 = +0.10737
eta = 1.00 -> x_10 = +1.00000
eta = 1.10 -> x_10 = +6.19174
```



The printed values match the closed-form powers $(1-2\eta)^{10}$: the cautious step $\eta = 0.05$ has only crawled down to 0.349, $\eta = 0.9$ has zig-zagged down to 0.107, $\eta = 1$ is right back at 1,

and $\eta = 1.1$ has already diverged to 6.19. Notice that the stability threshold $\eta = 1$ equals $2/f''$, because $f'' \equiv 2$ for x^2. As we will see in Section 34.1.5.4, this is no coincidence: any bound L on the curvature gives the safe step-size threshold $2/L$ for every smooth function.

34.1.5 Curvature and Taylor Series

How far can we trust the linear approximation, and how large a step size is safe? Both questions depend on how fast the slope itself changes.

34.1.5.1 The Second Derivative

Because f' is itself a function of x, we can differentiate it again. The result is the *second derivative*, $f'' = \frac{d^2 f}{dx^2} = \frac{d}{dx}(\frac{df}{dx})$, which measures the rate of change of the slope. Repeating this process n times yields the n-th derivative,

$$f^{(n)}(x) = \frac{d^n f}{dx^n} = \left(\frac{d}{dx}\right)^n f.$$

Geometrically, $f'' > 0$ means the slope is increasing, so the graph curves upward like a bowl; $f'' < 0$ means the slope is decreasing, so the graph curves downward like a dome. At a stationary point, this sign tells a local minimum apart from a local maximum.

Proposition (second-derivative test). *Let $f'(x_0) = 0$ and suppose $f''(x_0)$ exists. If $f''(x_0) > 0$, then x_0 is a strict local minimum; if $f''(x_0) < 0$, it is a strict local maximum.*

Proof. Because $f'(x_0) = 0$, the definition of $f''(x_0)$ simplifies to $f''(x_0) = \lim_{\epsilon \to 0} f'(x_0 + \epsilon)/\epsilon$. If this limit is positive, then the quotient $f'(x_0 + \epsilon)/\epsilon$ must be positive for all sufficiently small $\epsilon \neq 0$. Hence $f'(x_0 + \epsilon)$ shares the sign of ϵ: negative just to the left of x_0 and positive just to the right. By the second consequence of the Mean Value Theorem, x_0 is a strict local minimum. The case $f''(x_0) < 0$ follows identically with all signs reversed. ∎

Notice where the real work happened in that proof: turning a local sign pattern of f' into a minimum over an interval requires the Mean Value Theorem. Note also that the test certifies only a neighborhood of x_0, not the entire domain. When we move to many variables, the signs of the eigenvalues of the matrix of second derivatives will play this same role.

When $f''(x_0) = 0$ at a stationary point, the test is silent (Figure 34.5, bottom row): x^3, x^4, and $-x^4$ all satisfy $f'(0) = f''(0) = 0$, yet 0 is an inflection point for the first, a minimum for the second, and a maximum for the third; higher-order derivatives decide such flat stationary points.

34.1.5.2 The Taylor Polynomial

The tangent line matches the value and the slope of f at a base point x_0. To capture the bend as well, we can fit a parabola. A general quadratic $q(x) = ax^2 + bx + c$ has derivatives

$$q'(x) = 2ax + b, \qquad q''(x) = 2a,$$

so its curvature is the constant $2a$. Matching the curvature of f at x_0 fixes $a = f''(x_0)/2$, and matching the value and slope fixes b and c. For $f(x) = \sin(x)$, where $\sin' = \cos$ and $\sin'' = -\sin$, the best-fitting parabola at x_0 is

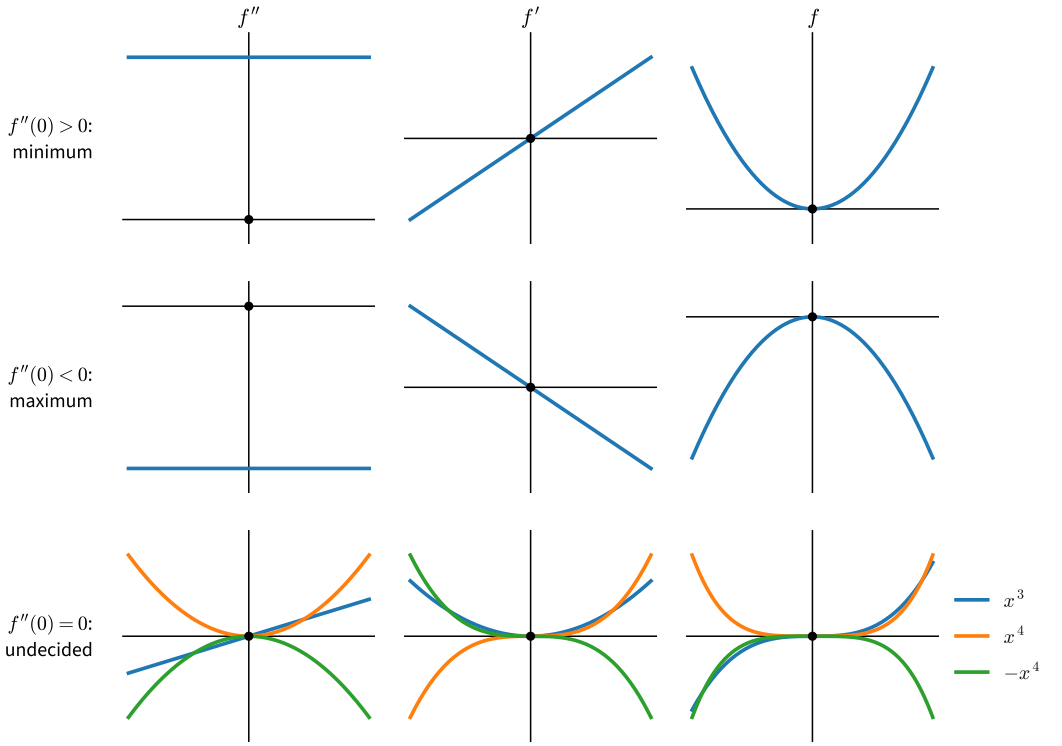


Figure 34.5: The second-derivative test. Rows: $f''(0) > 0$ (a bowl, minimum), $f''(0) < 0$ (a dome, maximum), and $f''(0) = 0$, where x^3, x^4, and $-x^4$ share $f'(0) = f''(0) = 0$ yet have an inflection point, a minimum, and a maximum at 0. Columns: f'', f', f.

$$q(x) = \sin(x_0) + \cos(x_0)\,(x - x_0) - \tfrac{1}{2}\sin(x_0)\,(x - x_0)^2.$$

Because this parabola follows the bend of the sine curve, it stays accurate over a noticeably wider interval than the tangent line (Figure 34.6, drawn at a base point where $\sin x_0 \neq 0$ so the parabola has nonzero curvature).

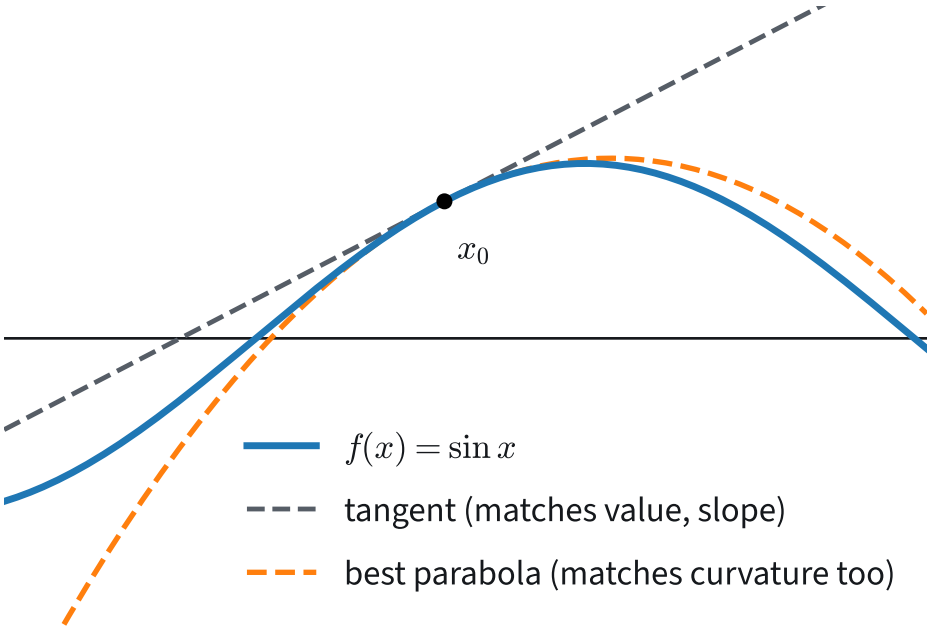

Figure 34.6: The sine curve with its two local models at x_0: the tangent line matches value and slope, while the best parabola also matches curvature and remains accurate over a wider interval.

For our running function at $x_0 = 0$, the values $s(0) = \log 2$, $s'(0) = \frac{1}{2}$, and $s''(0) = \frac{1}{4}$ produce the best parabola $\log 2 + \frac{x}{2} + \frac{x^2}{8}$. Its quadratic coefficient $\frac{1}{8}$ is the exact constant to which gap$/\epsilon^2$ converged for the logistic loss $\ell(w) = s(-w)$.

The same idea extends to any degree n. The degree-n **Taylor polynomial** of f at x_0 is

$$P_n(x) = \sum_{i=0}^{n} \frac{f^{(i)}(x_0)}{i!}(x - x_0)^i,$$

which is the unique polynomial of degree at most n whose value and first n derivatives agree with those of f at x_0. The factorials appear because differentiating $(x - x_0)^i$ exactly i times at x_0 produces $i!$, while every other term vanishes. In this notation, P_1 is the tangent line and P_2 is the best parabola. For e^x at $x_0 = 0$, where every derivative equals 1, we obtain $P_n(x) = \sum_{i=0}^{n} x^i/i!$, and each new term lets the polynomial hug the exponential curve a little farther from the origin. To know just how far we can trust P_n, and how rapidly its error grows beyond that range, we need an explicit formula for the remainder.

34.1.5.3 The Lagrange Remainder

The Mean Value Theorem yields an exact formula for the error of P_n, expressed in terms of a single unknown interior point. This is the centerpiece of the section: both the descent lemma and Newton's quadratic convergence rate fall out of its $n = 1$ case.

Proposition (Lagrange remainder). *If f is $(n+1)$-times differentiable on an open interval containing x_0 and x, with $x \neq x_0$, then*

$$f(x) = P_n(x) + R_n(x), \qquad R_n(x) = \frac{f^{(n+1)}(\xi)}{(n+1)!}\,(x - x_0)^{n+1}, \tag{34.5}$$

for some ξ strictly between x_0 and x. Note that the case $n = 0$ recovers the Mean Value Theorem, $f(x) = f(x_0) + f'(\xi)(x - x_0)$.

Proof. The one clever step is choosing the right auxiliary function; everything after that is straightforward differentiation. Fix x and treat the base point t as the variable: for t between x_0 and x, define

$$G(t) = f(x) - \sum_{k=0}^{n} \frac{f^{(k)}(t)}{k!}\,(x - t)^k - M\,\frac{(x - t)^{n+1}}{(n+1)!},$$

which is the error at x of the Taylor polynomial centered at t, minus a term of the form we expect that error to take. Choose the constant M so that $G(x_0) = 0$. The proof now finishes in three steps.

First, G vanishes at both endpoints. Our choice of M ensures $G(x_0) = 0$, while $G(x) = 0$ because every positive power of $(x - t)$ vanishes at $t = x$ and the $k = 0$ term leaves $f(x) - f(x) = 0$. Rolle's theorem therefore guarantees a point ξ strictly between x_0 and x where $G'(\xi) = 0$.

Second, differentiate $G(t)$ with respect to t. By the product rule, each summand with $k \geq 1$ contributes

$$-\frac{f^{(k+1)}(t)}{k!}(x - t)^k + \frac{f^{(k)}(t)}{(k-1)!}(x - t)^{k-1}$$

to $G'(t)$, while the $k = 0$ term contributes $-f'(t)$. Adjacent terms cancel in pairs (the sum telescopes), leaving only the highest-order derivative and the derivative of the M term:

$$G'(t) = -\frac{f^{(n+1)}(t)}{n!}\,(x - t)^n + M\,\frac{(x - t)^n}{n!}.$$

Third, evaluate at $t = \xi$. Because ξ lies strictly between x_0 and x, we have $(x - \xi)^n \neq 0$, so $G'(\xi) = 0$ forces $M = f^{(n+1)}(\xi)$. Plugging this back into $G(x_0) = 0$ yields Equation 34.5. ∎

The remainder looks just like the next term of the Taylor polynomial, except that the $(n+1)$-st derivative is evaluated at an unknown interior point ξ rather than at x_0. Whenever $f^{(n+1)}$

stays bounded near x_0, the error therefore scales as $|x - x_0|^{n+1}$: each additional matched derivative raises the order of accuracy by one.

Let us test this on our running function. For the softplus, $s''' = \sigma(1-\sigma)(1-2\sigma)$ vanishes at 0 and $s''''(0) = -\frac{1}{8}$, giving the fourth-degree polynomial

$$P_4(x) = \log 2 + \frac{x}{2} + \frac{x^2}{8} - \frac{x^4}{192}.$$

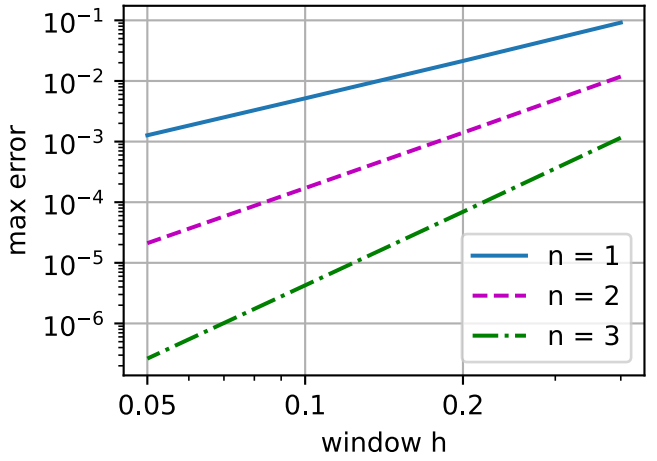
At $x = 0.5$, this evaluates to 0.974072 against the true value $s(0.5) = 0.974077$, an error of only 5×10^{-6}. In fact, the error is even smaller than an x^5 estimate would suggest, because $s(x) - \frac{x}{2} = \log\!\left(2\cosh\frac{x}{2}\right)$ is an even function, so all higher odd terms vanish and the next nonzero term is sixth order. That quartic term also explains why our earlier script printed 0.1249 instead of 0.1250 at $\epsilon = 0.1$: we were seeing $\frac{1}{8} - \frac{\epsilon^2}{192} = 0.12495$.

We can check the h^{n+1} scaling directly in code. If the worst-case error of P_n on the window $|x| \le h$ behaves like h^{n+1}, then halving h should divide the maximum error by 2^{n+1}: by 4 for the tangent line, 8 for the parabola, and 16 for the cubic. Let us verify this prediction on e^x at $x_0 = 0$.

```
# Max error of P_n for e^x on |x| <= h. Lagrange predicts error ~ h^(n+1),
# so halving h should divide it by 2^(n+1)
def taylor_error(n, h, m=1000):
    x = h * np.arange(-m, m + 1) / m
    P = sum(x**k / math.factorial(k) for k in range(n + 1))
    return np.max(np.abs(np.exp(x) - P))

hs = [0.4, 0.2, 0.1, 0.05]
errs = [[taylor_error(n, h) for h in hs] for n in (1, 2, 3)]
for n, e in zip((1, 2, 3), errs):
    ratios = ' '.join(f'{a / b:.1f}' for a, b in zip(e, e[1:]))
    print(f'n = {n}: ratios between successive windows {ratios}, '
          f'predicted {2**(n + 1)}')
d2l.plot(hs, errs, 'window h', 'max error', xscale='log', yscale='log',
         legend=['n = 1', 'n = 2', 'n = 3'])
```

```
n = 1: ratios between successive windows 4.3 4.1 4.1, predicted 4
n = 2: ratios between successive windows 8.4 8.2 8.1, predicted 8
n = 3: ratios between successive windows 16.7 16.3 16.2, predicted 16
```



The measured ratios indeed sit near 4, 8, and 16, and on the log–log plot the three error curves appear as straight lines with slopes 2, 3, and 4, matching $n+1$. The ratios slightly exceed the theoretical values on the wider windows because the factor e^{ξ} in the remainder is larger there.

The Lagrange remainder also answers when the infinite Taylor series reproduces the function itself. For e^x, every derivative equals e^x, so Equation 34.5 around $x_0 = 0$ gives

$$\left|e^x - P_n(x)\right| = \frac{e^{\xi}\,|x|^{n+1}}{(n+1)!} \le \frac{e^{|x|}\,|x|^{n+1}}{(n+1)!}.$$

For any fixed x, the right-hand side vanishes as $n \to \infty$ because factorials eventually outgrow powers. Hence

$$e^x = \sum_{n=0}^{\infty} \frac{x^n}{n!} = 1 + x + \frac{x^2}{2} + \frac{x^3}{6} + \cdots$$

on all of $\mathbb{R}$. Be careful, though: having infinitely many derivatives does not guarantee that a function equals its Taylor series. For $f(x) = e^{-1/x^2}$ (extended by $f(0) = 0$), every single derivative vanishes at 0, so its Taylor series at the origin is identically zero and agrees with f only at $x = 0$ (Figure 34.7). Luckily, nothing we do later depends on infinite series: we work exclusively with finite Taylor polynomials P_n, whose error Equation 34.5 bounds directly.

34.1.5.4 The Descent Lemma

Does a bound on curvature guarantee that gradient descent lowers any smooth function, just as it did for x^2? The Lagrange remainder with $n = 1$ answers yes. Among all results in this section, this is the one optimization theory uses most.

Proposition (descent lemma). *Let f be twice differentiable on an open interval I containing x and $x - \eta f'(x)$, with $|f''| \le L$ on I. Then*

$$f\big(x - \eta\, f'(x)\big) \;\le\; f(x) - \eta\Big(1 - \frac{L\eta}{2}\Big) f'(x)^2. \tag{34.6}$$

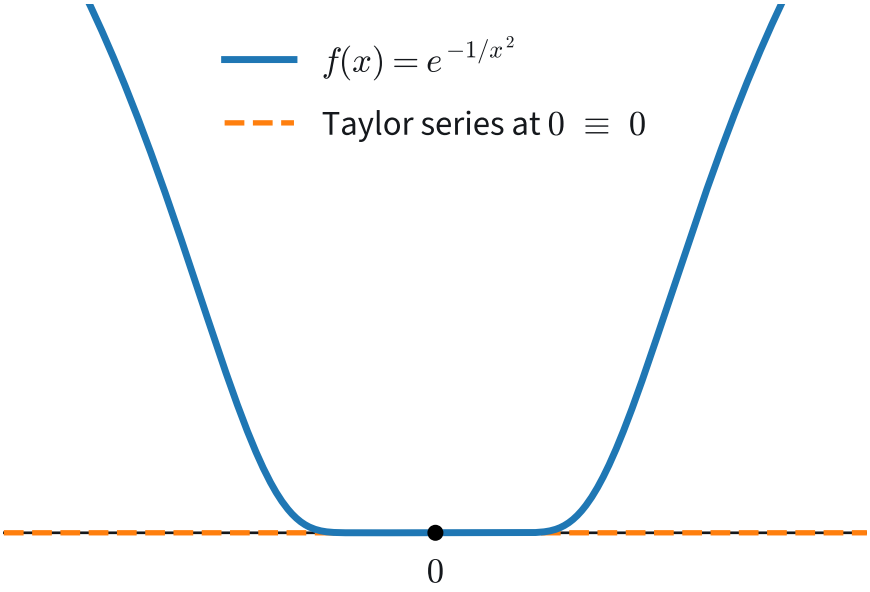


Figure 34.7: The smooth function $f(x) = e^{-1/x^2}$ has every derivative equal to zero at the origin, so its Taylor series there is identically zero. The series converges everywhere yet agrees with f only at $x = 0$: smooth does not imply analytic.

In particular, f strictly decreases whenever $0 < \eta < 2/L$ and $f'(x) \neq 0$, and the guaranteed decrease is maximized at $\eta = 1/L$, where it equals $f'(x)^2/(2L)$.

Proof. For any step u, the Lagrange remainder with $n = 1$ gives $f(x+u) = f(x)+f'(x)u+\frac{1}{2}f''(\xi)u^2 \leq f(x) + f'(x)u + \frac{L}{2}u^2$. Setting $u = -\eta f'(x)$ turns the right-hand side into $f(x) - \eta(1 - L\eta/2)f'(x)^2$. The factor $1 - L\eta/2$ is positive whenever $\eta < 2/L$, and the quadratic $\eta(1 - L\eta/2)$ attains its maximum at $\eta = 1/L$. ■

Geometrically, the lemma replaces the unknown local curvature $f''(\xi)$ with its worst-case bound L. The resulting quadratic $f(x)+f'(x)u+\frac{L}{2}u^2$ acts as an upper-bounding parabola that touches f at x and stays above it throughout I. The step $\eta = 1/L$ simply jumps to the exact minimizer of this ceiling parabola (Figure 34.8). This bound is the workhorse of smooth optimization (Nesterov 2018). In fact, it does not even require a second derivative: it holds whenever f' is *L-Lipschitz*, meaning that slopes at any two points differ by at most L times their distance, $|f'(u) - f'(v)| \leq L|u - v|$. That is the form used in multivariable optimization (Section 35.1), and exercise 1 proves it in one variable.

Let us check the lemma on two familiar functions. For x^2, we have $L = 2$, so $2/L = 1$ recovers the exact stability threshold we found from the closed form. For the logistic loss, $\ell''(w) = \sigma(-w)(1 - \sigma(-w)) \leq \frac{1}{4}$ with equality at $w = 0$, so $L = \frac{1}{4}$ and every step size $\eta < 8$ is guaranteed to decrease ℓ from any starting weight. Starting from $w = 0$ with $\eta = 1$ moves to $w_1 = 0.5$: the bound guarantees a loss at most $0.693147-(1-\frac{1}{8})\cdot\frac{1}{4} = 0.4744$, and the actual value is $\ell(0.5) = 0.4741$. The bound is nearly tight here because the curvature stays close to its maximum L over that short step. With the larger step $\eta = 4 = 1/L$, the bound promises 0.1931 while the actual loss drops all the way to $\ell(2) = 0.1269$: away from

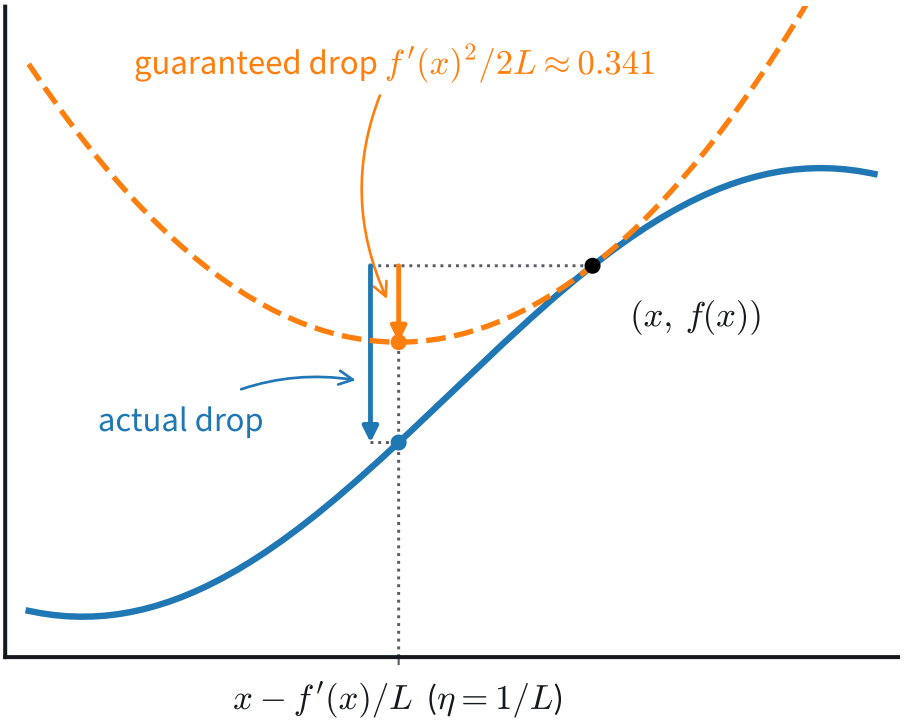

Figure 34.8: For $|f''| \le L$, $f(x) + f'(x)u + \frac{L}{2}u^2$ is a quadratic upper bound in the step u that equals f at the base point. The gradient step with $\eta = 1/L$ minimizes this bound and guarantees a decrease of at least $\frac{1}{2L}f'(x)^2$. Here $f(x) = \sin(2x)$ with $L = 4$, and the actual decrease exceeds the worst-case guarantee.

the origin, the curvature flattens out, so the curve descends even further than the worst-case ceiling predicts.

34.1.5.5 Newton's Method

The descent lemma builds its quadratic model using the global worst-case curvature L. If instead we use the actual local curvature $f''(x_t)$ at the current iterate, we obtain a step that minimizes any quadratic function in a single leap. The local model at x_t is the second-order Taylor polynomial P_2,

$$q(x) = f(x_t) + f'(x_t)\,(x - x_t) + \tfrac{1}{2} f''(x_t)\,(x - x_t)^2.$$

Whenever $f''(x_t) > 0$, this parabola opens upward and has a unique minimizer. Setting $q'(x) = f'(x_t) + f''(x_t)(x - x_t) = 0$ and solving for x yields the update of **Newton's method**:

$$x_{t+1} = x_t - \frac{f'(x_t)}{f''(x_t)}. \tag{34.7}$$

This is a gradient step with an adaptive local step size $1/f''(x_t)$, and on any upward-opening parabola it lands on the exact minimizer in one step. Figure 34.9 illustrates one step on $f(x) = x^4/4 - x$, whose minimizer is $x^\star = 1$. At $x_t = 2$, we have $f(2) = 2$, $f'(2) = 7$, and $f''(2) = 12$, so the parabola's minimizer lies at $x_{t+1} = 2 - 7/12 = 1.4167$.

Let us see how quickly Newton's method converges on $x^4/4 - x$ from $x_0 = 2$, and also test what happens on a second function, $x \arctan x - \frac{1}{2}\log(1 + x^2)$, starting from $x_0 = 1.4$ and $x_0 = 1.3$. We will analyze that second example right after inspecting the numbers.

```
# Newton on f(x) = x^4/4 - x: solve f'(x) = x^3 - 1 = 0, root x* = 1
x = 2.0
for t in range(6):
    print(f't = {t}: x = {x:.12f}, error = {abs(x - 1):.1e}')
    x = x - (x**3 - 1) / (3 * x**2)  # x - f'(x) / f''(x)

# Newton on the convex f(x) = x arctan(x) - log(1 + x^2)/2,
# with f' = arctan(x) and f'' = 1/(1 + x^2)
for x0 in [1.4, 1.3]:
    x, xs = x0, []
    for t in range(6):
        x = x - math.atan(x) * (1 + x**2)
        xs.append(x)
    print(f'from x0 = {x0}:', ', '.join(f'{v:.2f}' for v in xs))
```

```
t = 0: x = 2.000000000000, error = 1.0e+00
t = 1: x = 1.416666666667, error = 4.2e-01
t = 2: x = 1.110534409842, error = 1.1e-01
t = 3: x = 1.010636768405, error = 1.1e-02
t = 4: x = 1.000111557304, error = 1.1e-04
t = 5: x = 1.000000012443, error = 1.2e-08
from x0 = 1.4: -1.41, 1.45, -1.55, 1.85, -2.89, 8.71
from x0 = 1.3: -1.16, 0.86, -0.37, 0.03, -0.00, 0.00
```

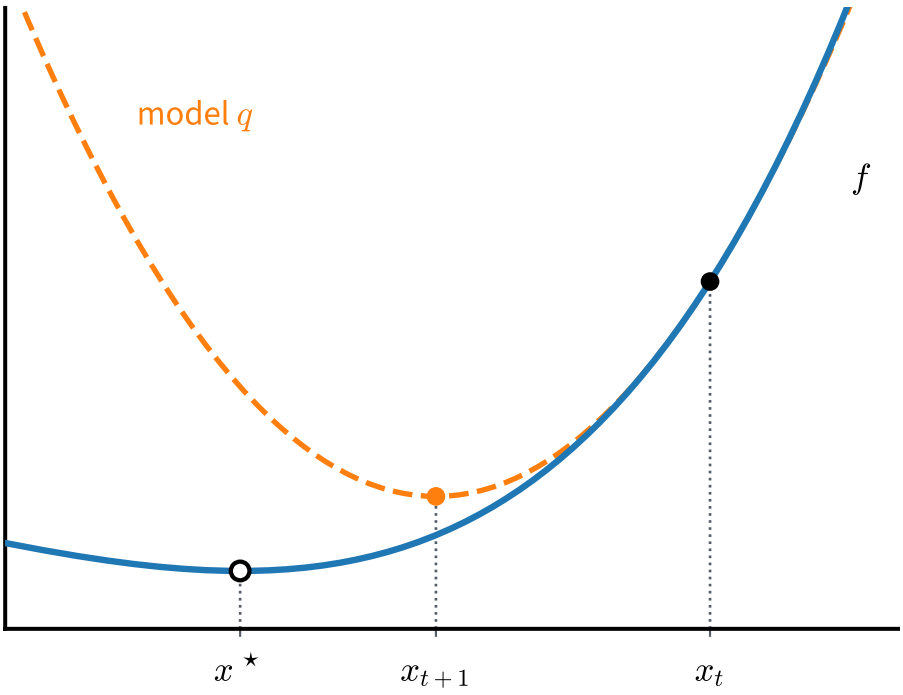

Figure 34.9: One Newton step on $f(x) = x^4/4 - x$ from $x_t = 2$. The parabola q matches the value, slope, and curvature of f at x_t; its minimizer is the next iterate $x_{t+1} = x_t - f'(x_t)/f''(x_t) = 2 - 7/12$, closer to the minimizer $x^\star = 1$.

On $x^4/4 - x$, the errors plummet through 1.0, 0.42, 0.11, 1.1×10^{-2}, 1.1×10^{-4}, and 1.2×10^{-8}: once close to the minimum, each step squares the previous error and roughly doubles the number of correct digits. By contrast, gradient descent on x^2 shrank the error by a constant factor $|1 - 2\eta|$ per step, gaining only a fixed number of digits at each iteration.

The Lagrange remainder explains why the error squares. Let $x^\star$ be a stationary point and let $e_t = x_t - x^\star$ denote the error at step t. Applying Equation 34.5 with $n = 1$ to f' around the base point x_t and evaluating at $x^\star$ gives $0 = f'(x_t) - f''(x_t)\, e_t + \frac{1}{2} f'''(\xi_t)\, e_t^2$. Dividing through by $f''(x_t) \neq 0$ and substituting Newton's update Equation 34.7 leaves

$$e_{t+1} = \frac{f'''(\xi_t)}{2 f''(x_t)}\, e_t^2 \tag{34.8}$$

for some ξ_t between x_t and $x^\star$, provided f is three times differentiable. For $x^4/4 - x$, the prefactor converges to $f'''(1)/(2f''(1)) = 6/(2 \cdot 3) = 1$, and the printed errors indeed yield $e_{t+1}/e_t^2 \approx 0.42, 0.64, 0.87$, and 0.99. The general multivariable theorem, giving quadratic convergence from any starting point close enough to a minimizer with positive curvature, appears in Section 35.2.

That qualification "close enough" is essential, even for a strictly convex function. Consider $f(x) = x \arctan x - \frac{1}{2}\log(1+x^2)$, which has $f'(x) = \arctan x$ and $f''(x) = 1/(1+x^2) > 0$, so it is strictly convex with a unique global minimum at 0. Starting from $x_0 = 1.4$, the second loop above prints $-1.41, 1.45, -1.55, 1.85, -2.89, 8.71$: Newton's method diverges wildly. Starting slightly closer at $x_0 = 1.3$, it converges smoothly (-1.16, 0.86, -0.37, 0.03, ...), with the threshold between convergence and divergence sitting near $x_0 \approx 1.39$.

The local parabola explains what went wrong. Far from the origin, the curvature $1/(1+x^2)$ becomes tiny, so the approximating parabola q is nearly flat and places its minimizer far past $x^\star$. The standard fix is to scale back the step by a factor chosen to ensure f actually decreases, a technique called *damping*. We develop damped Newton steps, and examine the cost of computing them in high dimensions, in Section 35.2.1.

34.1.6 Nondifferentiable Points

Every ReLU network is full of corners: $\mathrm{ReLU}(x) = \max(0, x)$ has no derivative at 0. Yet backpropagation still returns a number there. Which number does it pick, and in what sense is that number a valid slope?

34.1.6.1 One-Sided Derivatives

The difference quotient Equation 34.1 exposes the problem immediately. For $f(x) = |x|$ at $x = 0$,

$$\frac{|0 + \epsilon| - |0|}{\epsilon} = \frac{|\epsilon|}{\epsilon} = \begin{cases} +1 & \epsilon > 0, \\ -1 & \epsilon < 0. \end{cases}$$

The quotient is constant on either side of 0, but the two constants disagree. Approaching from the right, the graph rises with slope $+1$; approaching from the left, it falls with slope -1. These limits are the **one-sided derivatives**, $f'_+(0) = +1$ and $f'_-(0) = -1$, and an ordinary derivative exists only when the two match. The same calculation for ReLU at 0

gives $f'_-(0) = 0$ on the flat left side and $f'_+(0) = 1$ on the right. No tangent slope exists at these corners, yet an automatic differentiation engine must still return a number. Let us check what automatic differentiation actually returns.

```
# What autograd returns at the corner, where no derivative exists
for name, fn in [('d|x|/dx', tf.abs), ("ReLU'", tf.nn.relu)]:
    x = tf.Variable(0.0)
    with tf.GradientTape() as t:
        y = fn(x)
    print(f"{name} at 0: autograd returns {t.gradient(y, x).numpy():.1f}")
```

```
d|x|/dx at 0: autograd returns 0.0
ReLU' at 0: autograd returns 0.0
```

For $\mathrm{ReLU}'(0)$, autograd returns 0, the left-hand slope. For $\frac{d}{dx}|x|$ at 0, it returns a fixed value chosen by convention.

Here it returns 0, following the convention $\mathrm{sign}(0) = 0$.

34.1.6.2 Subgradients and Optimality

Although a corner has no single tangent line, it has an entire family of lines that touch the graph at the corner without ever rising above it. For a *convex* function, one whose chords all lie on or above its graph (Section 35.3), these supporting lines step into the role of the tangent. A number g is called a **subgradient** of a convex function f at x if

$$f(y) \geq f(x) + g\,(y - x) \quad \text{for all } y, \tag{34.9}$$

meaning that the line through $(x, f(x))$ with slope g lies everywhere on or below the graph of f. The set of all subgradients at x is the **subdifferential** $\partial f(x)$ (Rockafellar 1970). At any point where f is differentiable, $\partial f(x)$ contains only the single number $f'(x)$. At a corner, it expands into the closed interval between the one-sided derivatives, corresponding to the fan of supporting lines in Figure 34.10:

$$\partial|x|(0) = [-1, 1], \qquad \partial\,\mathrm{ReLU}(0) = [0, 1].$$

Every value returned by autograd above lies inside the corresponding interval.

Our running function shows intuitively where this interval comes from. The sharpened softplus $\mathrm{softplus}_\beta(x) = \frac{1}{\beta}s(\beta x)$ converges to $\mathrm{ReLU}(x)$ as $\beta \to \infty$, and its derivative is $\sigma(\beta x)$ (Figure 34.11). At $x = \pm 0.1$, the slopes are 0.40 and 0.60 when $\beta = 4$, and sharpen to 0.17 and 0.83 when $\beta = 16$. The subdifferential $[0, 1]$ is precisely the set of slopes that these smooth approximations approach as $\beta \to \infty$ and $x \to 0$ together.

Subgradients also yield a clean optimality test. Setting $g = 0$ in Equation 34.9 gives $f(y) \geq f(x)$ for all y, so a point x is a global minimizer of a convex function f if and only if

$$0 \in \partial f(x). \tag{34.10}$$

Both directions of the equivalence are immediate from that one line. For $|x|$, the membership $0 \in [-1, 1]$ certifies the origin as the global minimum even though no derivative exists

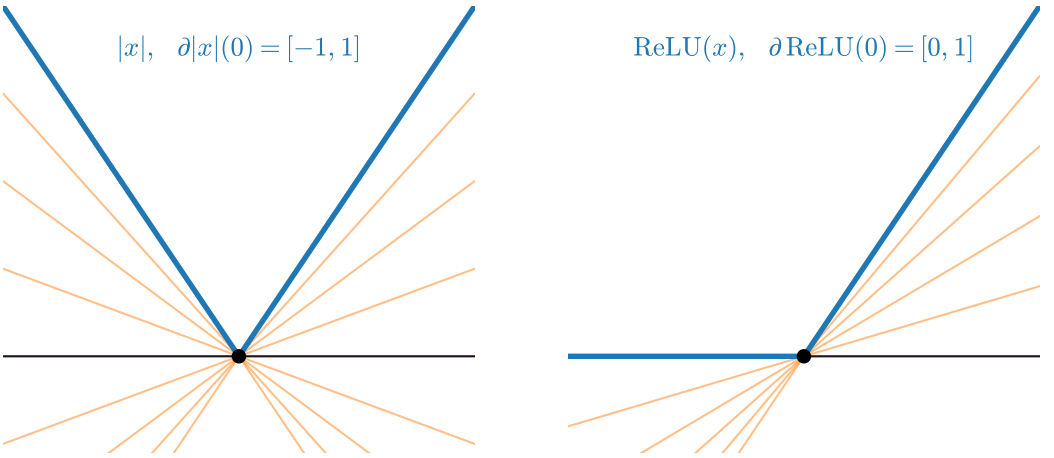

Figure 34.10: Two corners and their subdifferentials: the fan of supporting lines through the origin of $|x|$ (left) and of ReLU (right), with slopes running over $\partial|x|(0)$ and $\partial\,\mathrm{ReLU}(0)$ respectively. Off each corner there is a single tangent and the subdifferential collapses to the ordinary derivative.

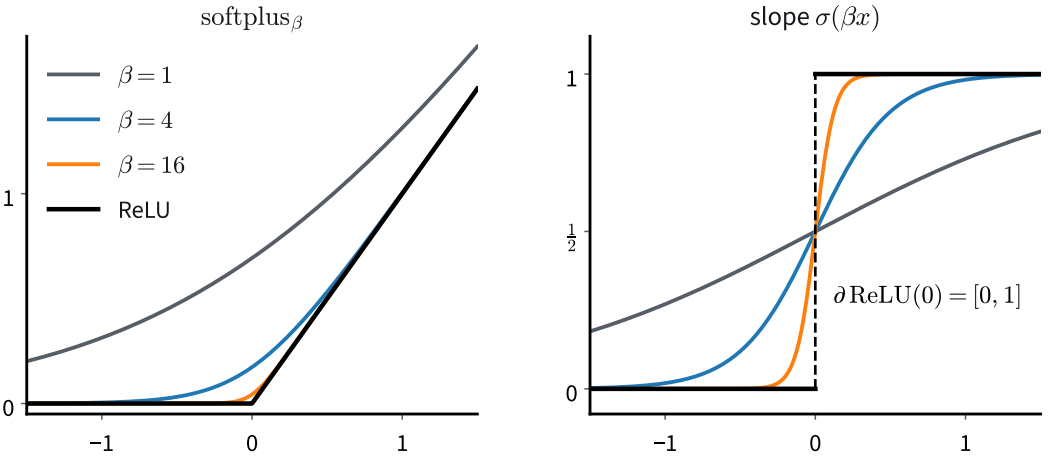

Figure 34.11: Smoothing the corner. Left: $\mathrm{softplus}_\beta(x) = \frac{1}{\beta}\log(1 + e^{\beta x})$ approaches ReLU as β grows. Right: its slope $\sigma(\beta x)$ steepens into the step from 0 to 1; near $x = 0$ the slopes of the smooth neighbors fill the interval $[0, 1]$, the subdifferential of ReLU at the corner.

there. Without convexity, by contrast, $f'(x) = 0$ is only necessary (Fermat's lemma): x^3 satisfies $f'(0) = 0$ yet has no minimum at all.

We extend subgradients to many variables in Section 35.3, but one caution belongs right here: unlike a true gradient step, a subgradient step is not guaranteed to descend. Right at the minimum of $|x|$, the number $g = \frac{1}{2}$ is a valid subgradient, yet stepping to $x = -\eta/2$ actually increases $|x|$. Subgradient methods therefore converge by gradually shrinking their step sizes rather than by guaranteeing progress on every step (Nesterov 2018).

34.1.6.3 Kinks in a Network

Each kink in a neural network originates in a simple convex building block such as $|x|$, ReLU, or the hinge loss. At the kink, autograd picks one fixed element from that block's subdifferential (for example, $\mathrm{ReLU}'(0) = 0$) and propagates it through the surrounding composition using the chain rule. Unfortunately, chaining valid subgradients of individual pieces can produce a number that is not a subgradient of the composite function at all. The simplest counterexample is the identity function written in a roundabout way:

$$\varphi(x) = \mathrm{ReLU}(x) - \mathrm{ReLU}(-x) = x \quad \text{for all } x.$$

Because $\varphi(x) = x$ everywhere, its only true slope at 0 is 1. Yet applying the chain rule mechanically gives $\varphi'(x) = \mathrm{ReLU}'(x) + \mathrm{ReLU}'(-x)$, which equals 1 everywhere except at $x = 0$, where the convention $\mathrm{ReLU}'(0) = 0$ yields $0 + 0 = 0$. Let us verify that automatic differentiation indeed does this.

```
# phi(x) = relu(x) - relu(-x) is the identity, so the true slope at 0 is 1
x = tf.Variable(0.0)
with tf.GradientTape() as t:
    phi = tf.nn.relu(x) - tf.nn.relu(-x)
print(f"autograd: phi'(0) = {t.gradient(phi, x).numpy():.1f}  (true slope: 1.0)")
```

```
autograd: phi'(0) = 0.0  (true slope: 1.0)
```

As predicted, autograd reports slope 0 for the identity function.

Triggering such an error requires a pre-activation to land on 0 exactly. In exact real arithmetic, when data and initial weights are drawn from continuous distributions, this occurs with probability zero at any fixed step. In finite floating-point arithmetic, however, exact zeros do occur. Bertoin et al. (2021) measured how often on a small fully connected network. We quote the figures of the authors' 2023 erratum (the revised arXiv version of the paper), which repairs a bug in the published experiments and reverses some of their conclusions. Backpropagation with $\mathrm{ReLU}'(0) = 0$ and with $\mathrm{ReLU}'(0) = 1$ produced different gradients on at least one minibatch for every initialization in 16-bit precision, for a little under half of all initializations in 32-bit precision, and for none in 64-bit precision.

Whether those discrepancies affect training is a separate question, and the answer is reassuring: practically not at all. In 32-bit arithmetic, only a few minibatches in a million are affected, and even on those the two gradients differ by a relative amount of only about 10^{-3}. In the corrected experiments, any choice of $\mathrm{ReLU}'(0)$ in $[0, 1]$ yields virtually identical training loss and test accuracy; training degrades only for extreme choices such as $\mathrm{ReLU}'(0) = 10^4$, and batch normalization and Adam tame even those. The convention is

therefore a real source of minor numerical differences between runs, yet a harmless one. Exercise 5 examines this behavior on a small scale.

Everything in this section concerned a single scalar weight. A neural network has millions of weights moving together: which joint direction lowers the loss, and what curvature means in many dimensions, are the subjects of Section 34.2.

34.1.7 Summary

The derivative $f'(x)$ is the slope of the linear approximation $f(x+\epsilon) = f(x)+\epsilon f'(x)+o(\epsilon)$. Proved from this approximation, the sum, product, and chain rules let us differentiate any composition built from a short table of elementary functions, such as $s' = \sigma$ for the softplus. To go from slopes at single points to guarantees over intervals, we rely on the Mean Value Theorem and its higher-order extension, the Lagrange remainder, which bounds the error of the degree-n Taylor polynomial by a multiple of $|x-x_0|^{n+1}$ whenever $f^{(n+1)}$ is bounded.

Applied at order $n = 1$, the Lagrange remainder gives the descent lemma: if $|f''| \le L$ on the step interval and $f'(x) \neq 0$, every gradient step with $0 < \eta < 2/L$ strictly lowers f. Replacing the global bound L with the local curvature $f''(x_t)$ gives Newton's step $-f'/f''$, which squares the error near a minimizer with $f'' > 0$ but can diverge far from it, even on a strictly convex function. Finally, at nondifferentiable corners of a convex function, the subdifferential $\partial f(x)$ replaces the derivative and $0 \in \partial f(x)$ characterizes global minima; autograd selects one element per kink, and although chaining those choices can fail to produce a true subgradient in floating point, the effect on training is negligible.

34.1.8 Exercises

1. **Smoothness of the logistic loss.** The descent lemma Equation 34.6 requires a bound L on the curvature.
   1. Use the Mean Value Theorem Equation 34.3 to show that if $|f''| \le L$ on an interval, then f' is L-Lipschitz there. Conversely, show from the definition Equation 34.1 that a twice differentiable f with an L-Lipschitz f' satisfies $|f''| \le L$.
   2. Logistic regression with one weight w, inputs $a_i \in \mathbb{R}$, and labels $y_i \in \{-1, 1\}$ minimizes

$$\ell(w) = \frac{1}{n}\sum_{i=1}^{n} \log(1 + e^{-y_i a_i w}). \tag{34.11}$$

      Express ℓ'' in terms of σ. Find the smallest L for which ℓ' is L-Lipschitz on all of $\mathbb{R}$, and the step sizes for which Equation 34.6 guarantees a decrease from every starting point.
   3. Prove the descent lemma when f is only differentiable and f' is L-Lipschitz on the interval of the step. For $u = -\eta f'(x)$ let $\psi(t) = f(x+tu)-f(x)-tf'(x)u-\frac{L}{2}t^2u^2$. Show that $\psi(0) = 0$ and $\psi'(t) = u\,(f'(x+tu) - f'(x)) - Ltu^2 \le 0$ for $t \in [0, 1]$, and conclude $\psi(1) \le 0$ from the Mean Value Theorem. This is the form of the lemma that optimization uses for functions of many variables.
2. **Entropy extremes.** The binary entropy of a coin that shows heads with probability p is

$$H(p) = -p \log p - (1-p) \log(1-p), \qquad 0 < p < 1. \tag{34.12}$$

1. Find the minimum of $f(x) = x \log x$ on $x \geq 0$, where $f(0) = 0$ is the limiting value. Why does the minimum not lie at the boundary $x = 0$?
2. Show that $H'(p) = -\log \frac{p}{1-p}$, the negative logit of p. Locate the stationary point of H and classify it with the second-derivative test.
3. Find the limit of $H'(p)$ as $p \to 0$. Then parameterize the coin by its logit z, so that $p = \sigma(z)$, and compute $\frac{d}{dz} H(\sigma(z))$. In which of the two parameterizations is the slope of H Lipschitz on the whole domain, so that Equation 34.6 certifies one step size of gradient descent on $-H$ for every starting point?

3. **Newton at degenerate minima.** For $p > 1$, the function $f_p(x) = |x|^p / p$ is convex with its unique minimum at $x = 0$.

   1. Show that f_p is differentiable everywhere, including at 0, with $f_p'(x) = \operatorname{sign}(x)\,|x|^{p-1}$, and compute $f_p''(x)$ for $x \neq 0$. For which p does $f_p''(0)$ exist, and what is its value?
   2. Show that Newton's method Equation 34.7 maps every $x_t \neq 0$ to $x_{t+1} = \frac{p-2}{p-1}\, x_t$. For which p does the iteration converge? How fast does it converge for $p = 4$?
   3. Which hypothesis of the local convergence statement in Section 34.1.5.5 fails for $p = 4/3$, and which fails for $p = 4$?
   4. For $p = 4/3$, the damped update $x_{t+1} = x_t - \alpha f_p'(x_t)/f_p''(x_t)$ shortens the Newton step by a factor $\alpha > 0$. For which α does it converge from every x_0, and at what rate?

   Adapted from MIT 18.01SC, Session 33 problems, "Cube Root of x".

4. code **Minimizers at kinks.** A support vector machine with one weight x, weight decay $\lambda > 0$, and a single training example whose label times input equals 1 minimizes

$$F(x) = \max(0, 1 - x) + \frac{\lambda}{2} x^2. \tag{34.13}$$

   1. Compute the subdifferential of the hinge loss $\max(0, 1-x)$ at every x from Equation 34.9.
   2. Take as given that adding a differentiable convex function q to a convex function h adds q' to every subgradient, $\partial(q+h)(x) = q'(x) + \partial h(x)$. Use the optimality condition Equation 34.10 to find the minimizer of F for every $\lambda > 0$. For which λ does it sit at the kink?
   3. Take $\lambda = 1/2$ and run the subgradient method $x_{t+1} = x_t - \eta_t g_t$ from $x_0 = 0$ for 10^4 steps, where g_t is the value that autograd returns for $F'(x_t)$ when the hinge is written as $\mathrm{ReLU}(1 - x)$. Compare the constant steps $\eta_t = 0.1$ and $\eta_t = 0.01$ with the decaying steps $\eta_t = 0.5/\sqrt{t+1}$. How does the final distance to the minimizer depend on the schedule?
   4. The kink $\{x = 1\}$ is a single point, which a draw from a density hits with probability zero. What do (b) and (c) imply for the argument in Section 34.1.6.3 that training rarely meets a kink?

5. code **Chained subgradients.** Autograd returns $\mathrm{ReLU}'(0) = 0$ and chains this value through every expression, as in Section 34.1.6.3.

1. Let f_1 and f_2 be convex, $g_1 \in \partial f_1(x)$, $g_2 \in \partial f_2(x)$, and $c_1, c_2 \geq 0$. Show from Equation 34.9 that $c_1 g_1 + c_2 g_2 \in \partial(c_1 f_1 + c_2 f_2)(x)$. Why does this argument not cover $\mathrm{ReLU}(x) - \mathrm{ReLU}(-x)$?
2. Show that for every real c,

$$k_c(x) = \mathrm{ReLU}(x) + \mathrm{ReLU}(-x) + c\,(x - \mathrm{ReLU}(x) + \mathrm{ReLU}(-x)) = |x|. \tag{34.14}$$

   Predict the value that autograd returns for $k_c'(0)$, and check the prediction for $c = 0$, 1, and 5. For which c is the returned value a subgradient of $|x|$ at 0?
3. Run gradient descent with the derivative from autograd on $\varphi(x) = \mathrm{ReLU}(x) - \mathrm{ReLU}(-x)$ for 10 steps from $x_0 = 0.5$, once with $\eta = 0.125$ and once with $\eta = 0.1$. What happens in each run? Why do the two step sizes behave differently? What does the difference imply for the probability-zero argument of Section 34.1.6.3 in floating-point arithmetic?

6. **Quartic descent.** ● The minimum of $f(x) = x^4/4$ is flat, since $f''(0) = 0$. Gradient descent Equation 34.4 on f reads $x_{t+1} = x_t - \eta x_t^3$.
   1. Using problem 1a, find the smallest L for which f' is L-Lipschitz on $[-R, R]$. Which starting points x_0 does the descent lemma Equation 34.6 cover for a given η? Why does no fixed η cover all of them?
   2. Show that the iterates converge to 0 if $\eta x_0^2 < 2$ and diverge if $\eta x_0^2 > 2$. What happens at $\eta x_0^2 = 2$? Compare this threshold with the starting points covered in (a).
   3. Show that $1/x_{t+1}^2 = 1/x_t^2 + 2\eta + O(x_t^2)$, and conclude that $x_t^2 \approx 1/(x_0^{-2} + 2\eta t)$. Check the prediction for $\eta = 0.1$ and $x_0 = 1$ at $t = 10$, 100, and 1000. How does this rate compare with gradient descent on x^2, and with Newton's method on $x^4/4$ in problem 3b?

7. code **Central differences.** ● The forward difference $D_+ f(x) = \frac{f(x+\epsilon) - f(x)}{\epsilon}$ and the central difference $D_0 f(x) = \frac{f(x+\epsilon) - f(x-\epsilon)}{2\epsilon}$ both approximate $f'(x)$.
   1. Use the Lagrange remainder Equation 34.5 to show $D_+ f(x) - f'(x) = \frac{1}{2} f''(\xi)\,\epsilon$ and $D_0 f(x) - f'(x) = \frac{1}{6} f'''(\xi')\,\epsilon^2$ for some ξ, ξ' near x, where f is three times continuously differentiable (the continuity of f''' merges two remainder points into one). Expand $f(x \pm \epsilon)$ to the needed order and subtract.
   2. For $f(x) = x^2 + 1701(x-4)^3$ at $x = 4$, show that the two errors are $\epsilon + 1701\epsilon^2$ and $1701\epsilon^2$. At $\epsilon = 0.1$ they are 17.11 and 17.01, nearly equal. The central difference raises the order of the error, which helps only once ϵ is small. At which ϵ is the central error a hundred times smaller than the forward one?

   In floating point, rounding puts a floor under ϵ. The gradient-check exercise of Section 34.3 balances it against the truncation error of (a).

8. code **Gradient descent past $2/L$.** ●● On $f(x) = x^2$, every step size $\eta > 2/L$ diverges. On other functions, gradient descent past this threshold can settle into an oscillation instead (Chen and Bruna 2023), a one-dimensional version of the edge of stability (Cohen et al. 2021). Let $x^\star$ be a local minimizer of a four times continuously

differentiable f with $f''(x^\star) > 0$, and write $T(x) = x - \eta f'(x)$ for one step of Equation 34.4.

1. Use Equation 34.3 to show that iterates that start close enough to $x^\star$ converge to it if $\eta < 2/f''(x^\star)$. Show that if $\eta > 2/f''(x^\star)$, every iterate in some neighborhood of $x^\star$, other than $x^\star$ itself, is followed by one farther from $x^\star$.
2. A period-2 orbit is a pair $a \neq b$ with $T(a) = b$ and $T(b) = a$. Show that for every period-2 orbit there is a point ξ strictly between a and b with $f''(\xi) = 2/\eta$.
3. Let $\eta = (1+\delta)\,2/f''(x^\star)$ with a small $\delta > 0$. Expand $T(T(x))$ around $x^\star$ to third order, and show that a period-2 orbit near $x^\star$ exists and attracts nearby iterates if

$$3f'''(x^\star)^2 - f''(x^\star)\,f''''(x^\star) > 0. \tag{34.15}$$

   Derive the half-width $|a-b|/2$ of the orbit to leading order in δ.
4. Run gradient descent on the double well $f(x) = \frac{1}{4}(x^2-1)^2$ from $x_0 = 0.5$ for 5000 steps for each step size $\eta \in [0.9, 1.5]$, and plot the last 100 iterates against η. Compare the half-width of the orbit near $\eta = 1$ with (c). Compare the range of η with a stable period-2 orbit with the range $1 < \eta < \sqrt{4.5} - 1$ in which Chen and Bruna (2023) prove convergence to the orbit from almost every $0 < x_0 < 1$.
5. Predict from (c) what gradient descent with $\eta = 2.02$ does on $\log\cosh x$ and on $x^2/2 + x^4/4$, both of which have $x^\star = 0$ and $f''(x^\star) = 1$. Confirm the predictions by running both from $x_0 = 0.01$ for 500 steps.

34.2 Multivariable Calculus

In the previous section, we studied a loss as a function of a single weight while holding every other weight fixed. Real training never works that way. Every step of gradient descent nudges all the weights at once, so we need to know how the loss responds to a joint move, and which joint move drives it down fastest. Having a million separate slopes, one per weight, does not by itself answer either question.

Yet under one modest hypothesis, those slopes answer both. When the loss is differentiable, the vector of slopes, called the *gradient*, predicts the effect of every small joint move at once to first order and points in the direction of steepest increase. To go further and tell a local minimum from a saddle, we need a symmetric table of second derivatives, the *Hessian*, which measures how the surface bends. This section develops what these two objects tell us about a function of many variables. How a program actually computes a gradient for a large network is a separate problem, which Section 34.3 takes up next.

Section 1.4 already stated the differentiation rules and put the gradient to work. Here we supply the foundations, much as Section 34.1 did for one variable: we prove when the linear approximation holds and how second derivatives classify critical points. Two results carry the entire section: the multivariable linear model and the second-derivative test. The short subsection on tangent planes and the closing material on Lagrange multipliers can safely be skipped on a first reading. Throughout, we will test each idea on a running example: the two-variable log-sum-exp function $f(x, y) = \log(e^x + e^y)$ evaluated at $(0, \log 2)$. Its gradient will turn out to be the familiar softmax.

34.2.1 Partial Derivatives and the Gradient

34.2.1.1 Partial Derivatives

If we freeze every weight except w_1, the loss becomes a function of a single variable. Its ordinary derivative is the *partial derivative* $\partial \ell / \partial w_1$ from Section 1.4: geometrically, it is the slope of the one-dimensional slice of the graph of ℓ obtained by varying only w_1. Just as in single-variable calculus, this slope predicts the effect of a small change ϵ_1 in w_1 alone,

$$\ell(w_1 + \epsilon_1, w_2, \dots, w_N) \approx \ell(w_1, w_2, \dots, w_N) + \epsilon_1 \frac{\partial \ell}{\partial w_1}(w_1, w_2, \dots, w_N). \tag{34.16}$$

Let us compute the partial derivatives of our running example $f(x, y) = \log(e^x + e^y)$. Holding y fixed and differentiating with respect to x gives $\partial f / \partial x = e^x / (e^x + e^y)$, and by symmetry $\partial f / \partial y = e^y / (e^x + e^y)$. At the point $(0, \log 2)$, we have $e^x = 1$ and $e^y = 2$, so $f(0, \log 2) = \log 3 \approx 1.0986$, $\partial f / \partial x = \frac{1}{3}$, and $\partial f / \partial y = \frac{2}{3}$. In other words, nudging y alone raises f twice as fast as nudging x alone.

34.2.1.2 Differentiability and the Gradient

Partial derivatives tell us the slope along each coordinate axis, one at a time. They do not automatically tell us what happens when all coordinates move together, for instance when we step from $(0, \log 2)$ by $\epsilon = (0.01, -0.03)$. It is tempting to guess that the two coordinate-wise changes simply add, giving $\frac{1}{3} \cdot 0.01 + \frac{2}{3} \cdot (-0.03)$. That guess is actually a strong claim about how f behaves near the point, and it requires a hypothesis.

The hypothesis is that near $\mathbf{w}$, the function ℓ looks linear up to an error that vanishes faster than the step size. Formally, we say that ℓ is *differentiable* at $\mathbf{w}$ if there exists a linear map Λ such that

$$\ell(\mathbf{w} + \epsilon) = \ell(\mathbf{w}) + \Lambda(\epsilon) + o(\|\epsilon\|), \tag{34.17}$$

where $o(\|\epsilon\|)$ denotes any remainder that, when divided by $\|\epsilon\|$, tends to zero as $\epsilon \to \mathbf{0}$.

Whenever such a linear map Λ exists, the partial derivatives determine it completely. Setting $\epsilon = h\mathbf{e}_i$ in Equation 34.17, dividing both sides by h, and letting $h \to 0$ forces $\Lambda(\mathbf{e}_i) = \partial \ell / \partial w_i$. Because Λ is linear, its action on any joint step ϵ is then fixed:

$$\Lambda(\epsilon) = \Lambda\Big(\sum_{i=1}^{N} \epsilon_i \mathbf{e}_i\Big) = \sum_{i=1}^{N} \epsilon_i \frac{\partial \ell}{\partial w_i} = \epsilon \cdot \nabla_{\mathbf{w}} \ell, \qquad \nabla_{\mathbf{w}} \ell = \left[\frac{\partial \ell}{\partial w_1}, \dots, \frac{\partial \ell}{\partial w_N}\right]^{\top}.$$

We call this column vector $\nabla_{\mathbf{w}} \ell$ of partial derivatives the *gradient* of ℓ. Substituting it back into Equation 34.17 gives the multivariable linear approximation

$$\ell(\mathbf{w} + \epsilon) = \ell(\mathbf{w}) + \epsilon \cdot \nabla_{\mathbf{w}} \ell(\mathbf{w}) + o(\|\epsilon\|). \tag{34.18}$$

Compare this with the one-variable approximation $f(x + \epsilon) \approx f(x) + \epsilon f'(x)$: the shape is identical, with the scalar slope replaced by a vector and ordinary multiplication replaced by a dot product. The gradient is the unique vector whose dot product with a step gives the

first-order change in ℓ. Of all the ways to think about a gradient, this is the one to remember. Throughout this book, we treat the gradient as a column vector.

Returning to our running example at $(0, \log 2)$, we have $\nabla f = [\frac{1}{3}, \frac{2}{3}]^\top$. Plugging $\epsilon = (0.01, -0.03)$ into Equation 34.18 predicts $f(0.01, \log 2 - 0.03) \approx \log 3 + \frac{1}{3}\cdot 0.01 - \frac{2}{3}\cdot 0.03 \approx 1.081946$. Notice that at *every* point (x, y), the two entries of ∇f are positive and sum to one: the gradient of log-sum-exp is the softmax $\mathbf{p} = \mathrm{softmax}(x, y)$, with entries $e^x/(e^x + e^y)$ and $e^y/(e^x + e^y)$.

It is worth pausing to see why differentiability asks for more than the mere existence of partial derivatives. Consider $f(x, y) = 2xy/(x^2 + y^2)$ with $f(0, 0) = 0$. Along both coordinate axes f is identically zero, so both partial derivatives at the origin are 0, leaving the constant function 0 as the only possible linear model. Yet along the diagonal $x = y \neq 0$, we have $f(x, x) = 1$ no matter how close we get to the origin, so no linear approximation can hold there. Here f is not even continuous at the origin, and Exercise 1 shows that even a continuous function can have all partial derivatives and still fail to be differentiable.

Fortunately, we rarely have to check Equation 34.17 directly. A convenient sufficient condition is that all partial derivatives exist in a neighborhood of $\mathbf{w}$ and are continuous at $\mathbf{w}$ (Rudin 1976). Since the partial derivatives of log-sum-exp are continuous everywhere, it is differentiable everywhere.

The definition of differentiability promises only that the approximation error is $o(\|\epsilon\|)$, meaning it shrinks faster than $\|\epsilon\|$. How much faster is it in practice? Before running the next cell, guess by what factor the error of the linear model shrinks when we cut the step $\epsilon = (0.01, -0.03)$ by a factor of ten. The experiment below uses plain NumPy to check.

```
import numpy as np
import tensorflow as tf
```

```
def lse(xy):  # f(x, y) = log(e^x + e^y), computed stably
    return np.logaddexp(xy[0], xy[1])

def grad_lse(xy):  # its gradient, the softmax of (x, y)
    return np.exp(xy - lse(xy))

xy0 = np.array([0.0, np.log(2)])
print('gradient:', grad_lse(xy0))
for scale in [1, 0.1, 0.01]:
    eps = scale * np.array([0.01, -0.03])
    linear = lse(xy0) + eps @ grad_lse(xy0)
    true = lse(xy0 + eps)
    print(f'|eps| {np.linalg.norm(eps):.1e}: linear {linear:.8f}, '
          f'true {true:.8f}, gap {true - linear:.3e}')
```

```
gradient: [0.33333333 0.66666667]
|eps| 3.2e-02: linear 1.08194562, true 1.08212418, gap 1.786e-04
|eps| 3.2e-03: linear 1.09694562, true 1.09694740, gap 1.779e-06
|eps| 3.2e-04: linear 1.09844562, true 1.09844564, gap 1.778e-08
```

At $\|\epsilon\| \approx 0.03$, the linear model misses the true value by 1.79×10^{-4} (only in the fourth decimal place), and each tenfold reduction in the step shrinks the gap by a factor of a hun-

dred. That means the error is second order in the step, which is considerably tighter than differentiability alone guarantees. Soon, the Hessian will let us predict this gap accurately (Section 34.2.3.2).

34.2.1.3 Directional Derivatives

So far we have used the gradient to predict small steps. It also gives the exact instantaneous slope along any direction, not just along the coordinate axes. Take any unit vector $\mathbf{u}$, substitute $\epsilon = h\mathbf{u}$ into Equation 34.18, divide by h, and let $h \to 0$. The $o(\|h\mathbf{u}\|)$ remainder vanishes, leaving

$$\lim_{h \to 0} \frac{\ell(\mathbf{w} + h\mathbf{u}) - \ell(\mathbf{w})}{h} = \mathbf{u} \cdot \nabla_{\mathbf{w}} \ell(\mathbf{w}). \tag{34.19}$$

The limit on the left is the *directional derivative* of ℓ along $\mathbf{u}$; the right side says it is simply the projection of the gradient onto $\mathbf{u}$. A single vector therefore encodes the slope in every possible direction at once.

Three directions for our running example at $(0, \log 2)$ illustrate the full range of behavior. Along the diagonal $\mathbf{u} = (1,1)/\sqrt{2}$, the slope is $(\tfrac{1}{3} + \tfrac{2}{3})/\sqrt{2} = 1/\sqrt{2} \approx 0.707$. In fact, this slope is the same at *every* point, because $f(x + t, y + t) = \log(e^t(e^x + e^y)) = f(x,y) + t$: moving a distance $\sqrt{2}\,t$ along the diagonal always raises f by t. Pointing directly against the gradient, along $\mathbf{u} = -(1,2)/\sqrt{5}$, gives the slope $-(\tfrac{1}{3} + \tfrac{4}{3})/\sqrt{5} = -\sqrt{5}/3 \approx -0.745$. Finally, along $\mathbf{u} = (2,-1)/\sqrt{5}$, the slope is $(\tfrac{2}{3} - \tfrac{2}{3})/\sqrt{5} = 0$, so to first order f does not change at all in that direction.

34.2.2 The Geometry of Gradients

34.2.2.1 Steepest Descent

Gradient descent (Section 2.1) nudges the parameters a short distance in the direction along which the loss drops fastest. By Equation 34.19, we are looking for the unit vector $\mathbf{v}$ whose projection $\mathbf{v} \cdot \nabla \ell$ is as negative as possible. Section 1.4 identified this direction from the cosine of the angle between $\mathbf{v}$ and the gradient; the Cauchy–Schwarz inequality gives an even cleaner proof and confirms that the direction is unique.

Proposition (steepest ascent and descent). *At any point where $\nabla \ell \neq \mathbf{0}$, among all unit vectors $\mathbf{v}$, the directional derivative $\mathbf{v} \cdot \nabla \ell$ is maximized by $\mathbf{v} = \nabla \ell / \|\nabla \ell\|$ and minimized by $\mathbf{v} = -\nabla \ell / \|\nabla \ell\|$. Thus $+\nabla \ell$ is the direction of steepest ascent and $-\nabla \ell$ is the direction of steepest descent.*

Proof. The Cauchy–Schwarz inequality (Section 33.1) states that $|\mathbf{v} \cdot \mathbf{g}| \le \|\mathbf{v}\|\|\mathbf{g}\|$, with equality if and only if $\mathbf{v}$ and $\mathbf{g}$ are collinear. For a unit vector $\mathbf{v}$ and $\mathbf{g} = \nabla \ell$, this reads

$$-\|\nabla \ell\| \;\le\; \mathbf{v} \cdot \nabla \ell \;\le\; \|\nabla \ell\|.$$

Each bound is attained uniquely by a unit vector collinear with $\nabla \ell$: the upper bound by $\mathbf{v} = \nabla \ell / \|\nabla \ell\|$ and the lower bound by $\mathbf{v} = -\nabla \ell / \|\nabla \ell\|$. $\blacksquare$

In our running example at $(0, \log 2)$, the steepest descent direction is $-(1,2)/\sqrt{5}$, with slope $-\|\nabla f\| = -\sqrt{5}/3 \approx -0.745$, the most negative of the three slopes we computed a moment ago. Taking a step along $-\nabla_{\mathbf{w}}\ell$ gives the familiar gradient-descent update

$$\mathbf{w} \leftarrow \mathbf{w} - \eta\, \nabla_{\mathbf{w}} \ell(\mathbf{w}).$$

Notice that the update does not normalize the gradient. Its step length is $\eta\|\nabla\ell\|$, which naturally shrinks as the gradient gets smaller near a minimum.

It is easy to overlook that "unit" in the proposition means unit *Euclidean* length, and that this is a modeling choice rather than a law of nature. If we instead constrain each coordinate of the step to have magnitude at most one, the steepest descent step becomes $-\operatorname{sign}(\nabla\ell)$ applied coordinate by coordinate. At $(0, \log 2)$, that step is $(-1,-1)$, with slope $-(\frac{1}{3} + \frac{2}{3}) = -1$. Adaptive optimizers like Adam, which divide each coordinate of the update by a running estimate of its scale (Chapter 9), behave much more like this sign step than like Euclidean steepest descent. Exercise 4 explores steepest descent under other norms.

34.2.2.2 Gradients and Level Sets

We can also read the gradient directly off a contour map, without talking about steps at all. A *level set* of ℓ is the collection of all points where ℓ takes a fixed value c. Because moving along a level set keeps ℓ constant, the directional derivative along any tangent direction should vanish.

Proposition (gradients are normal to level sets). *Let ℓ be differentiable at $\mathbf{x}$. Then $\nabla\ell(\mathbf{x})$ is orthogonal to every direction tangent at $\mathbf{x}$ to the level set $\{\mathbf{x}' : \ell(\mathbf{x}') = c\}$ passing through $\mathbf{x}$.*

Proof. A vector $\mathbf{v}$ is *tangent* to the level set at $\mathbf{x}$ if $\mathbf{v} = \gamma'(0)$ for some differentiable curve $\gamma(t)$ lying inside the level set with $\gamma(0) = \mathbf{x}$. Along such a curve, $\ell(\gamma(t)) = c$ for all t, so the derivative of $t \mapsto \ell(\gamma(t))$ at $t = 0$ must be zero. To first order, $\gamma(t) = \mathbf{x} + t\mathbf{v} + o(t)$, so Equation 34.18 tells us that this derivative equals $\mathbf{v} \cdot \nabla\ell(\mathbf{x})$. Hence $\mathbf{v} \cdot \nabla\ell(\mathbf{x}) = 0$. ∎

Let us check this on our running example. The level set of f passing through $(0, \log 2)$ is the curve $e^x + e^y = 3$. Differentiating along it gives $e^x\,dx + e^y\,dy = 0$, so the tangent direction at $(0, \log 2)$ is $(e^y, -e^x) = (2, -1)$. Taking the dot product with the gradient confirms $(2,-1) \cdot (\frac{1}{3}, \frac{2}{3}) = 0$, the direction of zero slope we found earlier.

On a contour map, the gradient therefore crosses every contour at a right angle and points toward higher values. Moreover, if neighboring contours differ by Δc and sit a distance d apart, the slope across them is roughly $\Delta c / d$, so the gradient is longest wherever the contours are packed most tightly (Figure 34.12).

34.2.2.3 Tangent Planes

If we drop the error term from the linear approximation Equation 34.18 and write the predicted height as z, we obtain the *tangent plane* to the graph of f at $\mathbf{x}_0$,

$$z = f(\mathbf{x}_0) + \nabla f(\mathbf{x}_0) \cdot (\mathbf{x} - \mathbf{x}_0). \tag{34.20}$$

For our running example at $(0, \log 2)$, this plane is $z = \log 3 + \frac{1}{3}x + \frac{2}{3}(y - \log 2)$. Rewriting Equation 34.20 as $\nabla f(\mathbf{x}_0) \cdot (\mathbf{x} - \mathbf{x}_0) - (z - f(\mathbf{x}_0)) = 0$ shows immediately that the vector

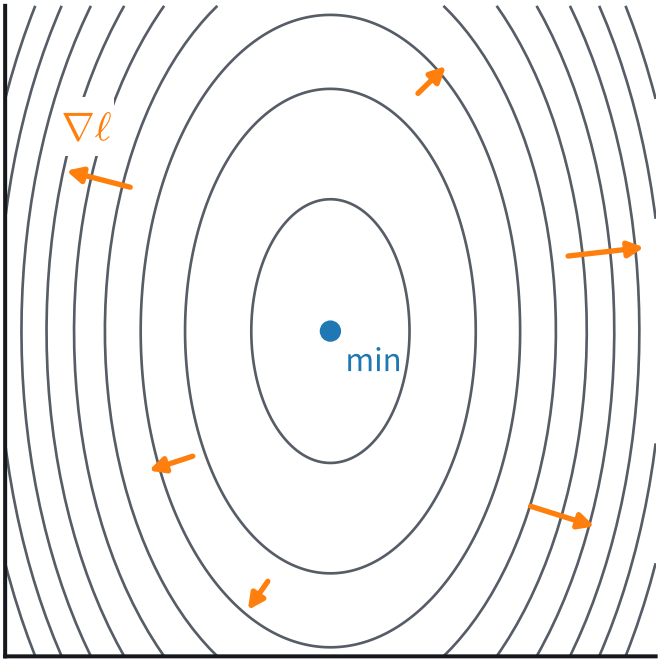

Figure 34.12: Contours of a loss ℓ (gray) with $\nabla \ell$ at several points. Each gradient is normal to its contour, points toward larger values, and is longest where the contours are packed most tightly.

$[\nabla f(\mathbf{x}_0), -1]^\top$ is normal to the tangent plane in $(\mathbf{x}, z)$-space. Dropping its height coordinate leaves $\nabla f(\mathbf{x}_0)$, which is the normal to the level curve in the base plane (Figure 34.13).

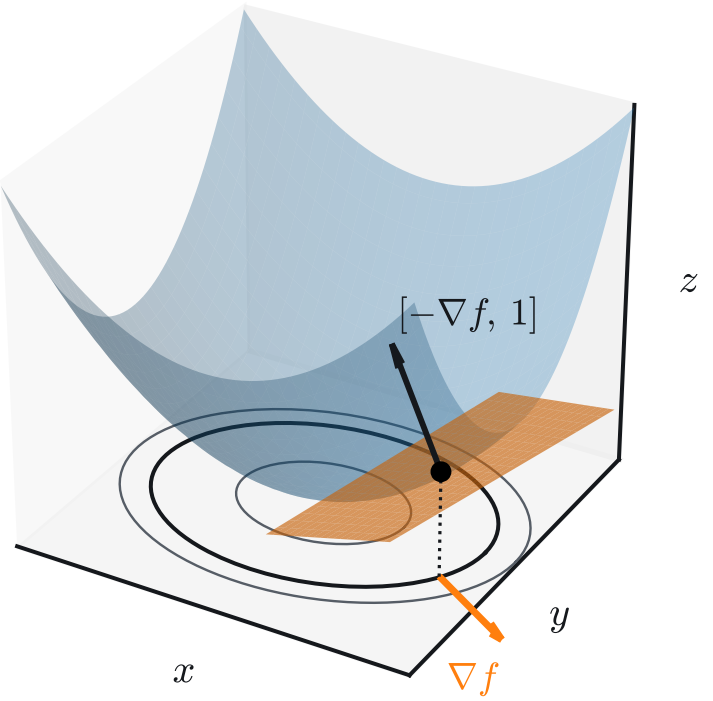

Figure 34.13: A surface $z = f(\mathbf{x})$ (blue) with its tangent plane at a point (orange). The vector $[-\nabla f, 1]$, the negative of $[\nabla f, -1]$, is normal to the plane (black arrow). Dropping the height coordinate leaves a multiple of ∇f, which on the base plane (orange arrow) is normal to the level curve through the point (black).

34.2.2.4 Critical Points

Deep learning losses are far too complicated to minimize in closed form, yet the linear model still gives a necessary condition that every minimum must obey, and gradient descent comes to rest right where this condition holds. Throughout this discussion, suppose f is defined on all of $\mathbb{R}^n$ and differentiable at $\mathbf{x}_0$.

If $\nabla f(\mathbf{x}_0) \neq \mathbf{0}$, we can step against it by setting $\epsilon = -\eta \nabla f(\mathbf{x}_0)$ with $\eta > 0$. By Equation 34.18, the resulting change in f is $-\eta \|\nabla f(\mathbf{x}_0)\|^2 + o(\eta)$, which is strictly negative for every sufficiently small η. Thus $\mathbf{x}_0$ cannot be a local minimum; repeating the argument with $+\eta$ shows it cannot be a local maximum either. Therefore, **at any local minimum or maximum, $\nabla f(\mathbf{x}_0) = \mathbf{0}$.** Points where the gradient vanishes are called *critical points*. This first-order condition is necessary, not sufficient, and the next example shows what else we need to be sure we have found a global extremum.

Consider $\psi(x, y) = x e^{-x^2 - y^2}$, a surface with a positive hill for $x > 0$ and a matching negative pit for $x < 0$. Its partial derivatives are

$$\frac{\partial \psi}{\partial x} = (1 - 2x^2)\, e^{-x^2 - y^2}, \qquad \frac{\partial \psi}{\partial y} = -2xy\, e^{-x^2 - y^2}.$$

Setting the second partial to zero forces either $x = 0$ or $y = 0$. Since $x = 0$ makes the first partial equal to $e^{-y^2} \neq 0$, we must have $y = 0$, and then $1 - 2x^2 = 0$ gives $x = \pm 1/\sqrt{2}$. The two critical points have values $\psi(\mp 1/\sqrt{2}, 0) = \mp e^{-1/2}/\sqrt{2} \approx \mp 0.4289$.

To conclude that $(-1/\sqrt{2}, 0)$ is the *global* minimum, however, we also need to know that a global minimum exists at all. Outside the disc of radius $R = 2$, the exponential decay forces $|\psi| \leq R e^{-R^2} < 0.04$, whereas inside the disc $\psi(-1/\sqrt{2}, 0) \approx -0.43$. Because ψ is continuous, it attains its minimum on the closed disc; since that minimum is below -0.04, it cannot lie on the boundary and must be a global minimum of ψ on all of $\mathbb{R}^2$, hence a critical point. Comparing our two candidates identifies $(-1/\sqrt{2}, 0)$ as the global minimum, and the same argument identifies $(+1/\sqrt{2}, 0)$ as the global maximum. Skip the existence check and the logic breaks down: x^3 has a single critical point yet no minimum anywhere.

Notice also what first-order information cannot do: both the minimum and the maximum have zero gradient, so the gradient alone cannot tell them apart. For that, we turn to second derivatives (Section 34.2.3.3).

34.2.3 The Hessian

34.2.3.1 Symmetry of the Hessian

The linear model captures only first-order behavior. Whether a critical point is a minimum, a maximum, or neither depends on how the surface curves away from its tangent plane, and curvature is measured by second derivatives. A function of n variables has n^2 second partial derivatives,

$$\frac{\partial^2 f}{\partial x_i \partial x_j} = \frac{\partial}{\partial x_i}\left(\frac{\partial f}{\partial x_j}\right),$$

which we collect into the *Hessian* matrix

$$\mathbf{H}_f(\mathbf{x}) = \begin{bmatrix} \frac{\partial^2 f}{\partial x_1 \partial x_1} & \cdots & \frac{\partial^2 f}{\partial x_1 \partial x_n} \\ \vdots & \ddots & \vdots \\ \frac{\partial^2 f}{\partial x_n \partial x_1} & \cdots & \frac{\partial^2 f}{\partial x_n \partial x_n} \end{bmatrix}. \tag{34.21}$$

Entry (i, j) measures how fast the j-th slope changes as we move along coordinate x_i. The Hessian is also written $\nabla^2 f$, and when the function and point are clear from context we simply write $\mathbf{H}$.

For log-sum-exp, let us write $(x_1, x_2) = (x, y)$ and differentiate the softmax entries $p_i = e^{x_i}/(e^{x_1} + e^{x_2})$ once more. Applying the quotient rule gives $\partial p_i / \partial x_j = p_i \delta_{ij} - p_i p_j$, where δ_{ij} is 1 when $i = j$ and 0 otherwise. In matrix form,

$$\mathbf{H}_f = \operatorname{diag}(\mathbf{p}) - \mathbf{p}\mathbf{p}^{\top}, \qquad \mathbf{H}_f(0,\log 2) = \begin{bmatrix} \frac{1}{3}-\frac{1}{9} & -\frac{2}{9} \\ -\frac{2}{9} & \frac{2}{3}-\frac{4}{9} \end{bmatrix} = \frac{2}{9}\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}. \tag{34.22}$$

This 2×2 matrix has eigenvalue 0 along $(1,1)$ and eigenvalue $\frac{4}{9}$ along $(1,-1)$. The zero eigenvalue matches what we already saw: along the diagonal $(1,1)$, $f(x+t,y+t) = f(x,y)+t$ is completely linear and has no curvature at all. We will meet this positive semidefinite, singular Hessian again in the second-derivative test.

The n^2 entries of a Hessian are not independent. Whenever f is twice continuously differentiable, the order of differentiation does not matter and the Hessian is symmetric, a classical result known as the Clairaut–Schwarz theorem (Rudin 1976). That symmetry is crucial: it guarantees real eigenvalues and orthogonal eigenvectors via the spectral theorem (Section 33.3), which makes the second-derivative test possible.

Proposition (symmetry of the Hessian; Clairaut–Schwarz). *Suppose the first partial derivatives of f and the mixed partials $\frac{\partial^2 f}{\partial x_i \partial x_j}$ and $\frac{\partial^2 f}{\partial x_j \partial x_i}$ exist near $\mathbf{x}$, and suppose the mixed partials are continuous at $\mathbf{x}$. Then*

$$\frac{\partial^2 f}{\partial x_i \partial x_j}(\mathbf{x}) = \frac{\partial^2 f}{\partial x_j \partial x_i}(\mathbf{x}).$$

When this holds for all i, j, the Hessian is symmetric: $\mathbf{H}_f = \mathbf{H}_f^{\top}$.

Proof. The idea is to realize both mixed partials as limits of the *same* quantity, the symmetric second difference

$$\Delta_h = \frac{f(\mathbf{x}+h\mathbf{e}_i+h\mathbf{e}_j) - f(\mathbf{x}+h\mathbf{e}_i) - f(\mathbf{x}+h\mathbf{e}_j) + f(\mathbf{x})}{h^2}, \tag{34.23}$$

which is visibly unchanged if we swap i and j. Our task is to express Δ_h as a mixed partial evaluated at a nearby point. Define the one-variable function $\varphi(t) = f(\mathbf{x}+t\mathbf{e}_i+h\mathbf{e}_j) - f(\mathbf{x}+t\mathbf{e}_i)$, so that $h^2\Delta_h = \varphi(h)-\varphi(0)$. Applying the mean value theorem (Section 34.1.3) twice, first to φ and then along x_j to the difference of first partials inside φ', gives numbers τ and σ between 0 and h such that

$$\begin{aligned} \varphi(h)-\varphi(0) &= h\,\varphi'(\tau) = h\Big[\frac{\partial f}{\partial x_i}(\mathbf{x}+\tau\mathbf{e}_i+h\mathbf{e}_j) - \frac{\partial f}{\partial x_i}(\mathbf{x}+\tau\mathbf{e}_i)\Big] \\ &= h^2\,\frac{\partial^2 f}{\partial x_j \partial x_i}(\mathbf{x}+\tau\mathbf{e}_i+\sigma\mathbf{e}_j). \end{aligned}$$

Thus $\Delta_h = \frac{\partial^2 f}{\partial x_j \partial x_i}(\xi_h)$ at a point ξ_h inside the square with corners $\mathbf{x}$ and $\mathbf{x}+h\mathbf{e}_i+h\mathbf{e}_j$, at distance at most $\sqrt{2}\,|h|$ from $\mathbf{x}$. Swapping the roles of i and j leaves Δ_h unchanged and yields $\Delta_h = \frac{\partial^2 f}{\partial x_i \partial x_j}(\xi_h')$ at another point of the same square. Letting $h \to 0$, continuity of the mixed partials at $\mathbf{x}$ sends the two expressions to the two mixed partials at $\mathbf{x}$. Because they agree for every h, their limits must agree as well. $\blacksquare$

The continuity hypothesis is strictly needed: there exist functions whose mixed partials exist everywhere yet fail to be continuous at the origin, where they disagree.

34.2.3.2 The Second-Order Taylor Approximation

Just as the gradient supplies the best linear approximation to f, the Hessian supplies the best *quadratic* approximation. To see where the coefficients come from, it helps to read them off an exact quadratic first. Take $f(x_1, x_2) = a + b_1 x_1 + b_2 x_2 + c_{11} x_1^2 + c_{12} x_1 x_2 + c_{22} x_2^2$. Evaluating its value, gradient, and Hessian Equation 34.21 at the origin gives

$$f(0,0) = a, \qquad \nabla f(0,0) = \begin{bmatrix} b_1 \\ b_2 \end{bmatrix}, \qquad \mathbf{H}_f(0,0) = \begin{bmatrix} 2c_{11} & c_{12} \\ c_{12} & 2c_{22} \end{bmatrix},$$

and assembling these pieces recovers the polynomial exactly: $f(\mathbf{x}) = f(\mathbf{0}) + \nabla f(\mathbf{0}) \cdot \mathbf{x} + \frac{1}{2} \mathbf{x}^{\top} \mathbf{H}_f(\mathbf{0})\, \mathbf{x}$. The factor of $\frac{1}{2}$ simply cancels the factor of 2 produced when we differentiate a square.

For a general function f, this quadratic is no longer exact, but restricting f to a line segment shows how accurate it is. Suppose f is twice continuously differentiable near the segment connecting $\mathbf{x}_0$ to $\mathbf{x}$. Write the displacement as $\delta = \mathbf{x} - \mathbf{x}_0$, and consider the single-variable slice $\varphi(t) = f(\mathbf{x}_0 + t\delta)$. By the linear model Equation 34.18, its first derivative is $\varphi'(t) = \sum_i \frac{\partial f}{\partial x_i}(\mathbf{x}_0 + t\delta)\, \delta_i$. Because each partial derivative in this sum is itself differentiable, applying the same step once more gives the second derivative: $\varphi''(t) = \sum_{i,j} \delta_j \frac{\partial^2 f}{\partial x_j \partial x_i}(\mathbf{x}_0 + t\delta)\, \delta_i = \delta^{\top} \mathbf{H}_f(\mathbf{x}_0 + t\delta)\, \delta$.

Now apply the one-variable Taylor theorem with Lagrange remainder (Section 34.1.5.2) of degree one to φ between 0 and 1: there is some $\tau \in (0,1)$ such that $\varphi(1) = \varphi(0) + \varphi'(0) + \frac{1}{2}\varphi''(\tau)$. Translating back to f gives

$$f(\mathbf{x}) = f(\mathbf{x}_0) + \nabla f(\mathbf{x}_0) \cdot \delta + \tfrac{1}{2} \delta^{\top} \mathbf{H}_f(\xi)\, \delta, \qquad \xi = \mathbf{x}_0 + \tau\delta.$$

This identity is exact, at the cost of evaluating the Hessian at an unknown intermediate point ξ on the segment rather than at $\mathbf{x}_0$. Because the second partials are continuous, replacing $\mathbf{H}_f(\xi)$ by $\mathbf{H}_f(\mathbf{x}_0)$ changes the quadratic term by at most $\frac{1}{2}\|\mathbf{H}_f(\xi) - \mathbf{H}_f(\mathbf{x}_0)\|\, \|\delta\|^2 = o(\|\delta\|^2)$. That yields the *second-order Taylor approximation*:

$$\begin{aligned} f(\mathbf{x}) = f(\mathbf{x}_0) &+ \nabla f(\mathbf{x}_0) \cdot (\mathbf{x} - \mathbf{x}_0) \\ &+ \frac{1}{2} (\mathbf{x} - \mathbf{x}_0)^{\top} \mathbf{H}_f(\mathbf{x}_0) (\mathbf{x} - \mathbf{x}_0) + o(\|\mathbf{x} - \mathbf{x}_0\|^2). \end{aligned} \tag{34.24}$$

This quadratic model misses f only by an error that vanishes faster than the squared step size, and it is the unique quadratic with that property. Whenever f has three continuous derivatives, the error is of third order in the step.

Along any single direction $\mathbf{v}$, a step $t\mathbf{v}$ produces a quadratic term of $\frac{t^2}{2} \mathbf{v}^{\top} \mathbf{H} \mathbf{v}$. The number $\mathbf{v}^{\top} \mathbf{H} \mathbf{v} = \frac{d^2}{dt^2} f(\mathbf{x}_0 + t\mathbf{v})\big|_{t=0}$ is the *second directional derivative*: it measures the curvature of the slice of f along $\mathbf{v}$.

We can now explain the gap left by the linear model in our first code cell. For the step $\epsilon = (0.01, -0.03)$ from $(0, \log 2)$, the Hessian Equation 34.22 predicts a second-order correction of $\frac{1}{2}\epsilon^\top \mathbf{H}\epsilon = \frac{1}{9}(\epsilon_1 - \epsilon_2)^2 = \frac{1}{9}(0.04)^2 \approx 1.78 \times 10^{-4}$, which closely matches the measured gap of 1.786×10^{-4}. Let us verify both the eigenvalues of $\mathbf{H}$ and the predicted gaps in code.

```
p = grad_lse(xy0)                # the softmax at (0, log 2)
H = np.diag(p) - np.outer(p, p)  # Hessian of log-sum-exp
print('9 H =', (9 * H).round(6).tolist())
print('eigenvalues:', np.linalg.eigvalsh(H).round(6) + 0.0)  # no '-0.'
for scale in [1, 0.1]:
    eps = scale * np.array([0.01, -0.03])
    print(f'|eps| {np.linalg.norm(eps):.1e}: '
          f'predicted gap {0.5 * eps @ H @ eps:.4e}')
```

```
9 H = [[2.0, -2.0], [-2.0, 2.0]]
eigenvalues: [0.       0.444444]
|eps| 3.2e-02: predicted gap 1.7778e-04
|eps| 3.2e-03: predicted gap 1.7778e-06
```

Both the matrix and its eigenvalues, 0 and $\frac{4}{9}$, match Equation 34.22. The predicted gaps of 1.7778×10^{-4} and 1.7778×10^{-6} agree with the measured 1.786×10^{-4} and 1.779×10^{-6} to two or three significant digits. The tiny leftover of about 10^{-6} in the first gap comes from the third-order term, and when the step shrinks by a factor of ten, that leftover drops by roughly a thousandfold, disappearing below the printed digits.

In the log-sum-exp example, one direction was completely flat. Let us look at a function that bends in both directions: $\psi(x, y) = xe^{-x^2-y^2}$ at the base point $\mathbf{x}_0 = (-1, 0)$. From the partial derivatives we computed earlier, $\psi(-1, 0) = -e^{-1}$ and $\nabla\psi(-1, 0) = (-e^{-1}, 0)$, and differentiating once more gives $\mathbf{H}_\psi(-1, 0) = 2e^{-1}\mathbf{I}$. Substituting these into Equation 34.24 yields the quadratic model $q(x, y) = e^{-1}(-1 - (x + 1) + (x + 1)^2 + y^2)$. As Figure 34.14 shows, the surface and its quadratic approximation are nearly indistinguishable near $(-1, 0)$ before pulling apart farther away.

If the error of this quadratic model is indeed third order, doubling the step size should multiply the gap by about eight. The next cell evaluates ψ and q at steps of d in each coordinate from $(-1, 0)$ to check.

```
def psi(x, y):
    return x * np.exp(-x**2 - y**2)

def quad(x, y):  # second-order Taylor model of psi at (-1, 0)
    return np.exp(-1) * (-1 - (x + 1) + (x + 1)**2 + y**2)

for d in [0.0, 0.05, 0.1, 0.3]:  # step d in each coordinate from (-1, 0)
    x, y = -1 + d, d
    print(f'step {d:.2f}: psi = {psi(x, y):.6f}, quadratic = {quad(x, y):.6f}, '
          f'gap = {abs(psi(x, y) - quad(x, y)):.6f}')
```

```
step 0.00: psi = -0.367879, quadratic = -0.367879, gap = 0.000000
step 0.05: psi = -0.384315, quadratic = -0.384434, gap = 0.000119
```

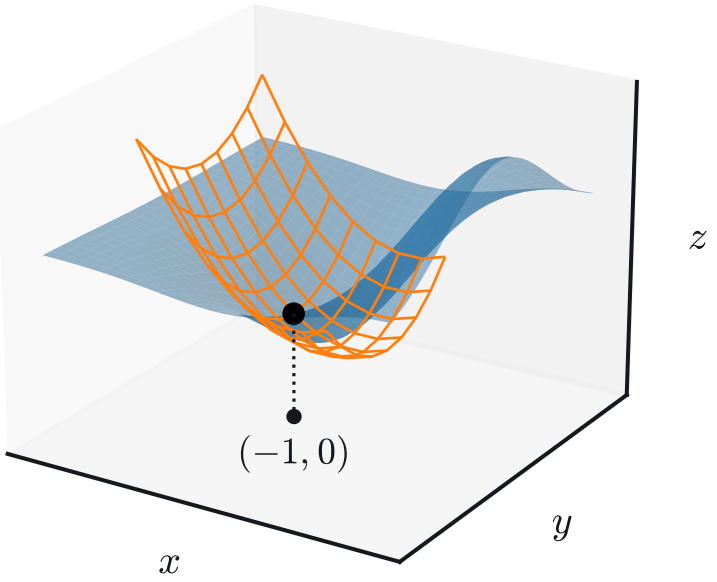

Figure 34.14: The surface $z = xe^{-x^2-y^2}$ (blue) and its second-order Taylor quadratic at the base point $(-1, 0)$ (orange). The two agree in value, slope, and curvature there, so they are nearly indistinguishable near the base point and separate farther out.

```
step 0.10: psi = -0.396388, quadratic = -0.397310, gap = 0.000921
step 0.30: psi = -0.391929, quadratic = -0.412025, gap = 0.020096
```

As expected, the gap vanishes at the base point, and doubling the step from 0.05 to 0.1 multiplies it by just under eight (from 0.000119 to 0.000921), matching a third-order remainder. Fitting this local quadratic and jumping directly to *its* minimum at each step is Newton's method, which Section 34.1.5.5 introduced in one variable and Section 9.1.5.1 develops as a multivariable optimizer.

34.2.3.3 The Second-Derivative Test

At a critical point $\mathbf{x}_0$, the linear term in Equation 34.24 disappears. Near $\mathbf{x}_0$, the function therefore behaves like its quadratic term up to an error of $o(\|\mathbf{x}-\mathbf{x}_0\|^2)$, so whether f rises or falls as we move away in a direction $\mathbf{v}$ is governed by the sign of $\mathbf{v}^\top \mathbf{H}\mathbf{v}$, provided that curvature is nonzero.

The eigenvalues of $\mathbf{H}$ organize these signs cleanly. Because $\mathbf{H}$ is symmetric, the spectral theorem (Section 33.3) guarantees an orthonormal basis of eigenvectors $\mathbf{q}_i$ with real eigenvalues λ_i. Expanded in this basis, the quadratic form becomes a simple weighted sum of squares:

$$\mathbf{v}^\top \mathbf{H}\mathbf{v} = \sum_{i=1}^{n} \lambda_i \, (\mathbf{q}_i^\top \mathbf{v})^2. \tag{34.25}$$

From this formula we can read the local geometry at a glance. If every $\lambda_i > 0$, the curvature is strictly positive in every direction and is at least $\lambda_{\min}\|\mathbf{v}\|^2$. If the eigenvalues have mixed signs, the surface bends upward along some eigenvectors and downward along others.

Proposition (second-order conditions). *Let f be twice continuously differentiable near a critical point $\mathbf{x}_0$, and write $\mathbf{H} = \mathbf{H}_f(\mathbf{x}_0)$.*

1. *If $\mathbf{x}_0$ is a local minimum, then $\mathbf{H} \succeq 0$ (all eigenvalues are ≥ 0).*
2. *If $\mathbf{H} \succ 0$ (all eigenvalues are > 0), then $\mathbf{x}_0$ is a strict local minimum.*
3. *If $\mathbf{H}$ has eigenvalues of both signs, then $\mathbf{x}_0$ is neither a local minimum nor a local maximum, regardless of any zero eigenvalues: it is a saddle point.*

The corresponding statements for maxima follow by applying the proposition to $-f$. When $\mathbf{H}$ is singular and semidefinite, neither case 2 nor case 3 applies, and the second-derivative test is inconclusive.

Proof. (1) Suppose instead that $\mathbf{v}^\top \mathbf{H}\mathbf{v} < 0$ for some direction $\mathbf{v}$. The one-variable slice $\varphi(t) = f(\mathbf{x}_0 + t\mathbf{v})$ has $\varphi'(0) = \nabla f(\mathbf{x}_0)\cdot\mathbf{v} = 0$ and $\varphi''(0) = \mathbf{v}^\top\mathbf{H}\mathbf{v} < 0$. By the single-variable second-derivative test, φ has a strict local maximum at $t = 0$, so f takes values strictly below $f(\mathbf{x}_0)$ arbitrarily close to $\mathbf{x}_0$, contradicting the assumption that $\mathbf{x}_0$ is a local minimum.

(2) This is the step that requires care, because we must control the remainder uniformly in all directions at once. Using the exact Taylor identity with $\nabla f(\mathbf{x}_0) = \mathbf{0}$, we have $f(\mathbf{x}_0+\delta) - f(\mathbf{x}_0) = \tfrac{1}{2}\delta^\top \mathbf{H}_f(\xi)\delta$ for some ξ on the segment from $\mathbf{x}_0$ to $\mathbf{x}_0+\delta$. Split the Hessian as $\mathbf{H}_f(\xi) = \mathbf{H} + (\mathbf{H}_f(\xi) - \mathbf{H})$. By Equation 34.25, the leading term satisfies $\delta^\top\mathbf{H}\delta \geq \lambda_{\min}\|\delta\|^2$. By continuity of the second partials, $\|\mathbf{H}_f(\xi) - \mathbf{H}\| \leq \tfrac{1}{2}\lambda_{\min}$ for all

sufficiently small δ. Combining the two bounds gives $f(\mathbf{x}_0+\delta)-f(\mathbf{x}_0)\geq\frac{1}{2}(\lambda_{\min}-\frac{1}{2}\lambda_{\min})\|\delta\|^2=\frac{1}{4}\lambda_{\min}\|\delta\|^2>0$ for every sufficiently small $\delta\neq\mathbf{0}$.

(3) Along an eigenvector with $\lambda>0$, the slice φ satisfies $\varphi'(0)=0$ and $\varphi''(0)=\lambda>0$, so f takes strictly larger values than $f(\mathbf{x}_0)$ arbitrarily close to $\mathbf{x}_0$. Along an eigenvector with $\lambda<0$, it takes strictly smaller values. ■

Of the three statements, the second is the one to remember, and the only one whose proof takes real work. Notice also that the inconclusive case is not just a theoretical footnote: along a zero eigenvector the quadratic model is completely flat, leaving higher-order terms in charge. For example, x^2+y^4 and x^2-y^4 share the same Hessian $\operatorname{diag}(2,0)$ at the origin, yet the first has a strict minimum there while the second has a saddle (Exercise 3 pushes this phenomenon even further). Figure 34.15 illustrates all four cases on the quadratic models from our running examples.

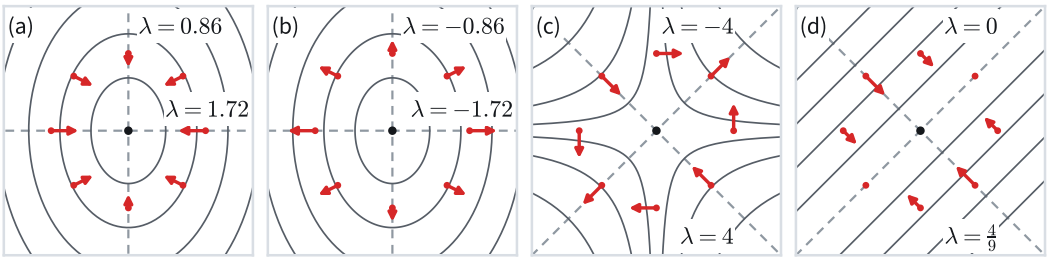

Figure 34.15: Contours of the quadratic model $\frac{1}{2}\mathbf{v}^\top\mathbf{H}\mathbf{v}$ (gray), its eigenvector directions with their eigenvalues (dashed), and descent arrows $-\mathbf{H}\mathbf{v}$ (red). (a) $\mathbf{H}\succ 0$: a minimum, every descent arrow points in. (b) $\mathbf{H}\prec 0$: a maximum. (c) Indefinite: a saddle; descent flows in along one eigenvector and out along the other. (d) Singular and semidefinite: the quadratic model is flat along the zero eigenvector, and second order is inconclusive.

In Figure 34.15, panel (a) shows the Hessian of ψ at $(-1/\sqrt{2},0)$, which equals $e^{-1/2}\operatorname{diag}(2\sqrt{2},\sqrt{2})$, while panel (b) shows its negative at $(+1/\sqrt{2},0)$. Panel (c) shows the origin of x^4+y^4-4xy, whose Hessian is $\left(\begin{smallmatrix}0&-4\\-4&0\end{smallmatrix}\right)$. Panel (d) reuses the log-sum-exp Hessian Equation 34.22 purely as an example matrix: log-sum-exp itself has no critical point, because its gradient, the softmax, never vanishes.

What happens when we implement the second-derivative test numerically and run it on a flat direction? A Hessian built from finite differences almost never produces an exact zero eigenvalue, so we must choose a tolerance below which an eigenvalue is treated as zero. In the next cell, the centered mixed difference `fxy` is the second difference Equation 34.23 with step $2h$ anchored at $(x-h,y-h)$.

```
def hessian(f, x, y, h=1e-4):  # 2x2 Hessian from second differences
    fxx = (f(x + h, y) - 2 * f(x, y) + f(x - h, y)) / h**2
    fyy = (f(x, y + h) - 2 * f(x, y) + f(x, y - h)) / h**2
    fxy = (f(x + h, y + h) - f(x + h, y - h)
           - f(x - h, y + h) + f(x - h, y - h)) / (4 * h**2)
    return np.array([[fxx, fxy], [fxy, fyy]])

def classify(lo, hi, tol=1e-6):  # from the smallest, largest eigenvalue
```

```
        if lo > tol:
            return 'minimum'
        if hi < -tol:
            return 'maximum'
        if lo < -tol < tol < hi:
            return 'saddle'
        return 'inconclusive'

    quartic = lambda x, y: x**4 + y**4 - 4 * x * y
    trough = lambda x, y: x**2 + y**4
    for fn, x0 in [(psi, -1 / np.sqrt(2)), (psi, 1 / np.sqrt(2)),
                   (quartic, 0.0), (trough, 0.0)]:
        lo, hi = np.linalg.eigvalsh(hessian(fn, x0, 0.0))
        print(f'({x0:+.4f}, 0): eigenvalues {lo:+.3f}, {hi:+.3f} '
              f'-> {classify(lo, hi)}')
```

```
(-0.7071, 0): eigenvalues +0.858, +1.716 -> minimum
(+0.7071, 0): eigenvalues -1.716, -0.858 -> maximum
(+0.0000, 0): eigenvalues -4.000, +4.000 -> saddle
(+0.0000, 0): eigenvalues +0.000, +2.000 -> inconclusive
```

At $(-1/\sqrt{2}, 0)$, the eigenvalues come out to 0.858 and 1.716 (matching $\sqrt{2}e^{-1/2}$ and $2\sqrt{2}e^{-1/2}$), confirming the global minimum we found earlier. At $(+1/\sqrt{2}, 0)$, both flip sign, confirming a maximum. At the origin of $x^4 + y^4 - 4xy$, the eigenvalues are ± 4, giving a saddle whose directions of rise and fall, $(1, -1)$ and $(1, 1)$, are rotated away from the coordinate axes. The fourth point is the instructive one. At the origin of $x^2 + y^4$, finite differences return $2h^2 = 2 \times 10^{-8}$ along the flat direction; because this sits below our tolerance, the program rightly reports "inconclusive" even though the origin is a strict minimum. Second-order information simply cannot see the quartic rise, and only the tolerance prevents the numerical test from claiming otherwise.

34.2.3.4 Saddles in High Dimension

In n dimensions, a local minimum requires all n eigenvalues of the Hessian to be nonnegative, and a nondegenerate minimum requires all n to be strictly positive. If the eigenvalue signs at a random critical point behaved like independent coin flips, all n would land positive with probability 2^{-n}, already vanishingly small when n is large.

Surprisingly, this coin-flip heuristic actually *overestimates* the chance of finding a minimum. Consider random symmetric matrices from the Gaussian orthogonal ensemble, whose diagonal entries have twice the variance of the off-diagonal entries. Even at $n = 2$, the exact probability that both eigenvalues are positive is $(1 - 1/\sqrt{2})/2 \approx 0.146$ rather than 0.25 (Exercise 4). For large n, the probability decays far faster than exponentially, like $\exp\left(-\frac{\ln 3}{4} n^2\right)$ (Dean and Majumdar 2006), because the eigenvalues of a random symmetric matrix repel one another and almost never crowd onto one side of zero.

In random high-dimensional landscapes, then, critical points at typical (high) function values are overwhelmingly saddles. Only at low function values does the Hessian shift toward positive eigenvalues so that minima begin to dominate (Bray and Dean 2007). Neural networks exhibit the same behavior: when Newton's method locates critical points on the loss surfaces of small networks, the high-loss critical points are saddles (Dauphin et al. 2014). Practically, when an optimizer stalls at high loss, a poor local minimum is the least likely

explanation. The optimizer may be lingering near a saddle or, more often still, crossing a poorly conditioned region in which the gradient is not small at all.

34.2.4 Constrained Optimization and Lagrange Multipliers

Until now, our variables were free to move in any direction. Many machine learning problems instead restrict the parameters to a surface: weights normalized to unit length, probabilities constrained to sum to one, or the closest point on a curve to the origin. In all of these, we want to minimize $f(\mathbf{x})$ subject to a constraint $g(\mathbf{x}) = c$. The unconstrained condition $\nabla f = \mathbf{0}$ no longer holds, because at the best feasible point ∇f need not vanish; it only has to produce no first-order decrease along moves that stay on the constraint surface. Remarkably, what replaces $\nabla f = \mathbf{0}$ follows directly from the geometry of level sets, without any second derivatives at all.

Suppose f and g are differentiable. At a feasible point, the admissible infinitesimal moves are the directions $\mathbf{v}$ tangent to the constraint surface $\{g = c\}$. At a constrained local minimizer $\mathbf{x}^\star$, no admissible move can decrease f to first order, so $\mathbf{v} \cdot \nabla f(\mathbf{x}^\star) \geq 0$ for every tangent direction $\mathbf{v}$. Because $-\mathbf{v}$ is tangent as well, we must have equality: $\nabla f(\mathbf{x}^\star)$ is orthogonal to every tangent direction. By our level-set proposition, $\nabla g(\mathbf{x}^\star)$ is also orthogonal to every tangent direction, which forces the two gradients to align.

Proposition (Lagrange condition). *Let $\mathbf{x}^\star$ be a local minimizer of f on $\{\mathbf{x} : g(\mathbf{x}) = c\}$. Assume that f is differentiable at $\mathbf{x}^\star$, that g is continuously differentiable near $\mathbf{x}^\star$, and that $\nabla g(\mathbf{x}^\star) \neq \mathbf{0}$. Then there exists a scalar μ, called the Lagrange multiplier, such that*

$$\nabla f(\mathbf{x}^\star) = \mu \, \nabla g(\mathbf{x}^\star). \tag{34.26}$$

Proof. The proof relies on one geometric fact about the constraint set. Under the last two hypotheses, $\{g = c\}$ is a smooth surface near $\mathbf{x}^\star$, and every vector $\mathbf{v}$ satisfying $\nabla g(\mathbf{x}^\star) \cdot \mathbf{v} = 0$ is the velocity $\gamma'(0)$ of a differentiable curve γ lying in $\{g = c\}$ with $\gamma(0) = \mathbf{x}^\star$ (Rudin 1976). Along such a curve, the one-variable function $t \mapsto f(\gamma(t))$ has a local minimum at $t = 0$, so its derivative there must vanish. Just as in the level-set proof, that derivative equals $\mathbf{v} \cdot \nabla f(\mathbf{x}^\star)$. Consequently, $\nabla f(\mathbf{x}^\star)$ is orthogonal to the entire hyperplane of vectors $\mathbf{v}$ orthogonal to $\nabla g(\mathbf{x}^\star)$. The only vectors orthogonal to that hyperplane are scalar multiples of $\nabla g(\mathbf{x}^\star)$, so $\nabla f(\mathbf{x}^\star) = \mu \nabla g(\mathbf{x}^\star)$. $\blacksquare$

Geometrically, at a constrained optimum the gradients of f and g are parallel, meaning the level set of f through $\mathbf{x}^\star$ is tangent to the constraint surface. Algebraically, pairing the n equations of Equation 34.26 with the constraint $g(\mathbf{x}) = c$ gives $n + 1$ equations in the $n + 1$ unknowns $\mathbf{x}$ and μ.

As a concrete example, let us find the points on the hyperbola $xy = 1$ closest to the origin: we want to minimize $f(x, y) = x^2 + y^2$ subject to $g(x, y) = xy = 1$. The gradients are $\nabla f = (2x, 2y)$ and $\nabla g = (y, x)$, and $\nabla g \neq \mathbf{0}$ everywhere on the hyperbola. The Lagrange condition gives $2x = \mu y$ and $2y = \mu x$. Substituting the second equation into the first yields $4x = \mu^2 x$, or $x(4 - \mu^2) = 0$. Since $x = 0$ is impossible on $xy = 1$, we must have $\mu = \pm 2$. Choosing $\mu = -2$ forces $y = -x$ and hence $xy = -x^2 = 1$, which has no real solution. That leaves $\mu = 2$ and $x = y$, giving the two candidates $(1, 1)$ and $(-1, -1)$, both with $f = 2$. Because $f = x^2 + 1/x^2$ grows without bound as $x \to 0$ or $|x| \to \infty$ on each branch, a global minimum must exist, so these two points are indeed the closest ones. At $(1, 1)$, the circle $x^2 + y^2 = 2$ kisses the hyperbola tangently, and $\nabla f = (2, 2) = 2 \, \nabla g$ (Figure 34.16).

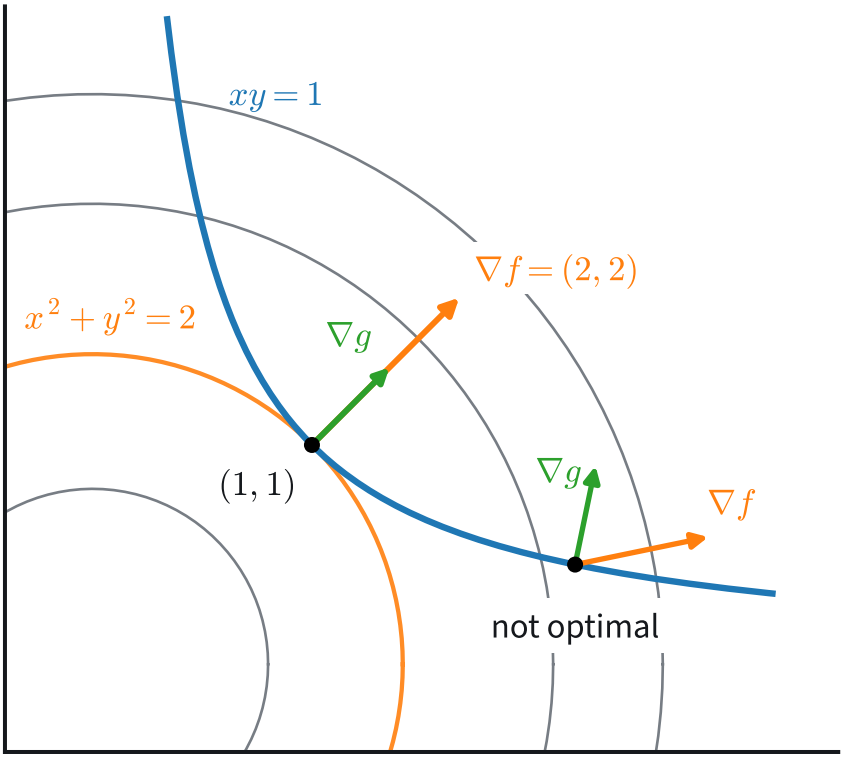

Figure 34.16: The closest point of $xy = 1$ to the origin. At $(1, 1)$ the circle $x^2 + y^2 = 2$ is tangent to the hyperbola and $\nabla f = (2, 2) = 2\nabla g$, so $\mu = 2$; the mirror solution $(-1, -1)$ is off the frame. At a feasible point that is not optimal the two gradients point in different directions, and ∇f keeps a component along the constraint.

The hyperbola makes the geometry easy to draw, but the same tool brings us straight back to our running example. Consider maximizing $\mathbf{z}\cdot\mathbf{p}-\sum_i p_i \log p_i$ over probability vectors $\mathbf{p}$ subject to $\sum_i p_i = 1$. Writing out the Lagrange condition gives $z_i - \log p_i - 1 = \mu$ for each coordinate i, which implies $p_i \propto e^{z_i}$. The optimal distribution is therefore the softmax, and the maximum value attained is the log-sum-exp (Section 35.7).

The regularity hypothesis $\nabla g(\mathbf{x}^\star) \neq \mathbf{0}$ cannot be dropped: without it, a Lagrange multiplier need not exist at all (Exercise 6 gives a clean counterexample). Later, Section 35.6 extends this condition to inequality constraints through the KKT conditions, and Section 35.7 develops the dual problem.

Every result in this section took the gradient as already known. For a two-variable formula on a blackboard, computing it by hand is effortless. For a neural network with a million weights, obtaining the gradient efficiently is the hard part.

34.2.5 Summary

A differentiable function changes, to first order, by the dot product of the step with its gradient; merely having partial derivatives does not guarantee this. Geometrically, the negative gradient points in the direction of steepest descent, and the gradient stands normal to every level set. One order higher, the symmetric Hessian defines the local quadratic approximation: at a critical point, the signs of its eigenvalues distinguish minima, maxima, and saddles, while a singular semidefinite Hessian leaves the test inconclusive. When the variables are restricted to a constraint surface $g(\mathbf{x}) = c$, the geometry of level sets replaces $\nabla f = \mathbf{0}$ with the Lagrange condition $\nabla f = \mu \nabla g$.

34.2.6 Exercises

1. **Directional derivatives without a gradient.** Let $f(x,y) = x^2 y/(x^2+y^2)$ for $(x,y) \neq (0,0)$ and $f(0,0) = 0$.
    1. Show that f is continuous at the origin.
    2. Compute the two partial derivatives of f at the origin and the directional derivative there along every unit vector $\mathbf{u} = [\cos\theta, \sin\theta]^\top$.
    3. Show that no vector $\mathbf{g}$ gives these directional derivatives as $\mathbf{u}\cdot\mathbf{g}$, so that f is not differentiable at the origin. Which hypothesis of the sufficient condition for differentiability in Section 34.2.1.2 fails? What does this function show that the counterexample $2xy/(x^2+y^2)$ there does not?
2. **Gradients of an elongated bowl.** Let $f(x,y) = x^2 + \kappa y^2$ with $\kappa \geq 1$. Its minimizer is the origin, and κ measures how much more strongly f curves along y than along x.
    1. Find a direction tangent to the level curve of f through $(1,1)$, check that it is orthogonal to $\nabla f(1,1)$, and compute the angle between $-\nabla f(1,1)$ and the direction $-[1,1]^\top$ from $(1,1)$ to the minimizer. At which points $(x,y) \neq (0,0)$ does the negative gradient point at the minimizer?
    2. Find the smallest value of the cosine of this angle over all points $(x,y) \neq (0,0)$, and the points where it is attained. (Hint: set $\rho = y/x$ and minimize over ρ.) Evaluate it for $\kappa = 10$. What does the result imply for a gradient-descent step on such a loss as κ grows?
3. **Flat directions.**

1. Give three functions of (x, y) that have a critical point at the origin with Hessian $\mathrm{diag}(2, 0)$ there: one with a strict local minimum, one with a local minimum that is not strict, and one without a local minimum.
2. The function $f(x, y) = (x - y^2)(x - 2y^2)$ also has Hessian $\mathrm{diag}(2, 0)$ at the origin. Show that its restriction to every line through the origin has a strict local minimum there. Sketch the region of the plane where $f < 0$, and show that the origin is nevertheless not a local minimum of f. What does this imply for testing a critical point by probing the loss along a few directions?
3. The *monkey saddle* $f(x, y) = x^3 - 3xy^2$ has a critical point at the origin. Compute its Hessian there, write f in polar coordinates, and find the directions along which f decreases. How does $\|\nabla f\|$ scale with the distance to the origin, compared with the saddle $x^2 - y^2$? What does this imply for gradient descent started near each of the two saddles?

4. code **Random Hessians.** ● A local minimum requires all n eigenvalues of the Hessian to be nonnegative, and a nondegenerate one requires them all positive; the section's coin-flip heuristic puts the latter at 2^{-n}. Test this heuristic on random symmetric matrices $\mathbf{A} = (\mathbf{G} + \mathbf{G}^\top)/\sqrt{2}$, where the $n \times n$ matrix $\mathbf{G}$ has independent standard normal entries.
   1. For $n = 2$, show that $s = (a_{11} + a_{22})/2$, $d = (a_{11} - a_{22})/2$, and a_{12} are independent standard normal variables, and that $\mathbf{A} \succ 0$ exactly when $s > \sqrt{d^2 + a_{12}^2}$. Use the rotational symmetry of the standard normal distribution in three dimensions to compute $P(\mathbf{A} \succ 0)$ exactly, and compare it with 2^{-2}.
   2. Estimate $P(\mathbf{A} \succ 0)$ by Monte Carlo for $n = 1, \dots, 6$, with 10^6 draws for $n \le 5$ and 10^7 draws, generated in batches, for $n = 6$. Plot $\log P$ against n together with $\log 2^{-n}$, and fit a quadratic in n to your estimates. Dean and Majumdar (2006) prove that $\log P \approx -\frac{\ln 3}{4} n^2$ for large n. Compare this coefficient with the quadratic coefficient of your fit. Does the heuristic over- or underestimate the probability of a minimum, and which property of the eigenvalues does it ignore?
   3. For large n the smallest eigenvalue of $\mathbf{A}$ lies close to $-2\sqrt{n}$. For $n = 5, 10, 20$, find the shift β at which half of the matrices $\mathbf{A} + \beta\mathbf{I}$ are positive definite, and compare it with $2\sqrt{n}$. In the random landscapes of Bray and Dean (2007), the Hessian at a critical point behaves like such a shifted matrix, with a shift that grows as the value of the random function at the critical point decreases. What does your result suggest about critical points of low loss?

5. [extended] **Saddles of a linear network.** ●● Let $\mathbf{A}$ be a symmetric $n \times n$ matrix with eigenvalues $\lambda_1 > \lambda_2 > \cdots > \lambda_n > 0$ and orthonormal eigenvectors $\mathbf{q}_1, \dots, \mathbf{q}_n$. A linear network with one hidden unit, input weights $\mathbf{v}$, and output weights $\mathbf{u}$ maps $\mathbf{x}$ to $\mathbf{u}\mathbf{v}^\top\mathbf{x}$. Trained on whitened inputs ($\mathbb{E}[\mathbf{x}\mathbf{x}^\top] = \mathbf{I}$) with targets $\mathbf{A}\mathbf{x}$, half its expected squared error is

$$\ell(\mathbf{u}, \mathbf{v}) = \tfrac{1}{2}\|\mathbf{A} - \mathbf{u}\mathbf{v}^\top\|_F^2.$$

   Baldi and Hornik (1989) showed that the local minima of such linear networks are global. This problem derives the complete set of critical points and compares it with the relation between loss and index that Dauphin et al. (2014) measured for nonlinear networks; the *index* of a critical point is the fraction of negative eigenvalues of its Hessian.

1. Compute $\nabla_{\mathbf{u}}\ell$ and $\nabla_{\mathbf{v}}\ell$. Show that the critical points are the origin and the points $\mathbf{u} = \alpha\mathbf{q}_i$, $\mathbf{v} = (\lambda_i/\alpha)\mathbf{q}_i$ with $\alpha \neq 0$, and compute ℓ at each of them.
2. Compute the eigenvalues of the $2n \times 2n$ Hessian at the balanced point $\mathbf{u} = \mathbf{v} = \sqrt{\lambda_i}\,\mathbf{q}_i$ and at the origin. (In the eigenvector basis, the Hessian splits into 2×2 blocks, one for each pair of coordinates along $\mathbf{q}_j$ in $\mathbf{u}$ and in $\mathbf{v}$.) How many eigenvalues are negative at each critical point? Explain the zero eigenvalue by a symmetry of ℓ, and conclude that every local minimum is global.
3. Take $n = 4$, $(\lambda_1, \dots, \lambda_4) = (4, 3, 2, 1)$, and a random orthonormal basis of eigenvectors. Run Newton's method from many random starting points of different scales, and record the loss and the index of every critical point it reaches. The Hessian is singular at every critical point other than the origin, so compute each Newton step by least squares. Plot the loss against the index, as in Figure 1 of Dauphin et al. (2014) . How often does Newton's method end at each kind of critical point, and where does gradient descent from small random initializations end?
4. Replace $\mathbf{u}\mathbf{v}^\top$ by $\mathbf{U}\mathbf{V}^\top$ with two hidden units, so that $\mathbf{U}$ and $\mathbf{V}$ are 4×2 matrices. Predict the loss values of the critical points from the rank-one analysis, and confirm them with Newton's method. How many zero eigenvalues does the Hessian have at the critical points, and which symmetry explains them? Is the index a monotone function of the loss?

6. **Lagrange multipliers and the Rayleigh quotient.** Let $\mathbf{A}$ be a symmetric $n \times n$ matrix. Maximize $f(\mathbf{x}) = \mathbf{x}^\top\mathbf{A}\mathbf{x}$ subject to $g(\mathbf{x}) = \|\mathbf{x}\|^2 = 1$.
   1. Write the Lagrange condition and show that it reads $\mathbf{A}\mathbf{x} = \mu\mathbf{x}$: every constrained critical point is a unit eigenvector, and its multiplier is the eigenvalue.
   2. Show that $f(\mathbf{x}) = \mu$ at every constrained critical point. Why does a constrained maximum exist? Conclude that the maximum is $\lambda_{\max}(\mathbf{A})$ and the minimum $\lambda_{\min}(\mathbf{A})$.
   3. For $\mathbf{A} = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ find the maximizers and minimizers and their values, and check at a maximizer that the level set of f through it is tangent to the unit circle.
   4. Which hypothesis of the Lagrange proposition does $g(\mathbf{x}) = \|\mathbf{x}\|^2$ satisfy at every point of the unit sphere? Now minimize the linear function $\mathbf{c}^\top\mathbf{x}$, $\mathbf{c} \neq \mathbf{0}$, subject to $\|\mathbf{x}\|^2 = 0$. What is the minimizer, and why does no multiplier μ satisfy $\nabla f = \mu\nabla g$ there?

34.3 The Chain Rule on Computational Graphs

Every training step in this book begins with a single call, `backward()` or `grad`, that returns the slope of the loss with respect to every weight in the network. In Section 34.2 we saw what those slopes mean: together they form the gradient, the vector that predicts how the loss changes under any small joint move of the parameters. What we have not yet explained is how a program computes millions of these slopes in roughly the time it takes to evaluate the network a few times. The naive approach, nudging one weight at a time and rerunning the network for each perturbation, requires a separate pass per weight and quickly becomes infeasible.

The chain rule does vastly better, and the reason is easy to see before writing down any algebra. A neural network is a deep composition of simple functions, so the derivatives with respect to its many weights share almost all of their work: every weight's influence has to travel through the later layers to reach the loss. A single nested formula hides this

shared structure, whereas a *computational graph* lays it bare: one node for each intermediate value and one directed edge for each direct dependence. Viewed on a graph, the chain rule becomes a sum over paths, and exploiting the shared work amounts to choosing how to group that sum. Grouping the paths from the output backward yields the derivative with respect to every input in a single pass. That grouping is backpropagation.

To make every step concrete and easy to verify by hand, we work on small graphs of scalar variables with integer values throughout. The entire development rests on one fact from Section 34.2: near any point where a function is differentiable, its change is approximated by the dot product of the step with its gradient, the linear model of Section 34.2.1.2. Extending the idea to layers that map vectors to vectors, and measuring its computational cost on real networks, comes in the two sections that follow.

34.3.1 The Chain Rule as a Sum over Paths

34.3.1.1 A Graph of Scalars

Let us start with a concrete example small enough to trace completely by hand. Four scalar inputs w, x, y, z feed through two layers of intermediate variables to produce a single scalar output:

$$\begin{aligned} f(u,v) &= (u+v)^2, \\ u(a,b) &= (a+b)^2, \qquad v(a,b) = (a-b)^2, \\ a(w,x,y,z) &= (w+x+y+z)^2, \qquad b(w,x,y,z) = (w+x-y-z)^2. \end{aligned} \tag{34.27}$$

These equations define a directed acyclic graph (Figure 34.17), where each node holds an intermediate value and each arrow indicates a direct functional dependence. There is nothing special about the squaring operations; we choose them simply because they keep all intermediate values and derivatives exact integers. Throughout this section, f denotes the scalar output of the graph under study.

34.3.1.2 Two Paths through One Step

Before tackling the whole graph, consider just its final composite step, $f(u(a,b), v(a,b))$, and ask how f responds when we nudge a by a small amount ϵ. Both intermediate nodes feel the perturbation according to their partial derivatives: u shifts to $u+\epsilon\frac{\partial u}{\partial a}$, and v shifts to $v+\epsilon\frac{\partial v}{\partial a}$. Substituting both shifts into the first-order linear approximation (Section 34.2.1.2) of f yields

$$f\big(u+\epsilon\tfrac{\partial u}{\partial a},\, v+\epsilon\tfrac{\partial v}{\partial a}\big) \approx f(u,v) + \epsilon\left[\frac{\partial f}{\partial u}\frac{\partial u}{\partial a} + \frac{\partial f}{\partial v}\frac{\partial v}{\partial a}\right].$$

Reading off the coefficient of ϵ gives the derivative of the composite function with respect to a, which is the multivariable chain rule:

$$\frac{\mathrm{d}f}{\mathrm{d}a} = \frac{\partial f}{\partial u}\frac{\partial u}{\partial a} + \frac{\partial f}{\partial v}\frac{\partial v}{\partial a}.$$

Notice the two different symbols for differentiation; we will keep them strictly separate from here on. The curly ∂ denotes the derivative of a single node's defining function with respect

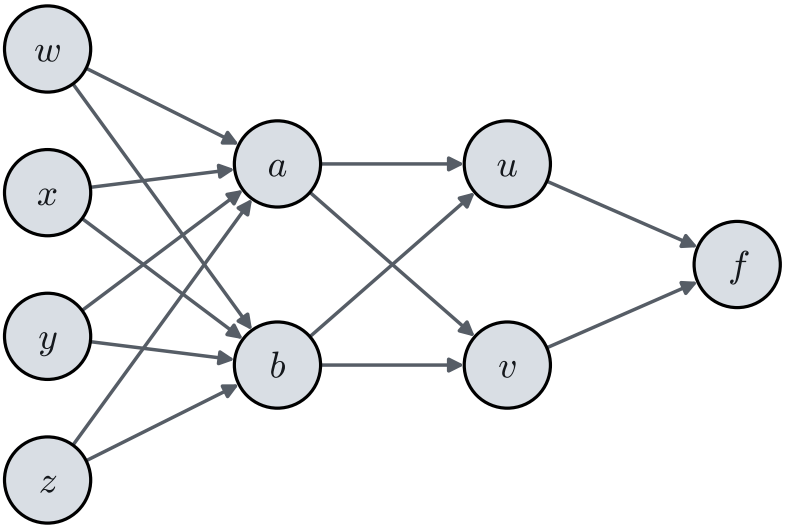

Figure 34.17: The dependency graph of Equation 34.27: each node represents a variable and each directed edge represents a direct functional dependence.

to one of its direct arguments, holding its other arguments fixed. The upright d denotes the *total* derivative $\mathrm{d}f/\mathrm{d}a$, which allows every variable downstream of a to respond. (For an input node, the total derivative coincides with the ordinary partial derivative of f viewed as a function of the inputs alone.) Geometrically, there are two directed *paths* by which a influences f, namely $a \to u \to f$ and $a \to v \to f$. Each path contributes the product of the derivatives along its edges, and the total derivative sums those contributions across all paths.

This derivation mirrors the one-variable proof of the chain rule (Section 34.1.2): we feed the linear change of the inner functions into the linear model of the outer one. Because two variables move simultaneously, however, f must be *differentiable* at (u, v), not merely possess partial derivatives. Recall the counterexample $2xy/(x^2+y^2)$ from Section 34.2.1.2: along the diagonal $x = y = t$, both partial derivatives vanish at the origin, so the chain rule would predict a derivative of 0 at $t = 0$, yet the function jumps discontinuously from 0 to 1 there.

34.3.1.3 Edge Derivatives and Total Derivatives

The same reasoning extends by induction to any directed acyclic graph. Define the *edge derivative* of a node with respect to one of its parents as the partial derivative of that node's function with respect to that parent, with all other parents held fixed. Then the total derivative of an output f with respect to an input x is

$$\frac{\mathrm{d}f}{\mathrm{d}x} = \sum_{\text{directed paths } x \to \cdots \to f} \; \prod_{\text{edges on the path}} (\text{edge derivative}). \tag{34.28}$$

In words, each directed path from x to f multiplies the local rates of change along its edges, and the total derivative adds those path products together.

A graph with a skip connection makes it clear why edge derivatives and total derivatives must never be confused. Consider the five-node system

$$\begin{aligned} p(x,y) &= x+y, \qquad q(x,y) = x-y, \\ r(p) &= p^2, \qquad s(q) = q^2, \\ f(r,p,s) &= r+p+s. \end{aligned} \tag{34.29}$$

Here f depends on r and s, and also directly on p through a skip edge (Figure 34.18). Consequently, the input y reaches f along three distinct paths: $y \to p \to r \to f$, the shortcut $y \to p \to f$, and $y \to q \to s \to f$. The local edge derivatives are $\partial f/\partial r = \partial f/\partial p = \partial f/\partial s = 1$, $\partial r/\partial p = 2p$, $\partial s/\partial q = 2q$, $\partial p/\partial y = 1$, and $\partial q/\partial y = -1$. Summing the three path products gives

$$\begin{aligned} \frac{\mathrm{d}f}{\mathrm{d}y} &= \underbrace{1 \cdot 2p \cdot 1}_{y\to p\to r\to f} + \underbrace{1 \cdot 1}_{y\to p\to f} + \underbrace{1 \cdot 2q \cdot (-1)}_{y\to q\to s\to f} \\ &= 2p + 1 - 2q = 1 + 4y. \end{aligned}$$

We can check this directly by substituting everything into f: $f = (x+y)^2 + (x+y) + (x-y)^2$, whose derivative with respect to y is indeed $1 + 4y$. At $(x, y) = (1, 2)$, we have $p = 3$ and $q = -1$, so the three paths contribute $6 + 1 + 2 = 9 = 1 + 4 \cdot 2$. Notice the sharp distinction at node p: the *edge* derivative $\partial f/\partial p$ is just 1 (holding r fixed), whereas the *total* derivative $\mathrm{d}f/\mathrm{d}p$ accounts for both the skip edge and the indirect route through r, giving $2p + 1 = 7$. Confusing these two quantities is the single most common mistake when applying the multivariable chain rule.

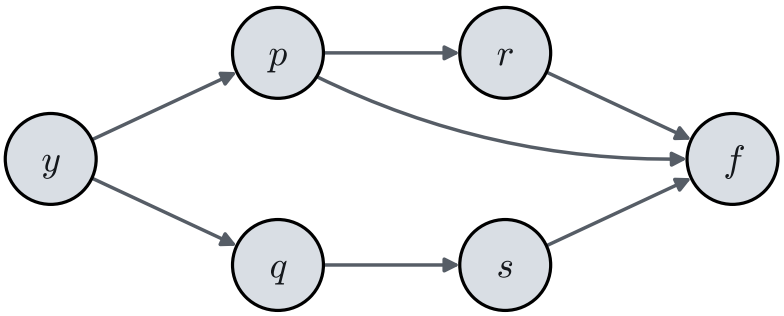

Figure 34.18: The dependency graph of Equation 34.29: the input y reaches f by three paths, namely $y \to p \to r \to f$, the skip edge $y \to p \to f$, and $y \to q \to s \to f$.

This path-sum viewpoint also explains how gradients travel through deep architectures. Mechanisms that open or close paths, such as the gates in an LSTM (Section 12.1) or the

skip connections in a residual network (Section 7.4), shape learning directly by controlling which paths carry gradient signal back to earlier layers.

34.3.2 Backpropagation

As a mathematical identity, the sum over paths Equation 34.28 is completely general: it gives every derivative of every computational graph. As a literal algorithm, however, it is hopeless, because the number of paths can grow exponentially with depth. Even a simple chain of m stages with two parallel nodes per stage already contains 2^m paths from start to finish. Fortunately, those paths overlap heavily, and any sub-product shared by many paths needs to be computed only once. The order in which we factor out those shared sub-products determines the computational cost.

34.3.2.1 Forward Mode

Let us compare two ways of factoring the sum on our four-input function Equation 34.27 at the point $(w, x, y, z) = (1, 1, -2, 1)$. A *forward pass* evaluates the nodes in topological order: $a = 1^2 = 1$, $b = 3^2 = 9$, $u = 10^2 = 100$, $v = (-8)^2 = 64$, and $f = 164^2 = 26896$. From these node values we read off all the local edge derivatives:

$$\begin{aligned}
\frac{\partial f}{\partial u} &= \frac{\partial f}{\partial v} = 2(u+v) = 328, \\
\frac{\partial u}{\partial a} &= \frac{\partial u}{\partial b} = 2(a+b) = 20, \\
\frac{\partial v}{\partial a} &= 2(a-b) = -16, \qquad \frac{\partial v}{\partial b} = -2(a-b) = 16, \\
\frac{\partial a}{\partial w} &= \frac{\partial a}{\partial x} = \frac{\partial a}{\partial y} = \frac{\partial a}{\partial z} = 2(w+x+y+z) = 2, \\
\frac{\partial b}{\partial w} &= \frac{\partial b}{\partial x} = 2(w+x-y-z) = 6, \qquad \frac{\partial b}{\partial y} = \frac{\partial b}{\partial z} = -6.
\end{aligned}$$

Each edge derivative is a local number computed solely from a node and its immediate parents.

To find $\mathrm{d}f/\mathrm{d}w$, notice that all four paths from w to f pass first through a or b and then through u or v. Factoring the paths from the input w forward through the graph gives

$$\begin{aligned}
\frac{\mathrm{d}f}{\mathrm{d}w} &= \frac{\partial f}{\partial u}\Big(\frac{\partial u}{\partial a}\frac{\partial a}{\partial w} + \frac{\partial u}{\partial b}\frac{\partial b}{\partial w}\Big) + \frac{\partial f}{\partial v}\Big(\frac{\partial v}{\partial a}\frac{\partial a}{\partial w} + \frac{\partial v}{\partial b}\frac{\partial b}{\partial w}\Big) \\
&= 328\,(20 \cdot 2 + 20 \cdot 6) + 328\,(-16 \cdot 2 + 16 \cdot 6) \\
&= 328 \cdot 224 = 73472.
\end{aligned}$$

The two parenthesized sums are simply $\mathrm{d}u/\mathrm{d}w = 160$ and $\mathrm{d}v/\mathrm{d}w = 64$, the total derivatives of the intermediate nodes with respect to w. Propagating the sensitivity to one input forward through the graph in this way is called *forward mode*. We can verify this calculation in plain Python:

```
w, x, y, z = 1, 1, -2, 1
# Forward pass: node values
a, b = (w + x + y + z)**2, (w + x - y - z)**2
u, v = (a + b)**2, (a - b)**2
f = (u + v)**2
print('a, b, u, v, f =', a, b, u, v, f)

# Edge derivatives
df_du, df_dv = 2*(u + v), 2*(u + v)
du_da, du_db, dv_da, dv_db = 2*(a + b), 2*(a + b), 2*(a - b), -2*(a - b)
da_dw, db_dw = 2*(w + x + y + z), 2*(w + x - y - z)

# Forward mode: push the dependence on w through the graph
du_dw, dv_dw = du_da*da_dw + du_db*db_dw, dv_da*da_dw + dv_db*db_dw
df_dw = df_du*du_dw + df_dv*dv_dw
print('df/dw =', df_dw)
```

```
a, b, u, v, f = 1 9 100 64 26896
df/dw = 73472
```

Forward mode returns $\mathrm{d}f/\mathrm{d}w = 73472$, but none of its intermediate derivatives can be reused for x, y, or z: both $\mathrm{d}u/\mathrm{d}w$ and $\mathrm{d}v/\mathrm{d}w$ are tied to w alone. Because training a neural network requires the derivative of a single scalar loss with respect to every parameter, computing them one input at a time leaves most of the shared structure unused.

34.3.2.2 Adjoints and the Backward Pass

The remedy is to reverse the perspective: keep the output fixed rather than the input. Forward mode fixed one input and asked how every downstream node responds to it. Now we fix the single output f and ask how it responds to every upstream node. Define the *adjoint* $\bar{n}$ of a node n as the total derivative $\mathrm{d}f/\mathrm{d}n$ of the output with respect to n: the sum of the edge-derivative products over all directed paths from n to f. Every such path must leave n through one of its immediate children c, and the remaining paths from c to f sum to $\bar{c}$. Grouping the path sum Equation 34.28 by this first edge turns it into a simple recursion:

$$\bar{f} = 1, \qquad \bar{n} = \sum_{\text{children } c \text{ of } n} \bar{c}\,\frac{\partial c}{\partial n}. \tag{34.30}$$

Only local edge derivatives and the adjoints of downstream nodes appear on the right-hand side. Starting from $\bar{f} = 1$ and visiting the nodes in reverse topological order, every child's adjoint is already known by the time we need it. On the skip-edge graph Equation 34.29, for instance, the recursion gives $\bar{r} = 1$ and $\bar{p} = \bar{r} \cdot 2p + \bar{f} \cdot 1 = 7$, matching the total derivative we found earlier. Applying the same sweep to our four-input graph gives:

- $\bar{u} = \bar{v} = 328$;
- $\bar{a} = \bar{u} \cdot 20 + \bar{v} \cdot (-16) = 1312$ and $\bar{b} = \bar{u} \cdot 20 + \bar{v} \cdot 16 = 11808$;
- $\bar{w} = \bar{x} = \bar{a} \cdot 2 + \bar{b} \cdot 6 = 73472$ and $\bar{y} = \bar{z} = \bar{a} \cdot 2 - \bar{b} \cdot 6 = -68224$.

A single *backward pass* thus produces the partial derivatives with respect to all four inputs at once (Figure 34.19). Let us run this backward sweep in Python, reusing the edge derivatives from the previous cell.

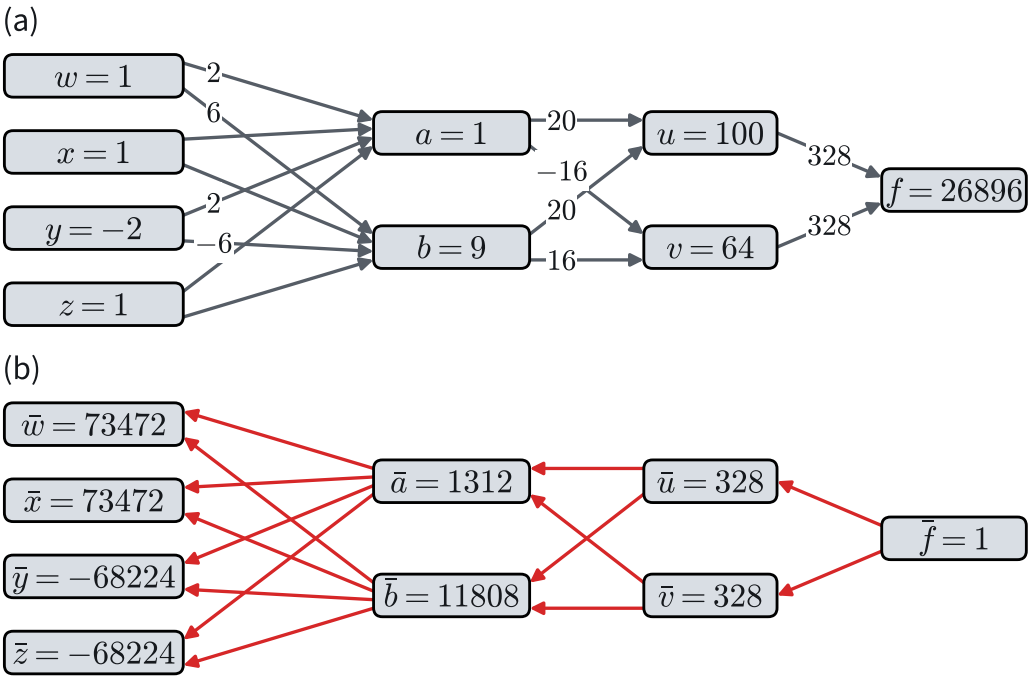

Figure 34.19: (a) The forward pass records every node value and local edge derivative. (b) The backward pass accumulates adjoints starting from $\bar{f} = 1$, giving $\bar{a} = 328 \cdot 20 + 328 \cdot (-16) = 1312$ and $\bar{w} = 1312 \cdot 2 + 11808 \cdot 6 = 73472$.

```
da_dy, db_dy = 2*(w + x + y + z), -2*(w + x - y - z)  # also for x, z
# Backward pass: adjoints from the output toward the inputs
u_bar, v_bar = df_du, df_dv
a_bar = u_bar*du_da + v_bar*dv_da
b_bar = u_bar*du_db + v_bar*dv_db
print(f'adjoints: u {u_bar}, v {v_bar}, a {a_bar}, b {b_bar}')
w_bar = a_bar*da_dw + b_bar*db_dw  # x enters a, b like w
y_bar = a_bar*da_dy + b_bar*db_dy  # z enters a, b like y
print('gradient:', {'w': w_bar, 'x': w_bar, 'y': y_bar, 'z': y_bar})
```

```
adjoints: u 328, v 328, a 1312, b 11808
gradient: {'w': 73472, 'x': 73472, 'y': -68224, 'z': -68224}
```

The derivatives with respect to w and x match, as do those with respect to y and z, because f depends on its inputs only through the combinations $w + x$ and $y + z$.

A quick operation count makes the advantage concrete. Forward mode needs six multiplications per input (two each for $\mathrm{d}u/\mathrm{d}w$, $\mathrm{d}v/\mathrm{d}w$, and $\mathrm{d}f/\mathrm{d}w$), or 24 in total for all four inputs. The backward pass needs four multiplications to compute $\bar{a}$ and $\bar{b}$ and then two per input, or 12 in total, because it traverses the shared upper part of the graph only once. A factor of two on a toy graph is modest, but the gap widens rapidly with the number of inputs: every additional input costs forward mode an entire pass through the graph, whereas the backward pass needs only two more multiplications.

34.3.2.3 Backpropagation in a Framework

Computing derivatives by propagating adjoints from the output back to the inputs is *backpropagation* (Rumelhart et al. 1986), which Section 4.3 applies to multilayer perceptrons. Every modern automatic differentiation engine executes the same two passes: it records intermediate values (or the operations needed to form edge derivatives) during the forward pass, and then accumulates adjoints during the backward pass. Let us check our hand computation against the framework's automatic differentiation on the same four inputs.

```
wxyz = tf.Variable([1., 1., -2., 1.])
with tf.GradientTape() as t:
    w, x, y, z = tf.unstack(wxyz)
    a, b = (w + x + y + z)**2, (w + x - y - z)**2
    u, v = (a + b)**2, (a - b)**2
    f = (u + v)**2
print(t.gradient(f, wxyz).numpy())  # one backward pass
```

```
[ 73472.  73472. -68224. -68224.]
```

The framework returns $(73472, 73472, -68224, -68224)$, matching the adjoints from our hand calculation. The agreement is exact rather than approximate because every intermediate number is an integer below 2^{24}, which single precision represents without rounding error.

So far every node in our graphs has been a scalar, and we could count multiplications on the back of an envelope. In a real neural network, each layer maps a vector to a vector, so the edge derivatives become matrices and the order in which those matrices are multiplied matters far more than the order of scalar multiplications. We take that step in Section 34.4.

34.3.3 Summary

On a computational graph, the total derivative of an output with respect to an input equals the sum, over all directed paths between them, of the products of the local edge derivatives. The adjoint of a node, the total derivative of the output with respect to that node, collects every path leaving it. Factoring those paths by their first outgoing edge yields a recursion that, run backward from the output, computes every adjoint in a single pass. This reverse accumulation is backpropagation. Propagating one input forward instead computes only that input's derivative, which is why differentiating a scalar loss with respect to many parameters is always done backward.

34.3.4 Exercises

1. code **Backward pass for two tanh units.** A network with one input x, two hidden units, and one output computes, for a target t,

$$h_i = \tanh(w_i x + b_i) \quad (i = 1, 2), \qquad f = v_1 h_1 + v_2 h_2, \qquad \ell = \tfrac{1}{2}(f - t)^2.$$

   1. Draw the dependency graph of ℓ. In plain Python, write a forward pass that stores every intermediate value and a backward pass that returns the partial derivatives of ℓ with respect to all six parameters $w_1, b_1, w_2, b_2, v_1, v_2$. Check them against automatic differentiation at $x = 1.5$, $t = 0.5$, and $(w_1, b_1, w_2, b_2, v_1, v_2) = (0.5, 0, -1, 0.2, 1, -0.5)$. Which intermediate derivative does every one of the six partials reuse?
   2. Set $w_1 = 5$ and $x = 2$, keeping the other values. Compute $\partial \ell / \partial w_1$ with the plain-Python backward pass and explain its size from the product of edge derivatives along its path. Compare it with the value that automatic differentiation returns in single precision, and explain the difference. What does this imply for training a unit whose pre-activation is large?
   3. Set $w_1 = w_2$, $b_1 = b_2$, and $v_1 = v_2$. Show from the backward pass that both units receive identical gradients, so that gradient descent keeps them identical at every step. What does this imply for the initialization of hidden units?

2. **Paths through a residual stack.** ● In a one-dimensional model of the residual networks of Section 7.4, scalar blocks compute $x_{l+1} = x_l + g_l(x_l)$ for $l = 0, \dots, m-1$ with differentiable functions g_l.

   1. Use the chain rule to write $\partial x_m / \partial x_0$ as a product of m factors.
   2. Expand the product and match each term to a directed path from x_0 to x_m in the dependency graph. How many paths are there, and how many of them pass through exactly k of the functions g_l? Compare the number of paths with the number of multiplications that a backward pass needs to compute $\partial x_m / \partial x_0$.
   3. For a trained network of $m = 54$ residual blocks, Veit et al. (2016) found that almost all of the gradient flows along the paths through 5 to 17 blocks. What fraction of all paths are these? Now assume that $g_l'(x_l) = c > 0$ for every block. Which value of c makes the paths through about 11 blocks contribute the most to $\partial x_m / \partial x_0$, and what share of the derivative do the paths through 5 to 17 blocks then carry?

3. code **Gradient checks in single precision.** ● A gradient check compares a backward pass with the central difference $(f(w + h, x, y, z) - f(w - h, x, y, z))/(2h)$. Let

f be the function of Equation 34.27, whose exact partial derivative at $(w, x, y, z) = (1, 1, -2, 1)$ is $\partial f/\partial w = 73472$.

1. Implement f in NumPy and compute the central difference at this point for $h = 10^{-1}, 10^{-2}, \dots, 10^{-12}$, once in `float64` and once in `float32`. Plot the relative error against h on log-log axes for both precisions, and read off the best h and the smallest relative error of each.
2. The error of the central difference is a truncation part of order h^2 plus a rounding part of order $\varepsilon_{\text{mach}}|f|/h$, where the machine epsilon $\varepsilon_{\text{mach}}$ is about 2.2×10^{-16} for `float64` and 1.2×10^{-7} for `float32`. By which factors should the best h and the smallest relative error change from `float64` to `float32`? Compare the predicted factors with the plot.
3. Which tolerance on the relative error can a `float32` gradient check use without rejecting a correct backward pass? Why are gradient checks run in double precision?
4. Why does the `float32` estimate become exactly zero for the smallest values of h?

34.4 Matrix Calculus

In the last two sections we treated a loss as a function of scalar variables. In Section 34.2 we assembled its gradient as a column of partial derivatives, and in Section 34.3 we computed that column by a backward pass through a graph with one number per node. A neural network, however, is not written in scalars: each layer maps a vector to a vector, and its weights form a matrix. What is the derivative of a loss with respect to a vector or a matrix, and how do we compute it for a whole layer at once?

A network small enough to work by hand shows what is needed. Consider a network with two inputs, two ReLU hidden units, and one output,

$$g(\mathbf{x}) = \mathbf{w}_2^{\top} \varphi(\mathbf{W}_1 \mathbf{x} + \mathbf{b}), \qquad \mathbf{W}_1 = \begin{pmatrix} 1 & 2 \\ 3 & -1 \end{pmatrix}, \quad \mathbf{b} = \begin{pmatrix} 0 \\ -4 \end{pmatrix}, \quad \mathbf{w}_2 = \begin{pmatrix} 2 \\ -1 \end{pmatrix},$$

where φ applies $\max(0, \cdot)$ to each entry. At $\mathbf{x} = (1, 1)$ the pre-activations are $\mathbf{W}_1\mathbf{x} + \mathbf{b} = (3, -2)$, so the second hidden unit is off, the hidden vector is $(3, 0)$, and the output is $g = 6$. A training step raises three questions about this output. First, if the input moves by a small δ, the output changes by $2\delta_1 + 4\delta_2$, a row of two numbers that is the transpose of the column gradient. Second, if the weight matrix moves by $\Delta\mathbf{W}_1$, the output changes by $2\,\Delta W_{11} + 2\,\Delta W_{12}$ and not at all through the second row, so the derivative with respect to a matrix is itself a matrix, $\left(\begin{smallmatrix} 2 & 2 \\ 0 & 0 \end{smallmatrix}\right)$. Third, the hidden layer $\mathbf{x} \mapsto \varphi(\mathbf{W}_1\mathbf{x} + \mathbf{b})$ maps a vector to a vector. Neither a scalar slope nor a gradient vector describes its derivative, yet the output depends on $\mathbf{W}_1$ only through that layer.

Derivatives like these are surprisingly easy to get wrong by hand. If you drop a transpose on a square weight matrix, the dimensions still match, no error is raised, and training simply goes astray. Reference tables of matrix derivatives run to hundreds of entries, yet looking up formulas does little to protect against that kind of slip.

This section answers all three questions with a single object and a single principle. The derivative of a vector-valued map is a matrix, the *Jacobian*, defined as the map's best linear approximation. Composing maps multiplies their Jacobians, so the derivative of a network becomes a product of matrices, one per layer. Every gradient a layer needs (linear

and quadratic forms, least squares, matrix products, and softmax) then follows from one method: write down the first-order change of the function and read off the gradient as its coefficient. That same method produces the backward pass of each layer used in Section 4.3, as well as $\mathbf{p} - \mathbf{y}$, the classifier gradient of Section 3.1.2.2.

Three results are worth remembering: the product of Jacobians Equation 34.36, the rule that a gradient always has the shape of its variable, and the backward rule Equation 34.39 for a matrix product. You can skip the proof of the chain rule on a first reading, but not the differential method (Section 34.4.3.1), since everything that follows relies on it.

We use the following imports throughout this section.

```
import numpy as np
import tensorflow as tf
```

34.4.1 The Jacobian

34.4.1.1 The Best Linear Approximation

Near $\mathbf{x} = (1, 1)$ the hidden layer of our network is affine, so its linear approximation is exact there and leaves no error to study. Let us therefore begin with a curved map that we will reuse as a running example here and in the next section, returning to the network once the definition is in place:

$$\mathbf{f}(x, y) = \begin{pmatrix} x + \sin y \\ y + x^2/2 \end{pmatrix}, \qquad \mathbf{x}_0 = (0.5,\ 0.5).$$

At $\mathbf{x}_0$, the map evaluates to $\mathbf{f}(\mathbf{x}_0) = (0.9794,\ 0.6250)$. Each of the two outputs has two partial derivatives: $\partial f_1/\partial x = 1$, $\partial f_1/\partial y = \cos y = 0.8776$, $\partial f_2/\partial x = x = 0.5$, and $\partial f_2/\partial y = 1$. We arrange these four numbers in a matrix with one row per output and one column per input,

$$\mathbf{J}(\mathbf{x}_0) = \begin{pmatrix} 1 & \cos 0.5 \\ 0.5 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0.8776 \\ 0.5 & 1 \end{pmatrix}.$$

Column j records how both outputs respond when input j moves. This matrix is the derivative of $\mathbf{f}$ at $\mathbf{x}_0$, in the sense that $\mathbf{f}(\mathbf{x}_0 + \delta) \approx \mathbf{f}(\mathbf{x}_0) + \mathbf{J}\delta$ for small δ, and no other matrix approximates $\mathbf{f}$ as closely.

In one variable, the derivative is the slope of the best straight-line fit, $f(x + \delta) \approx f(x) + f'(x)\,\delta$. The vector-valued generalization rests on the same local approximation. We say that $\mathbf{f} : \mathbb{R}^n \to \mathbb{R}^m$ is *differentiable* at $\mathbf{x}$ if there is a matrix $\mathbf{J} \in \mathbb{R}^{m \times n}$ such that

$$\mathbf{f}(\mathbf{x} + \delta) = \mathbf{f}(\mathbf{x}) + \mathbf{J}\,\delta + o(\|\delta\|), \tag{34.31}$$

meaning that the error of the linear model $\mathbf{f}(\mathbf{x}) + \mathbf{J}\delta$ divided by $\|\delta\|$ tends to zero as $\delta \to \mathbf{0}$. Whenever such a matrix exists, it is unique. We call it the *Jacobian* $\mathbf{J}_\mathbf{f}(\mathbf{x})$, and its entries are simply the partial derivatives:

$$[\mathbf{J}_{\mathbf{f}}]_{ij} = \frac{\partial f_i}{\partial x_j}. \tag{34.32}$$

To see why, substitute the perturbation $\delta = t\,\mathbf{e}_j$ (a small step along coordinate axis j) into Equation 34.31 and look at component i. Dividing by t and letting $t \to 0$ leaves $\partial f_i/\partial x_j$ in the (i, j) slot, regardless of which matrix $\mathbf{J}$ we started with. The partial derivatives therefore supply the entries of $\mathbf{J}$, while the linear approximation is what defines it.

The existence of partial derivatives alone does not guarantee differentiability. Consider the function $f(x, y) = 2xy/(x^2 + y^2)$ with $f(0, 0) = 0$ from Section 34.2.1.2: both partials are 0 at the origin, yet f equals 1 everywhere along the diagonal $x = y$. The only candidate Jacobian is the zero row vector, whose approximation error along the diagonal remains 1 no matter how small δ is, so f has no Jacobian at the origin. Continuity of the partial derivatives is sufficient to rule out such behavior: if every partial $\partial f_i/\partial x_j$ exists in a neighborhood of $\mathbf{x}$ and is continuous at $\mathbf{x}$, then $\mathbf{f}$ is differentiable at $\mathbf{x}$ (Rudin 1976).

Figure 34.20 illustrates the definition geometrically: near $\mathbf{x}_0$, the map acts like its Jacobian. A circle of radius r around $\mathbf{x}_0$ maps nearly onto the ellipse $\mathbf{f}(\mathbf{x}_0) + \mathbf{J}\delta$ ($\|\delta\| = r$), whose semi-axes are r times the singular values of $\mathbf{J}$ (as shown in Section 33.5, any matrix maps the unit circle to an ellipse with these semi-axes). Here the singular values are 1.706 and 0.329, so the circle of radius 0.35 becomes an ellipse with semi-axes 0.60 and 0.12. The largest gap between the true image and the ellipse is 0.061 at $r = 0.35$ and 0.015 at $r = 0.175$: halving the radius cuts the gap fourfold.

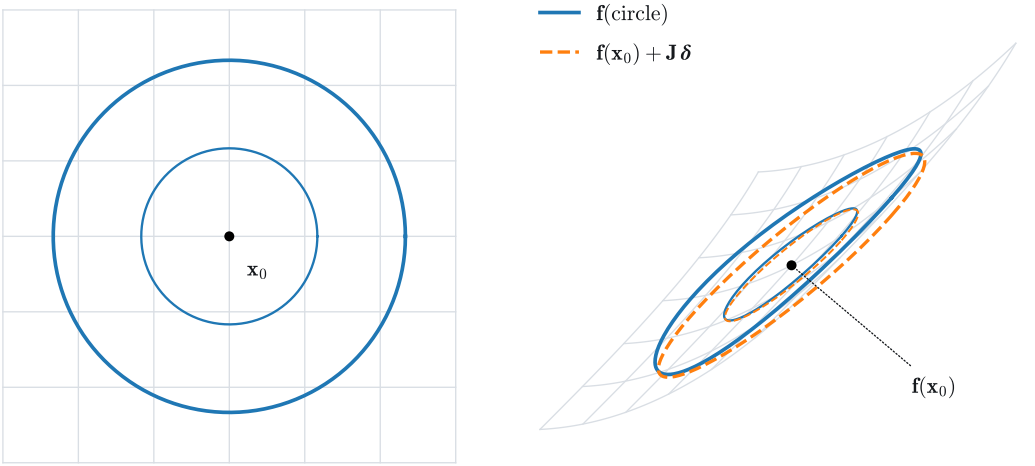

Figure 34.20: A differentiable map is locally its Jacobian. Two circles of radius 0.35 and 0.175 around $\mathbf{x}_0 = (0.5, 0.5)$ (left) and their images under $\mathbf{f}(x, y) = (x + \sin y,\ y + x^2/2)$ (right, blue) against the ellipses $\mathbf{f}(\mathbf{x}_0) + \mathbf{J}(\mathbf{x}_0)\delta$ (orange, dashed). The semi-axes of each ellipse are the radius times the singular values 1.71 and 0.33 of $\mathbf{J}$. Halving the radius cuts the largest gap between image and ellipse from 0.061 to 0.015, the $o(\|\delta\|)$ remainder.

The definition guarantees that the error of the linear model divided by $\|\delta\|$ tends to zero, but it does not say how fast. Let us shrink a perturbation tenfold at a time and inspect that ratio.

```
def f(v):                                   # the running map, R^2 -> R^2
    x, y = v
    return np.array([x + np.sin(y), y + x**2 / 2])

def J(v):                                   # its Jacobian, entry by entry
    x, y = v
    return np.array([[1.0, np.cos(y)], [x, 1.0]])

x0 = np.array([0.5, 0.5])
for s in [1, 0.1, 0.01, 0.001]:
    delta = s * np.array([0.2, 0.1])
    err = np.linalg.norm(f(x0 + delta) - f(x0) - J(x0) @ delta)
    print(f'|delta| = {np.linalg.norm(delta):.1e}   '
          f'error / |delta| = {err / np.linalg.norm(delta):.1e}')
```

```
|delta| = 2.2e-01   error / |delta| = 9.0e-02
|delta| = 2.2e-02   error / |delta| = 9.0e-03
|delta| = 2.2e-03   error / |delta| = 9.0e-04
|delta| = 2.2e-04   error / |delta| = 9.0e-05
```

The ratio drops from 0.09 to 0.009, 0.0009, and 0.00009. It tends to zero, confirming the $o(\|\delta\|)$ remainder in the definition. Notice that it also falls tenfold for every tenfold reduction in $\|\delta\|$, which means the error itself falls a hundredfold and is $O(\|\delta\|^2)$. The definition promises only the first property; the faster quadratic decay holds because $\mathbf{f}$ has continuous second derivatives.

34.4.1.2 Gradients, Hessians, and the Shape of a Derivative

Both the gradient and the Hessian from Section 34.2 are special cases of the Jacobian. Viewing them this way settles a shape question that arises in every hand derivation: whether a derivative is a row or a column, and how a derivative with respect to a matrix should be arranged.

For a scalar-valued function $f : \mathbb{R}^n \to \mathbb{R}$ ($m = 1$), the Jacobian is a single row, $\partial f/\partial \mathbf{x} = [\partial f/\partial x_1, \dots, \partial f/\partial x_n]$, and Equation 34.31 becomes the first-order expansion $f(\mathbf{x} + \delta) \approx f(\mathbf{x}) + (\partial f/\partial \mathbf{x})\,\delta$. In Section 34.2 we wrote the gradient as a column vector. The two are simply transposes of each other,

$$\nabla_{\mathbf{x}} f = \left(\frac{\partial f}{\partial \mathbf{x}}\right)^{\top}, \tag{34.33}$$

and we use both in this book, each for its own purpose. Jacobians of vector-valued maps are $m \times n$, with one row per output, so that the chain rule below composes cleanly without transposes. Gradients of scalars are column vectors, $\nabla_{\mathbf{x}} f$, matching the shape of $\mathbf{x}$ so an optimizer can subtract them directly. For our opening network, $\partial g/\partial \mathbf{x} = (2,\ 4)$ is a 1×2 Jacobian, while $\nabla_{\mathbf{x}} g = (2, 4)^{\top}$ is the column gradient.

A scalar function of a matrix $\mathbf{W} \in \mathbb{R}^{p \times q}$ needs one more convention. We define its gradient $\nabla_{\mathbf{W}} f$ as the $p \times q$ matrix with entries $\partial f/\partial W_{ij}$, matching the shape of $\mathbf{W}$. The first-order expansion then reads

$$f(\mathbf{W}+\mathbf{E}) = f(\mathbf{W}) + \langle \nabla_{\mathbf{W}} f,\ \mathbf{E}\rangle + o(\|\mathbf{E}\|), \qquad \langle \mathbf{A}, \mathbf{B}\rangle = \operatorname{tr}(\mathbf{A}^{\top}\mathbf{B}) = \sum_{ij} A_{ij}B_{ij}, \quad (34.34)$$

where the inner product $\langle \cdot, \cdot \rangle$ multiplies two matrices of the same shape entry by entry and sums the products, just like the ordinary dot product of the matrices flattened into vectors. In words, the first-order change in f is the sum over all entries of "sensitivity times nudge". In our opening example, $\nabla_{\mathbf{W}_1} g$ is the 2×2 matrix $\left(\begin{smallmatrix} 2 & 2 \\ 0 & 0 \end{smallmatrix}\right)$, and $\langle \nabla_{\mathbf{W}_1} g, \Delta\mathbf{W}_1 \rangle = 2\,\Delta W_{11} + 2\,\Delta W_{12}$ recovers the change we found earlier. This gives a single sanity check for every formula in the section: a gradient always has the shape of its variable. If a derived gradient does not, a transpose is missing.

Differentiating once more brings in the Hessian. The gradient field $\nabla f : \mathbb{R}^n \to \mathbb{R}^n$ is itself a vector-valued map, and its Jacobian is the matrix of second partials, the Hessian $\mathbf{H}_f$, whose entries are $[\mathbf{H}_f]_{ij} = \partial^2 f / \partial x_i \partial x_j$. Strictly speaking, $[\mathbf{J}_{\nabla f}]_{ij} = \partial^2 f / \partial x_j \partial x_i$ takes the two derivatives in the opposite order, but the two agree, and $\mathbf{H}_f$ is symmetric, whenever the mixed partials are continuous (the Clairaut–Schwarz theorem of Section 34.2).

34.4.2 The Chain Rule for Jacobians

A neural network is a composition of layers. On a graph of scalars, the chain rule summed the product of derivatives over every path from an input to an output (Section 34.3.1). When the layers are vector-valued maps, that sum over paths becomes a matrix product.

34.4.2.1 Composition as a Matrix Product

Proposition (chain rule). *If $\mathbf{f} : \mathbb{R}^n \to \mathbb{R}^p$ is differentiable at $\mathbf{x}$ and $\mathbf{g} : \mathbb{R}^p \to \mathbb{R}^m$ is differentiable at $\mathbf{f}(\mathbf{x})$, then $\mathbf{g} \circ \mathbf{f}$ is differentiable at $\mathbf{x}$ and*

$$\mathbf{J}_{\mathbf{g}\circ\mathbf{f}}(\mathbf{x}) = \mathbf{J}_{\mathbf{g}}\big(\mathbf{f}(\mathbf{x})\big)\,\mathbf{J}_{\mathbf{f}}(\mathbf{x}). \quad (34.35)$$

Proof. Write $\mathbf{y} = \mathbf{f}(\mathbf{x})$, $\mathbf{A} = \mathbf{J}_{\mathbf{f}}(\mathbf{x})$, and $\mathbf{B} = \mathbf{J}_{\mathbf{g}}(\mathbf{y})$. The idea is simply to substitute the linear model for $\mathbf{f}$ into the linear model for $\mathbf{g}$. By Equation 34.31, $\mathbf{f}(\mathbf{x}+\delta) = \mathbf{y} + \mathbf{A}\delta + o(\|\delta\|)$. Calling that displacement $\eta = \mathbf{A}\delta + o(\|\delta\|)$ and passing it to $\mathbf{g}$ gives

$$\mathbf{g}\big(\mathbf{f}(\mathbf{x}+\delta)\big) = \mathbf{g}(\mathbf{y}) + \mathbf{B}\,\eta + o(\|\eta\|) = \mathbf{g}(\mathbf{y}) + \mathbf{B}\mathbf{A}\,\delta + o(\|\delta\|).$$

The second equality relies on two facts. First, multiplying an $o(\|\delta\|)$ remainder by the fixed matrix $\mathbf{B}$ leaves it $o(\|\delta\|)$. Second, because $\|\eta\| \le \|\mathbf{A}\|\,\|\delta\| + o(\|\delta\|)$ is bounded by a constant multiple of $\|\delta\|$, the remainder $o(\|\eta\|)$ from $\mathbf{g}$ is also $o(\|\delta\|)$; this is the one step that is not purely algebraic. The coefficient of δ is therefore a matrix satisfying Equation 34.31, and by uniqueness it is the Jacobian of the composite: $\mathbf{J}_{\mathbf{g}\circ\mathbf{f}} = \mathbf{B}\mathbf{A}$. ∎

Looking at a single entry of the product recovers the scalar sum over paths: $[\mathbf{B}\mathbf{A}]_{ik} = \sum_j (\partial g_i / \partial y_j)(\partial f_j / \partial x_k)$ sums, over all intermediate variables y_j, the product of derivatives along each path from x_k to g_i.

34.4.2.2 The Jacobian of a Network

Returning to our opening network, we can view it as a composition of three maps: the affine transformation $\mathbf{a} = \mathbf{W}_1\mathbf{x} + \mathbf{b}$, the ReLU activation $\mathbf{h} = \varphi(\mathbf{a})$, and the linear output $g = \mathbf{w}_2^\top \mathbf{h}$. The first map is already affine, so its Jacobian is $\mathbf{W}_1$; the bias shifts the value without changing the slope. The ReLU acts on each entry independently, with slope 1 where $a_i > 0$ and 0 where $a_i < 0$, so its Jacobian is the diagonal matrix $\operatorname{diag}(\mathbf{m})$ formed from the *mask* $\mathbf{m}$ of these slopes. Finally, the output map has Jacobian $\mathbf{w}_2^\top$. At $\mathbf{x} = (1, 1)$, where $\mathbf{a} = (3, -2)$ and $\mathbf{m} = (1, 0)$, the chain rule multiplies the three factors:

$$\mathbf{J}_g(\mathbf{x}) = \mathbf{w}_2^\top \operatorname{diag}(\mathbf{m})\, \mathbf{W}_1 = \begin{pmatrix} 2 & -1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} 1 & 2 \\ 3 & -1 \end{pmatrix} = \begin{pmatrix} 2 & 0 \end{pmatrix} \begin{pmatrix} 1 & 2 \\ 3 & -1 \end{pmatrix} = \begin{pmatrix} 2 & 4 \end{pmatrix}.$$

The mask zeroes out the second entry of $\mathbf{w}_2^\top$, so the second row of $\mathbf{W}_1$ never reaches the output: the weights of an inactive unit contribute nothing to the derivative (Figure 34.21). The resulting row $(2, 4)$ matches the change $2\delta_1 + 4\delta_2$ from the opening. At a different input, the mask changes and so does the Jacobian. For instance, at $\mathbf{x} = (2, -3)$ the pre-activations are $(-4, 5)$, the mask flips to $(0, 1)$, and $\mathbf{J}_g = (0,\ -1)\, \mathbf{W}_1 = (-3,\ 1)$. Because ReLU is piecewise linear, a finite difference along each axis reproduces these entries exactly for any step small enough to keep the mask fixed (exercise 1).

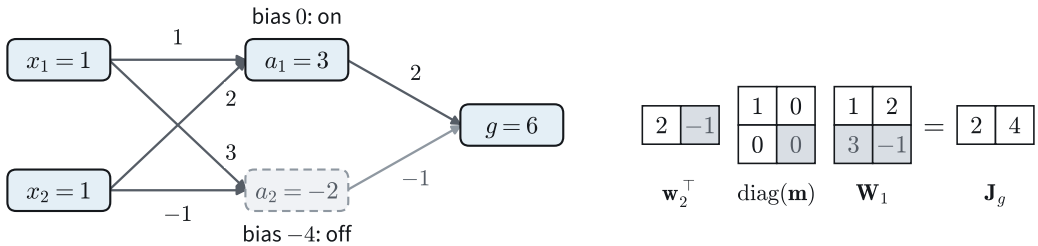

Figure 34.21: The Jacobian of the 2-2-1 ReLU network at $\mathbf{x} = (1, 1)$ is the product of three matrices. The second unit's pre-activation is -2, so its mask entry is 0 and the second row of $\mathbf{W}_1$ never reaches the output: $\mathbf{J}_g = \mathbf{w}_2^\top \operatorname{diag}(1, 0)\, \mathbf{W}_1 = (2,\ 4)$.

Every multilayer perceptron is built from the same two kinds of factors. A dense layer $\mathbf{x} \mapsto \mathbf{W}\mathbf{x}$ has Jacobian $\mathbf{W}$. An elementwise activation $\varphi(\mathbf{x}) = (\varphi(x_1), \dots, \varphi(x_n))$ does not couple distinct coordinates, so its Jacobian is diagonal: $\mathbf{J}_\varphi(\mathbf{x}) = \operatorname{diag}(\varphi'(x_1), \dots, \varphi'(x_n))$. This assumes that φ is differentiable at every x_i; ReLU has no derivative at 0, where frameworks supply a fixed value by convention (Section 34.1.6). A network of depth K is a composition $\mathbf{f} = \mathbf{f}_K \circ \cdots \circ \mathbf{f}_1$, and iterating Equation 34.35 turns its derivative into a single product,

$$\mathbf{J} = \mathbf{J}_K\, \mathbf{J}_{K-1} \cdots \mathbf{J}_1, \tag{34.36}$$

with each factor evaluated at the input of its own layer. For alternating dense layers and activations, this becomes $\mathbf{J} = \operatorname{diag}(\varphi_K')\, \mathbf{W}_K \cdots \operatorname{diag}(\varphi_1')\, \mathbf{W}_1$: weight matrices interleaved with diagonal matrices. Because multiplying a vector by a diagonal matrix simply scales each entry, each activation factor costs $O(n)$ operations rather than $O(n^2)$.

Let us now define the 2-2-1 network in code, which we will reuse later in the section, and compare the product $\mathbf{w}_2^\top \operatorname{diag}(\mathbf{m})\mathbf{W}_1$ against the gradient returned by automatic differentiation.

```
W1, b = tf.constant([[1.0, 2.0], [3.0, -1.0]]), tf.constant([0.0, -4.0])
w2, x = tf.constant([2.0, -1.0]), tf.constant([1.0, 1.0])

def g(x, W1, b, w2):                          # the 2-2-1 ReLU network
    return tf.tensordot(w2, tf.nn.relu(tf.linalg.matvec(W1, x) + b), 1)

m = tf.cast(tf.linalg.matvec(W1, x) + b > 0, tf.float32)   # the ReLU mask
with tf.GradientTape() as tape:
    tape.watch(x)
    out = g(x, W1, b, w2)
print('by hand    :', (w2[None, :] @ tf.linalg.diag(m) @ W1)[0].numpy())
print('by autograd:', tape.gradient(out, x).numpy())
```

```
by hand    : [2. 4.]
by autograd: [2. 4.]
```

Both lines print $(2, 4)$, as expected.

The product Equation 34.36 also tells us how large or small a derivative can grow through a deep network. When every factor is the same matrix $\mathbf{W}$ (as in a recurrent network applying one weight matrix at every step, ignoring the activations), the product simplifies to $\mathbf{W}^K$. For a diagonalizable matrix $\mathbf{W} = \mathbf{V}\Lambda\mathbf{V}^{-1}$ we have $\mathbf{W}^K = \mathbf{V}\Lambda^K\mathbf{V}^{-1}$, so for large K its norm grows or shrinks like $|\lambda_{\max}|^K$, where $\lambda_{\max}$ is the eigenvalue of largest magnitude: $0.9^{50} \approx 0.005$, whereas $1.1^{50} \approx 117$. This exponential scaling is the vanishing and exploding gradient problem of deep and recurrent networks (Section 4.4, Section 8.5). Keep in mind that $|\lambda_{\max}|^K$ describes only the long-run rate. When the eigenvectors in $\mathbf{V}$ are far from orthogonal, the product can grow for many steps before eventually decaying (Section 33.4.2.3), and a product of distinct factors is governed by singular values rather than eigenvalues (Section 33.4.2.5).

Notice, however, an important limitation of Equation 34.36 for training: it gives the derivative with respect to the *input*. The weight matrices $\mathbf{W}_k$ appear in it as fixed factors rather than variables, so it does not yet tell us how the output changes when a weight changes. Computing weight gradients requires one more rule per layer, which Section 34.4.3.2 derives and applies to this same network.

34.4.2.3 The Order of Multiplication

Because matrix multiplication is associative, we may bracket the product Equation 34.36 in any order and obtain the exact same matrix. Yet different bracketings differ enormously in cost, by a factor that grows with the width of the network. In training we want the gradient of a scalar loss ℓ, so the chain starts on the left with a row vector: the $1 \times h$ Jacobian $\mathbf{u}^\top = \partial\ell/\partial\mathbf{h}_K$ of the loss with respect to the last layer's output $\mathbf{h}_K$. Multiplying from the left keeps every intermediate result a row vector, so every step is a matrix–vector product. Multiplying from the right instead forms expensive matrix–matrix products all the way across until the row vector finally arrives at the end. The cheap order is the one that keeps every step a matrix–vector product.

A quick operation count makes the gap concrete. Consider $\mathbf{u}^\top \mathbf{J}_3\mathbf{J}_2\mathbf{J}_1$ with shapes $1\times h$, $h\times h$, $h \times h$, and $h \times n$, taking $h = n = 1000$ and recalling that multiplying a $p \times q$ matrix by a $q \times r$ matrix costs pqr multiplications. From the left, we perform three matrix–vector products for a total of $h^2 + h^2 + hn = 3 \times 10^6$ multiplications. From the right, forming $\mathbf{J}_2\mathbf{J}_1$ and then $\mathbf{J}_3(\mathbf{J}_2\mathbf{J}_1)$ costs $h^2 n = 10^9$ multiplications each, and the final product with $\mathbf{u}^\top$ adds $hn = 10^6$, totaling 2.001×10^9. Three million against two billion is a factor of about 670, or $2h/3$ (Figure 34.22).

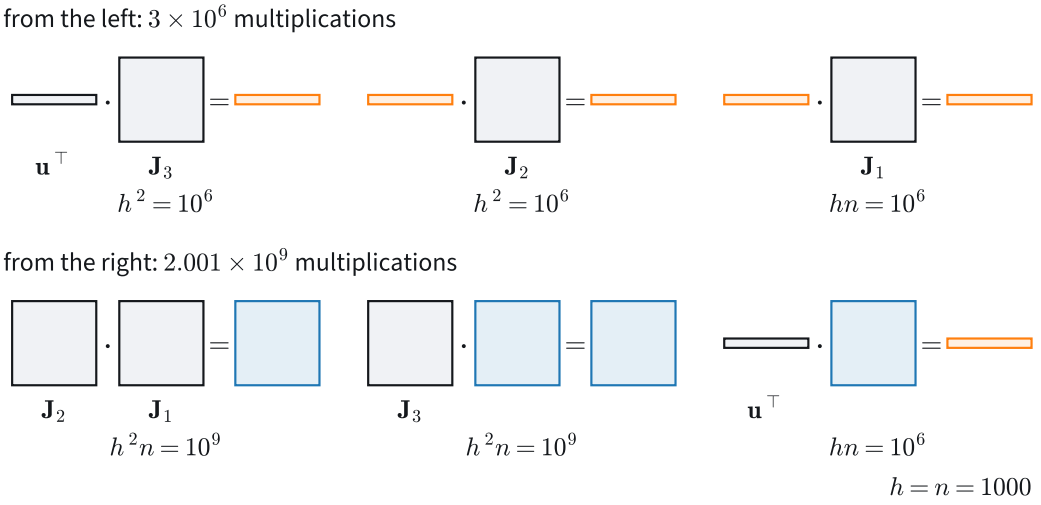

Figure 34.22: Two orders for $\mathbf{u}^\top \mathbf{J}_3\mathbf{J}_2\mathbf{J}_1$ with $h = n = 1000$. From the left every intermediate is a $1 \times h$ row and every step is a matrix–vector product: 3×10^6 multiplications. From the right the first two steps are matrix–matrix products of 10^9 multiplications each. The shapes, not the depth, decide the cost.

These two orders correspond to two directions through the network. Multiplying from the left propagates the sensitivity of the output backward through the layers, at the cost of one matrix–vector product per layer. Multiplying from the right is the cheap order when a column vector $\mathbf{v}$ stands at the right end of the chain: it propagates a single input direction forward and yields $\mathbf{J}\mathbf{v}$. Algorithms that automate these two orders are called reverse-mode and forward-mode automatic differentiation (Section 34.5).

The count above assumed layers of equal width. When the factors have varying shapes, neither end-to-end order need be optimal. For a chain, the cheapest parenthesization can be found by dynamic programming (exercise 2); for a general computation graph, the problem is NP-complete (Naumann 2008).

34.4.3 Derivatives with Respect to Vectors and Matrices

Training a layer requires the gradient of a scalar loss with respect to vectors and matrices alike: its input, its weights, and its bias. In this section we derive every gradient we need with a single method, one that automatically returns each result in the shape of its variable.

34.4.3.1 The Differential Method

Write $d\mathbf{x}$ for a small perturbation of the variable and df for the part of the resulting change in f that is linear in $d\mathbf{x}$—simply the term $\mathbf{J}\delta$ of Equation 34.31 with δ renamed $d\mathbf{x}$. By Equation 34.31 and Equation 34.34, this linear part is an inner product with the gradient,

$$df = \langle \nabla f,\, d\mathbf{x} \rangle, \tag{34.37}$$

for both vector variables ($\langle \mathbf{a}, \mathbf{b} \rangle = \mathbf{a}^\top \mathbf{b}$) and matrix variables. We can read Equation 34.37 in two ways. Given the gradient, it tells us how f responds to a nudge. Given f, it gives a direct recipe for the gradient: compute df using the ordinary rules of differentiation, rearrange it into the form $\langle \mathbf{M},\, d\mathbf{x} \rangle$, and read off $\nabla f = \mathbf{M}$. This reading is unambiguous because a linear function of $d\mathbf{x}$ can be written as $\langle \mathbf{M}, d\mathbf{x} \rangle$ for only one $\mathbf{M}$: setting $d\mathbf{x}$ to the matrix with a single 1 in position (i, j) and zeros elsewhere isolates M_{ij}.

Four familiar rules suffice to compute df. First, the differential is linear. Second, it obeys the product rule $d(\mathbf{AB}) = d\mathbf{A}\,\mathbf{B} + \mathbf{A}\,d\mathbf{B}$, because expanding $(\mathbf{A} + d\mathbf{A})(\mathbf{B} + d\mathbf{B})$ differs from $\mathbf{AB} + d\mathbf{A}\,\mathbf{B} + \mathbf{A}\,d\mathbf{B}$ only by the second-order term $d\mathbf{A}\,d\mathbf{B}$. Third, it commutes with transposition, $d(\mathbf{A}^\top) = (d\mathbf{A})^\top$. Fourth, a scalar function applied entry by entry obeys the scalar chain rule in every entry, $d\varphi(\mathbf{X}) = \varphi'(\mathbf{X}) \odot d\mathbf{X}$, where $\odot$ denotes elementwise multiplication.

To rearrange df into the form $\langle \mathbf{M}, d\mathbf{x} \rangle$, we need just one more tool. The *move rule* shifts a factor standing next to $d\mathbf{x}$ across to the other side of the inner product:

$$\langle \mathbf{A},\, \mathbf{BC} \rangle = \langle \mathbf{B}^\top \mathbf{A},\, \mathbf{C} \rangle = \langle \mathbf{AC}^\top,\, \mathbf{B} \rangle,$$

which follows directly from the cyclic property of the trace, $\operatorname{tr}(\mathbf{XY}) = \operatorname{tr}(\mathbf{YX})$: $\operatorname{tr}(\mathbf{A}^\top \mathbf{BC}) = \operatorname{tr}\big((\mathbf{B}^\top \mathbf{A})^\top \mathbf{C}\big) = \operatorname{tr}(\mathbf{CA}^\top \mathbf{B}) = \operatorname{tr}\big((\mathbf{AC}^\top)^\top \mathbf{B}\big)$. In words, a factor to the left of the variable moves across as its transpose on the left, while a factor to the right moves across as its transpose on the right. An elementwise factor moves across unchanged, $\langle \mathbf{A}, \mathbf{B} \odot \mathbf{C} \rangle = \langle \mathbf{A} \odot \mathbf{B}, \mathbf{C} \rangle$, since both sides equal $\sum_{ij} A_{ij} B_{ij} C_{ij}$.

The two simplest cases take one line each. For a linear form, $d(\mathbf{a}^\top \mathbf{x}) = \mathbf{a}^\top d\mathbf{x} = \langle \mathbf{a}, d\mathbf{x} \rangle$, so $\nabla_{\mathbf{x}}\, \mathbf{a}^\top \mathbf{x} = \mathbf{a}$. For a quadratic form, the product rule hits both copies of $\mathbf{x}$:

$$\begin{aligned} d(\mathbf{x}^\top \mathbf{A} \mathbf{x}) &= d\mathbf{x}^\top \mathbf{A}\mathbf{x} + \mathbf{x}^\top \mathbf{A}\, d\mathbf{x} = \mathbf{x}^\top \mathbf{A}^\top d\mathbf{x} + \mathbf{x}^\top \mathbf{A}\, d\mathbf{x} \\ &= \big\langle (\mathbf{A} + \mathbf{A}^\top)\mathbf{x},\, d\mathbf{x} \big\rangle. \end{aligned}$$

In the second equality we transposed a 1×1 matrix: $d\mathbf{x}^\top \mathbf{A}\mathbf{x}$ is a scalar, so it equals its own transpose $\mathbf{x}^\top \mathbf{A}^\top d\mathbf{x}$. Reading off the coefficient yields $\nabla_{\mathbf{x}}\, \mathbf{x}^\top \mathbf{A}\mathbf{x} = (\mathbf{A} + \mathbf{A}^\top)\mathbf{x}$, which simplifies to $2\mathbf{A}\mathbf{x}$ whenever $\mathbf{A}$ is symmetric.

Writing out indices offers a second route. Entry by entry, the same derivative is $\partial(\sum_{ij} x_i A_{ij} x_j)/\partial x_k = \sum_j A_{kj} x_j + \sum_i x_i A_{ik}$, recovering the k-th entry of $(\mathbf{A} + \mathbf{A}^\top)\mathbf{x}$. Index derivations are longer, but they leave no doubt about transposes; Section 4.3 uses them to derive the matrix-product rule.

A fast sanity check on any matrix identity is to set every matrix to 1×1, in which case the formula must reduce to the familiar scalar rule. Our quadratic-form gradient passes,

since $\frac{d}{dx}(ax^2) = 2ax = (a+a)x$. This 1×1 *check* reliably catches a wrong coefficient or a missing term, but it is blind to transposes and factor order because 1×1 matrices commute and equal their own transposes. The shape rule catches most transpose errors, though unfortunately not when the factor is square—the exact pitfall we warned about at the start of the section. For square factors, only a numerical check will catch the mistake. Take $\mathbf{A} = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$ and $\mathbf{x} = (1, 2)$. Then $\mathbf{x}^\top \mathbf{A}\mathbf{x} = x_1 x_2$, whose true gradient $(x_2, x_1) = (2, 1)$ equals $(\mathbf{A} + \mathbf{A}^\top)\mathbf{x}$. The naive guess $2\mathbf{A}\mathbf{x} = (4, 0)$, suggested by the scalar rule $2ax$, passes the 1×1 check, has the right shape, and is still wrong.

The differential method handles matrix variables with no extra effort. For the least-squares loss $\ell = \|\mathbf{W}\mathbf{x} - \mathbf{y}\|^2$ with residual $\mathbf{r} = \mathbf{W}\mathbf{x} - \mathbf{y}$, varying $\mathbf{W}$ gives $d\mathbf{r} = d\mathbf{W}\,\mathbf{x}$, and the move rule shifts $\mathbf{x}$ to the other side: $d\ell = 2\mathbf{r}^\top d\mathbf{r} = \langle 2\mathbf{r},\ d\mathbf{W}\,\mathbf{x}\rangle = \langle 2\mathbf{r}\mathbf{x}^\top,\ d\mathbf{W}\rangle$. Therefore,

$$\nabla_{\mathbf{W}} \|\mathbf{W}\mathbf{x} - \mathbf{y}\|^2 = 2\,(\mathbf{W}\mathbf{x} - \mathbf{y})\,\mathbf{x}^\top, \tag{34.38}$$

a rank-one outer product of the residual with the input, automatically in the shape of $\mathbf{W}$. When $\mathbf{x}$ varies instead, $d\mathbf{r} = \mathbf{W}\,d\mathbf{x}$ and $\nabla_{\mathbf{x}}\ell = 2\mathbf{W}^\top \mathbf{r}$. In both cases, the gradient is twice the residual multiplied by the transpose of whichever factor multiplies the variable.

34.4.3.2 Backward Rules of a Layer

Inside a network, a layer $\mathbf{Y} = \mathbf{F}(\mathbf{X})$ is one step in a long computation ending in a scalar loss ℓ. Forming its full Jacobian is out of the question: a 1000×1000 weight matrix applied to a minibatch of 1000 examples produces 10^6 outputs from 10^6 weights, so the Jacobian of outputs with respect to weights would have 10^{12} entries. Fortunately, backpropagation needs far less. All a layer must do is turn the gradient of the loss with respect to its output into the gradients with respect to its inputs and weights. Following Section 34.3.2, we write $\bar{\mathbf{Y}} = \nabla_{\mathbf{Y}}\ell$ for the adjoint of $\mathbf{Y}$—now a matrix of the same shape as $\mathbf{Y}$ holding the total derivative of the loss with respect to each entry of $\mathbf{Y}$.

Proposition (backward rule of a layer). *Let $\mathbf{Y} = \mathbf{F}(\mathbf{X})$ be differentiable at $\mathbf{X}$ and let ℓ be a differentiable scalar function of $\mathbf{Y}$. Then the adjoint $\bar{\mathbf{X}}$ of the composite $\ell(\mathbf{F}(\mathbf{X}))$ is the unique matrix satisfying*

$$\langle \bar{\mathbf{X}},\ d\mathbf{X}\rangle = \langle \bar{\mathbf{Y}},\ d\mathbf{Y}\rangle \quad \textit{for every } d\mathbf{X},$$

where $d\mathbf{Y}$ is the first-order change of $\mathbf{F}$ caused by $d\mathbf{X}$.

Proof. By the chain rule Equation 34.35 (viewing matrices as flattened vectors), the linear part of the composite is the linear part of ℓ applied to the linear part of $\mathbf{F}$: $d\ell = \langle \bar{\mathbf{Y}}, d\mathbf{Y}\rangle$. Because $d\mathbf{Y}$ is linear in $d\mathbf{X}$, so is $d\ell$, which means it can be written as $\langle \mathbf{M}, d\mathbf{X}\rangle$ for a unique matrix $\mathbf{M}$. By Equation 34.37, $\mathbf{M} = \bar{\mathbf{X}}$. ■

In practice, applying this proposition comes down to applying the move rule. For a vector layer with $d\mathbf{y} = \mathbf{J}\,d\mathbf{x}$, it gives $\langle \bar{\mathbf{y}}, \mathbf{J}\,d\mathbf{x}\rangle = \langle \mathbf{J}^\top \bar{\mathbf{y}}, d\mathbf{x}\rangle$, so $\bar{\mathbf{x}} = \mathbf{J}^\top \bar{\mathbf{y}}$: the backward rule of a layer is simply the transpose of its linearization. The transpose of a linear map is also called its adjoint, which is where the name comes from. Written as $\bar{\mathbf{x}}^\top = \bar{\mathbf{y}}^\top \mathbf{J}$, this is just one step of the left-to-right order in Equation 34.36. A row vector times a Jacobian is called a *vector–Jacobian product*. The proposition lets us compute it for matrix variables without ever forming the Jacobian.

The single most frequent derivative in deep learning is that of a matrix product. Depending on whether we process a minibatch or a single vector, the weights stand on the right or the left of the data, so let us derive both layouts together. A minibatch $\mathbf{X} \in \mathbb{R}^{n\times d}$ with one example per row (the convention throughout the main text) multiplies the weight matrix $\mathbf{W} \in \mathbb{R}^{d\times q}$ to produce $\mathbf{Y} = \mathbf{X}\mathbf{W}$. The product rule gives $d\mathbf{Y} = d\mathbf{X}\,\mathbf{W} + \mathbf{X}\,d\mathbf{W}$, and the move rule splits the inner product into one term per variable: $\langle \bar{\mathbf{Y}}, d\mathbf{X}\,\mathbf{W}\rangle + \langle \bar{\mathbf{Y}}, \mathbf{X}\,d\mathbf{W}\rangle = \langle \bar{\mathbf{Y}}\mathbf{W}^\top, d\mathbf{X}\rangle + \langle \mathbf{X}^\top\bar{\mathbf{Y}}, d\mathbf{W}\rangle$. Reading off both coefficients gives

$$\bar{\mathbf{X}} = \bar{\mathbf{Y}}\,\mathbf{W}^\top, \qquad \bar{\mathbf{W}} = \mathbf{X}^\top\bar{\mathbf{Y}}. \tag{34.39}$$

For a single example written as a column vector, $\mathbf{y} = \mathbf{W}\mathbf{x}$, the exact same calculation yields

$$\bar{\mathbf{W}} = \bar{\mathbf{y}}\,\mathbf{x}^\top, \qquad \bar{\mathbf{x}} = \mathbf{W}^\top\bar{\mathbf{y}},$$

matching the pattern of Equation 34.38: the weight gradient is the outer product of the output adjoint with the input. The two layouts are simply transposes of each other. If $\mathbf{x}_i^\top$ and $\bar{\mathbf{y}}_i^\top$ are the rows of $\mathbf{X}$ and $\bar{\mathbf{Y}}$, the minibatch formula $\mathbf{X}^\top\bar{\mathbf{Y}} = \sum_i \mathbf{x}_i\bar{\mathbf{y}}_i^\top$ sums one such outer product per example.

The backward pass of a linear layer therefore consists of two matrix products, each the same size as the forward product: the forward pass costs ndq multiplications and the backward pass costs $2ndq$. Checking shapes confirms both transposes: $\bar{\mathbf{Y}}\mathbf{W}^\top$ is $n\times d$ like $\mathbf{X}$, and $\mathbf{X}^\top\bar{\mathbf{Y}}$ is $d\times q$ like $\mathbf{W}$. Backward rules for more elaborate matrix operations (inverses, determinants, and decompositions) follow from the very same method (Mike B. Giles 2008).

Two more layers complete a multilayer perceptron. An elementwise activation $\mathbf{Y} = \varphi(\mathbf{X})$ has $d\mathbf{Y} = \varphi'(\mathbf{X}) \odot d\mathbf{X}$, so moving $\varphi'(\mathbf{X})$ across the inner product gives $\bar{\mathbf{X}} = \varphi'(\mathbf{X}) \odot \bar{\mathbf{Y}}$—the diagonal Jacobian from earlier, applied directly as a mask. A bias addition $\mathbf{y} = \mathbf{z} + \mathbf{b}$ has $d\mathbf{y} = d\mathbf{b}$, so $\bar{\mathbf{b}} = \bar{\mathbf{y}}$. For a minibatch, the bias is broadcast across rows via $\mathbf{Z} = \mathbf{X}\mathbf{W} + \mathbf{1}\mathbf{b}^\top$, which is just another matrix product and gives $\bar{\mathbf{b}} = \bar{\mathbf{Z}}^\top\mathbf{1}$, summing the adjoint over all examples. These three local rules are the building blocks from which Section 4.3 assembles the full backward pass of a multilayer perceptron.

They also let us derive the weight-gradient matrix from the opening. Running the network of Figure 34.21 backward from $\bar{g} = 1$, one layer at a time, at $\mathbf{x} = (1, 1)$:

1. The output $g = \mathbf{w}_2^\top\mathbf{h}$ gives $\bar{\mathbf{h}} = \mathbf{w}_2 = (2, -1)$ and $\bar{\mathbf{w}}_2 = \mathbf{h} = (3, 0)$.
2. The ReLU gives $\bar{\mathbf{a}} = \mathbf{m} \odot \bar{\mathbf{h}} = (2, 0)$, and the bias gives $\bar{\mathbf{b}} = \bar{\mathbf{a}} = (2, 0)$.
3. The affine map $\mathbf{a} = \mathbf{W}_1\mathbf{x} + \mathbf{b}$ gives $\bar{\mathbf{W}}_1 = \bar{\mathbf{a}}\,\mathbf{x}^\top = \left(\begin{smallmatrix} 2 & 2 \\ 0 & 0 \end{smallmatrix}\right)$ and $\bar{\mathbf{x}} = \mathbf{W}_1^\top\bar{\mathbf{a}} = (2, 4)$.

Notice that $\bar{\mathbf{x}}$ is the transpose of the Jacobian row $(2, 4)$ we found earlier, and $\bar{\mathbf{W}}_1$ is the matrix we obtained in the opening by nudging the weights. Differentiating `g` with respect to $\mathbf{W}_1$, $\mathbf{b}$, and $\mathbf{w}_2$ in code confirms all three arrays.

```
W1, b, w2 = tf.Variable(W1), tf.Variable(b), tf.Variable(w2)
with tf.GradientTape() as tape:
    out = g(x, W1, b, w2)
gW1, gb, gw2 = tape.gradient(out, [W1, b, w2])
h = tf.nn.relu(tf.linalg.matvec(W1, x) + b)
show = lambda t: (np.asarray(t) + 0.0).tolist()  # + 0.0 turns -0.0 into 0.0
print('dg/dW1 = (w2*m) x^T:', show(tf.tensordot(w2 * m, x, axes=0)),
```

```
      '  autograd:', show(gW1))
print('dg/db  = w2*m      :', show(w2 * m), '  autograd:', show(gb))
print('dg/dw2 = h         :', show(h), '  autograd:', show(gw2))
```

```
dg/dW1 = (w2*m) x^T: [[2.0, 2.0], [0.0, 0.0]]   autograd: [[2.0, 2.0], [0.0, 0.0]]
dg/db  = w2*m      : [2.0, 0.0]   autograd: [2.0, 0.0]
dg/dw2 = h         : [3.0, 0.0]   autograd: [3.0, 0.0]
```

It is worth noting where the zeros land. The inactive hidden unit leaves three zeros behind: a zero row in $\bar{\mathbf{W}}_1$, a zero in $\bar{\mathbf{b}}$, and a zero in $\bar{\mathbf{w}}_2$ (because its output $h_2 = 0$ is what $w_{2,2}$ multiplies). A training step on this input leaves all four of that unit's parameters untouched.

We still owe the numerical test that catches a misplaced transpose on a square factor. A test that cannot fail proves nothing, so we design this one to expose the mistake: every factor below is a random square (and hence nonsymmetric) matrix, and we print each correct rule beside a plausible wrong guess of the same shape. We test both the quadratic form and the matrix product. For the product, we differentiate the scalar $\langle \bar{\mathbf{Y}}, \mathbf{XW} \rangle$ for a random $\bar{\mathbf{Y}}$; by our backward-rule proposition, its gradients with respect to $\mathbf{X}$ and $\mathbf{W}$ are precisely $\bar{\mathbf{X}}$ and $\bar{\mathbf{W}}$.

```
A, x = tf.constant(np.random.randn(3, 3)), tf.constant(np.random.randn(3))
X, W, Ybar = (tf.constant(np.random.randn(3, 3)) for _ in range(3))  # square
ok = lambda u, v: np.allclose(u, v, atol=1e-5)
T = tf.transpose
with tf.GradientTape(persistent=True) as tape:
    tape.watch([x, X, W])
    quad = tf.tensordot(x, tf.linalg.matvec(A, x), 1)
    s = tf.reduce_sum(Ybar * (X @ W))
gx, (gX, gW) = tape.gradient(quad, x), tape.gradient(s, [X, W])
print('grad x^T A x: (A + A^T) x', ok(gx, tf.linalg.matvec(A + T(A), x)),
      '| wrong guess 2 A x       ', ok(gx, 2 * tf.linalg.matvec(A, x)))
print('Xbar        : Ybar W^T   ', ok(gX, Ybar @ T(W)),
      '| wrong guess Ybar W      ', ok(gX, Ybar @ W))
print('Wbar        : X^T Ybar   ', ok(gW, T(X) @ Ybar),
      '| wrong guess (X^T Ybar)^T', ok(gW, T(T(X) @ Ybar)))
```

```
grad x^T A x: (A + A^T) x True | wrong guess 2 A x        False
Xbar        : Ybar W^T    True | wrong guess Ybar W       False
Wbar        : X^T Ybar    True | wrong guess (X^T Ybar)^T False
```

The derived rules print `True` and the wrong guesses print `False`. Here the design of the test matters even more than its outcome. With rectangular factors, say $\mathbf{X}$ of shape 3×4 and $\mathbf{W}$ of shape 4×2, the two wrong guesses for the product would not even execute: a misplaced transpose would trigger a shape error before any number is compared, which is the shape rule doing its job. Likewise, with a symmetric $\mathbf{A}$, the wrong guess $2\mathbf{Ax}$ would have matched the true gradient and slipped past the test. The treacherous case is a square, nonsymmetric factor, so that is what a numerical check must draw.

The matrix-product rule handles losses in which both factors of a product are unknown just as easily, such as the matrix-factorization loss $\|\mathbf{X} - \mathbf{UV}\|_F^2$ in exercise 3. In every case, the backward rule multiplies the incoming adjoint by the transposes of whatever multiplied the variable on the forward pass. Notice also which forward values each rule requires: $\mathbf{X}$ and $\mathbf{W}$ for the matrix product, $\varphi'(\mathbf{X})$ for the activation, and nothing at all for the bias. A

backward pass must retain those intermediate values from the forward pass, a memory cost that Section 34.5 measures directly.

34.4.3.3 Softmax and Cross-Entropy

The derivative a classifier evaluates most often is that of softmax composed with cross-entropy loss. Softmax converts a vector of scores $\mathbf{z}$, the *logits*, into a probability vector: setting $S = \sum_k e^{z_k}$, we have $p_i = e^{z_i}/S$. The same quotient rule that gave the log-sum-exp Hessian in Section 34.2 for two logits yields the softmax Jacobian for any number of classes. Writing $\delta_{ij} = 1$ if $i = j$ and 0 otherwise,

$$\frac{\partial p_i}{\partial z_j} = \frac{\delta_{ij} e^{z_i} S - e^{z_i} e^{z_j}}{S^2} = p_i(\delta_{ij} - p_j), \qquad \mathbf{J}_{\text{softmax}} = \operatorname{diag}(\mathbf{p}) - \mathbf{p}\mathbf{p}^\top. \tag{34.40}$$

In words, increasing logit i raises p_i at rate $p_i(1 - p_i)$ and lowers every other probability p_j at rate $p_i p_j$. As a quick check, $\mathbf{J}\mathbf{1} = \mathbf{p} - \mathbf{p}(\mathbf{p}^\top \mathbf{1}) = \mathbf{0}$ because the probabilities sum to one. This must hold, since adding the same constant to every logit leaves $\mathbf{p}$ unchanged; consequently, the softmax Jacobian is always singular.

Notice that $\mathbf{J}_{\text{softmax}}$ is also symmetric, a property an arbitrary Jacobian need not have. The reason is that it is actually a Hessian: softmax is the gradient of the log-sum-exp function $\operatorname{LSE}(\mathbf{z}) = \log \sum_k e^{z_k}$, our chapter's running example, because $\partial \operatorname{LSE}/\partial z_i = e^{z_i}/S = p_i$, and the Jacobian of a gradient is its Hessian. What Equation 34.40 adds to that two-logit formula is a clean statistical reading of the matrix. It is the covariance matrix of a one-hot vector drawn with probabilities $\mathbf{p}$, so for every $\mathbf{z}$ and every vector $\mathbf{v}$ the quadratic form $\mathbf{v}^\top \mathbf{J} \mathbf{v} = \sum_i p_i v_i^2 - \left(\sum_i p_i v_i\right)^2$ is the variance of the entries of $\mathbf{v}$ under the distribution $\mathbf{p}$. Because a variance is never negative, this Hessian is positive semidefinite everywhere, proving that log-sum-exp is convex. A constant vector $\mathbf{v}$ has zero variance, recovering the null vector $\mathbf{1}$ once again.

Now compose softmax with the cross-entropy loss $\ell = -\sum_i y_i \log p_i$ against a target distribution $\mathbf{y}$. The chain rule multiplies the row $\partial \ell / \partial \mathbf{p} = (-y_i/p_i)_i$ by Equation 34.40, and the algebra collapses dramatically:

$$\frac{\partial \ell}{\partial z_j} = -\sum_i \frac{y_i}{p_i} p_i(\delta_{ij} - p_j) = -y_j + p_j \sum_i y_i = p_j - y_j, \qquad \text{that is,} \qquad \nabla_{\mathbf{z}} \ell = \mathbf{p} - \mathbf{y}. \tag{34.41}$$

The gradient with respect to the logits is simply predicted probability minus target, the formula written as $\hat{\mathbf{y}} - \mathbf{y}$ in Section 3.1.2.2. Because the final step used only $\sum_i y_i = 1$, the result holds for any probability vector $\mathbf{y}$, not just one-hot labels—so label smoothing and distillation targets obey the exact same formula. For a target that does not sum to one, the gradient is instead $\left(\sum_i y_i\right)\mathbf{p} - \mathbf{y}$. At $\mathbf{z} = (1, -0.5, 2)$, for example, we have $\mathbf{p} = (0.254,\ 0.057,\ 0.690)$; with the second class as the target, the gradient is $(0.254,\ -0.943,\ 0.690)$.

In practice, libraries fuse softmax and cross-entropy into a single primitive for numerical stability (Section 3.3.5.2, Section 35.8.2). Below, we compute the softmax Jacobian at $\mathbf{z}$ by automatic differentiation and print its eigenvalues, which our variance argument predicts

must be nonnegative with one zero. We then differentiate the fused loss for both the one-hot target above and the two-hot target $\mathbf{y} = (1, 1, 0)$, whose entries do not sum to one.

```
z = tf.constant([1.0, -0.5, 2.0])
with tf.GradientTape() as tape:
    tape.watch(z)
    p = tf.nn.softmax(z)
J = tape.jacobian(p, z)                          # the Jacobian, by autograd
print('eigenvalues of J:', np.linalg.eigvalsh(J.numpy()).round(3) + 0.0)
for y in [tf.constant([0.0, 1.0, 0.0]), tf.constant([1.0, 1.0, 0.0])]:
    with tf.GradientTape() as tape:
        tape.watch(z)
        loss = -tf.reduce_sum(y * tf.nn.log_softmax(z))
    print(f'y = {y.numpy()}: d loss / d z = {tape.gradient(loss, z).numpy().round(4)}, '
          f'p - y = {(p - y).numpy().round(4)}')
```

```
eigenvalues of J: [0.    0.079 0.378]
y = [0. 1. 0.]: d loss / d z = [ 0.2537 -0.9434  0.6897], p - y = [ 0.2537 -0.9434  0.6897]
y = [1. 1. 0.]: d loss / d z = [-0.4926 -0.8868  1.3793], p - y = [-0.7463 -0.9434  0.6897]
```

The eigenvalues are 0, 0.079, and 0.378: one zero, corresponding to the direction $\mathbf{1}$, and two positive values. For the one-hot target, the gradient of the fused loss is $\mathbf{p} - \mathbf{y} = (0.2537, -0.9434, 0.6897)$, matching our hand calculation. For the two-hot target, however, it returns $(-0.4926, -0.8868, 1.3793)$, which is $2\mathbf{p} - \mathbf{y}$ rather than the $\mathbf{p} - \mathbf{y}$ printed beside it. "Prediction minus target" is a property of targets that sum to one, not of the loss alone.

Here we multiplied $\mathbf{J}_K \cdots \mathbf{J}_1$ by hand for a simple three-layer chain. In practice, a program must handle arbitrary computation graphs that branch and merge, retain the forward values that each backward rule needs, and compute all gradients at a cost that stays a small constant multiple of evaluating the network, no matter how many parameters it has. That program is automatic differentiation, the subject of Section 34.5.

34.4.4 Summary

The Jacobian of a map $\mathbf{f} : \mathbb{R}^n \to \mathbb{R}^m$ is the $m \times n$ matrix of its best linear approximation, with entries $[\mathbf{J}_\mathbf{f}]_{ij} = \partial f_i / \partial x_j$; both the gradient (a single row, written as a column) and the Hessian (the Jacobian of the gradient) are special cases of it. A network's derivative with respect to its input is the product of its layers' Jacobians, $\mathbf{J}_K \cdots \mathbf{J}_1$, and the order of multiplication governs the cost: three million versus two billion multiplications for three layers of width 1000. The differential rule $df = \langle \nabla f, d\mathbf{x} \rangle$ derives every gradient a layer needs automatically in the shape of its variable, including the matrix-product backward rules $\bar{\mathbf{X}} = \bar{\mathbf{Y}}\mathbf{W}^\top$ and $\bar{\mathbf{W}} = \mathbf{X}^\top \bar{\mathbf{Y}}$, as well as the collapse of softmax with cross-entropy to $\mathbf{p} - \mathbf{y}$. While the shape rule and the 1×1 check catch most slips in a hand derivation, a misplaced transpose on a square factor escapes both and requires a numerical test on a nonsymmetric matrix.

34.4.5 Exercises

1. **Jacobian of a ReLU network.** Let $\mathbf{g}(\mathbf{x}) = \mathbf{W}_2 \, \varphi(\mathbf{W}_1 \mathbf{x} + \mathbf{b})$ with $\mathbf{W}_1 \in \mathbb{R}^{h \times n}$, $\mathbf{b} \in \mathbb{R}^h$, $\mathbf{W}_2 \in \mathbb{R}^{m \times h}$, and the elementwise ReLU φ. Assume that no entry of the pre-activation

$\mathbf{W}_1\mathbf{x}+\mathbf{b}$ is zero. By Equation 34.35, $\mathbf{J}_\mathbf{g}(\mathbf{x}) = \mathbf{W}_2\mathbf{M}(\mathbf{x})\mathbf{W}_1$, where the diagonal matrix $\mathbf{M}(\mathbf{x})$ has the entry 1 for each active hidden unit and 0 for each inactive one.

   1. Show that $\mathbf{g}(\mathbf{x}+\delta) = \mathbf{g}(\mathbf{x}) + \mathbf{J}_\mathbf{g}(\mathbf{x})\,\delta$ holds exactly for every sufficiently small δ, so that the remainder in Equation 34.31 vanishes identically. For the 2-2-1 network of this section at $\mathbf{x} = (1, 1)$, find the largest r such that this holds for all δ with $\|\delta\|_\infty < r$. For $n = m = 2$, how does the image of a small circle under $\mathbf{g}$ differ from the one in Figure 34.20?
   2. Let k hidden units be active at $\mathbf{x}$. Show that $\operatorname{rank}\mathbf{J}_\mathbf{g}(\mathbf{x}) \le k$. For $n = m = 2$ and $k = 1$, what is the image of a small circle around $\mathbf{x}$?
   3. Describe the set of inputs at which some pre-activation is zero. What happens to $\mathbf{J}_\mathbf{g}$ when $\mathbf{x}$ crosses this set?

2. code **Cheapest chain order.** ● By Equation 34.36 the Jacobian of a chain of K maps is $\mathbf{J}_K \cdots \mathbf{J}_1$ with $\mathbf{J}_k \in \mathbb{R}^{d_k \times d_{k-1}}$. Multiplying a $p \times q$ matrix by a $q \times r$ matrix costs pqr multiplications.
   1. Give the costs of the forward order, which multiplies from the right, and of the reverse order, which multiplies from the left, as functions of $d_0, \dots, d_K$. Evaluate both for $(d_0, \dots, d_4) = (1000, 10, 1000, 10, 1000)$, a map whose layers alternate between wide and narrow, and compare with the section's count for $(1 \times h)(h \times h)(h \times h)(h \times n)$.
   2. Write a dynamic program over the sub-chains $\mathbf{J}_j \cdots \mathbf{J}_i$ that finds the cheapest parenthesization, and run it on the dimensions of (a). Which order does it choose, and how much cheaper is it than the better of the two orders of (a)?
   3. For a scalar output, $d_K = 1$, compare the optimum with the reverse order on a few thousand random dimension vectors, with K between 2 and 6 and each of $d_0, \dots, d_{K-1}$ drawn uniformly from $\{1, \dots, 10\}$. Characterize the vectors for which some other order is cheaper.

3. code **Backward rules of a matrix product.**
   1. For $\mathbf{Y} = \mathbf{X}\mathbf{W}$, derive Equation 34.39 by the differential method, then derive it again by indices to confirm the transposes.
   2. Verify both rules with the vector–Jacobian product `tape.gradient(..., output_gradients=...)` on $\mathbf{X} \in \mathbb{R}^{3\times4}$, $\mathbf{W} \in \mathbb{R}^{4\times2}$ and a random adjoint $\bar{\mathbf{Y}}$. Count the multiplications of the forward product and of the two backward products.
   3. For the factorization loss $\|\mathbf{X} - \mathbf{U}\mathbf{V}\|_F^2$ with $\mathbf{R} = \mathbf{X} - \mathbf{U}\mathbf{V}$, check $\nabla_\mathbf{U} = -2\mathbf{R}\mathbf{V}^\top$ and $\nabla_\mathbf{V} = -2\mathbf{U}^\top\mathbf{R}$ numerically. Then write the alternating least-squares step that sets one gradient to zero with the other factor fixed, and show that each step is one linear solve.

4. **Softmax vector–Jacobian product.** A backward pass never forms the softmax Jacobian Equation 34.40. It maps the adjoint $\mathbf{u} = \bar{\mathbf{p}}$ of the probabilities to the adjoint $\bar{\mathbf{z}} = \mathbf{J}_{\text{softmax}}^\top \mathbf{u}$ of the logits.
   1. Show that $\mathbf{J}_{\text{softmax}}^\top \mathbf{u} = \mathbf{p} \odot \big(\mathbf{u} - (\mathbf{p}^\top \mathbf{u})\,\mathbf{1}\big)$, where $\odot$ is the elementwise product. For n classes, count the operations of this formula and those of forming $\mathbf{J}_{\text{softmax}}$ and multiplying it by $\mathbf{u}$.
   2. Self-attention applies softmax to each row of an $n \times n$ score matrix $\mathbf{S}$ and produces the weights $\mathbf{P}$. How many entries does the Jacobian of $\mathbf{P}$ with respect to $\mathbf{S}$ have, and how many of them can be nonzero? For $n = 4096$ tokens in float32, compare the memory of the full Jacobian, of its nonzero entries, and of the adjoint of $\mathbf{S}$ that the formula of (a), applied row by row, returns.

5. code **The LayerNorm Jacobian.** Layer normalization (Ba et al. 2016) maps $\mathbf{x} \in \mathbb{R}^n$ to $\hat{\mathbf{x}} = (\mathbf{x} - \mu\mathbf{1})/\sigma$ with $\mu = \frac{1}{n}\sum_i x_i$ and $\sigma^2 = \frac{1}{n}\sum_i (x_i - \mu)^2 > 0$ (no learned scale and no ϵ).

   1. Show by the differential method that $\mathbf{J} = \frac{1}{\sigma}(\mathbf{I} - \frac{1}{n}\mathbf{1}\mathbf{1}^\top - \frac{1}{n}\hat{\mathbf{x}}\hat{\mathbf{x}}^\top)$. *Hint:* $d\mu = \frac{1}{n}\mathbf{1}^\top d\mathbf{x}$ and $d\sigma = \frac{1}{n}\hat{\mathbf{x}}^\top d\mathbf{x}$.
   2. Show that $\mathbf{1}$ and $\hat{\mathbf{x}}$ are orthogonal and that $\|\hat{\mathbf{x}}\|^2 = n$. Conclude that $\sigma\mathbf{J}$ is the orthogonal projection onto the complement of $\operatorname{span}\{\mathbf{1}, \hat{\mathbf{x}}\}$ and that $\operatorname{rank}\mathbf{J} = n-2$ for $n \geq 2$. Which two changes of the input can LayerNorm not see, and why?
   3. Check (a) and the two null vectors against the Jacobian computed by automatic differentiation for a random $\mathbf{x} \in \mathbb{R}^5$, and print the eigenvalues of $\mathbf{J}$.
6. **Log-determinant gradient.** ● A normalizing flow (Rezende and Mohamed 2015) passes a random vector $\mathbf{X}$ through invertible layers. For one layer $\mathbf{Y} = \mathbf{g}(\mathbf{X})$, the log-density of $\mathbf{Y}$ at $\mathbf{g}(\mathbf{x})$ is $\log p_{\mathbf{X}}(\mathbf{x}) - \log|\det \mathbf{J}_{\mathbf{g}}(\mathbf{x})|$, by the change-of-variables formula for densities. For a linear layer $\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$ the correction is $-\log|\det \mathbf{A}|$, so maximum-likelihood training differentiates $\log|\det \mathbf{A}|$ with respect to $\mathbf{A}$.
   1. Expand $\det(\mathbf{I}+t\mathbf{M})$ to first order in t and use $\det(\mathbf{A}+d\mathbf{A}) = \det\mathbf{A}\,\det(\mathbf{I}+\mathbf{A}^{-1}d\mathbf{A})$ to derive Jacobi's formula $d\det\mathbf{A} = \det\mathbf{A}\,\operatorname{tr}(\mathbf{A}^{-1}d\mathbf{A})$ for invertible $\mathbf{A}$. Conclude with Equation 34.37 that $\nabla_{\mathbf{A}} \log|\det\mathbf{A}| = \mathbf{A}^{-\top}$. Why does the sign of $\det\mathbf{A}$ not matter?
   2. Check the identity on a random invertible 3×3 matrix by central differences of `np.linalg.slogdet`.
   3. How does the norm of the gradient behave as $\mathbf{A}$ approaches a singular matrix? What does this imply for a flow layer whose weight matrix is nearly singular?
7. **Gradient of the spectral norm.** ● Spectral normalization (Miyato et al. 2018) divides each weight matrix $\mathbf{W}$ of a network by its largest singular value $\sigma_1(\mathbf{W})$, so training differentiates σ_1.
   1. Let $\mathbf{S}$ be a real symmetric matrix with a simple eigenvalue λ and unit eigenvector $\mathbf{q}$, and perturb it to $\mathbf{S} + t\mathbf{E}$ with $\mathbf{E}$ symmetric. Take as given that $\lambda(t)$ and $\mathbf{q}(t)$, defined by $(\mathbf{S}+t\mathbf{E})\mathbf{q} = \lambda\mathbf{q}$ and $\mathbf{q}^\top\mathbf{q} = 1$, are differentiable near $t = 0$ (the implicit function theorem gives this because λ is simple). Differentiate both equations at $t = 0$ to show the Hellmann–Feynman theorem $\lambda'(0) = \mathbf{q}^\top\mathbf{E}\,\mathbf{q}$, and give $\nabla_{\mathbf{S}}\lambda$ for the inner product $\operatorname{tr}(\mathbf{A}^\top\mathbf{B})$.
   2. Apply (a) to $\sigma_1(\mathbf{W})^2 = \lambda_{\max}(\mathbf{W}^\top\mathbf{W})$ to show that $\nabla_{\mathbf{W}}\sigma_1 = \mathbf{u}_1\mathbf{v}_1^\top$ when $\sigma_1 > 0$ is simple, where $\mathbf{u}_1$ and $\mathbf{v}_1$ are the top left and right singular vectors. Why is $\sigma_1 > 0$ needed? Consider $\mathbf{W} = \mathbf{w} \in \mathbb{R}^{n\times 1}$ near $\mathbf{w} = \mathbf{0}$. Check the formula by central differences on a random 5×3 matrix in NumPy.
   3. Compute $\sigma_1(\mathbf{I} + t\,\operatorname{diag}(1,-1))$ for small t of both signs. Is σ_1 differentiable at the 2×2 identity, and which hypothesis of (a) fails there?

   Adapted from Alan Edelman and Steven G. Johnson, Matrix Calculus for Machine Learning and Beyond, problem set 2, MIT 18.S096, IAP 2023, Problem 3.

34.5 Automatic Differentiation

Throughout the Basics part of this book, every gradient came from a single call to the framework's automatic differentiation engine. The previous section showed what that call computes mathematically: the derivative of a network is a product of Jacobians, one per layer, and the order in which we multiply those matrices determines the cost. A real program, however, is not a neat list of matrices; it is a sequence of additions, multiplications, and function calls. How does a framework extract those factors from ordinary code, and how does it multiply them in the cheap order?

How much the cheap order saves becomes unmistakable on a modern network. Consider

a model with 10^8 parameters that outputs a single scalar loss ℓ. Every training step needs the derivative of ℓ with respect to all 10^8 parameters. The direct finite-difference approach nudges one parameter at a time, reruns the network, and divides the change in ℓ by the nudge. That requires 10^8 runs per step. At 10 ms per run, computing a single gradient would take 10^6 s, nearly twelve days, and the choice of step size would still introduce truncation and rounding errors. Backpropagation returns all 10^8 derivatives, exact up to floating-point rounding, for roughly the cost of three forward runs, about 30 ms. This section explains where that factor of 10^8 goes.

The core idea is surprisingly simple: a product of Jacobians can be evaluated from either end. Starting from the input end, each pass propagates one input direction forward, so 10^8 inputs demand 10^8 passes. Starting from the loss end, each pass propagates one output direction backward, and a scalar loss has only a single output.

In Section 1.5, we saw how to invoke both modes in a deep learning framework. Here we open the hood. We will build forward mode and reverse mode from scratch in a few dozen lines of Python, prove that they return true derivatives, trace a backward pass by hand, and measure the cost of each mode. We will then compose the two modes to compute second-order curvature along a direction and to differentiate the solution of an equation without differentiating through the solver itself. Two takeaways stand above the rest: evaluating a program on *dual numbers* yields derivatives automatically (the section's one proposition), and every sweep costs only a small multiple of one program evaluation, with forward mode needing one sweep per input direction and reverse mode one per output direction. Readers on a first pass may save Section 34.5.3 for a second reading.

Three small running examples will anchor the discussion: the chapter's log-sum-exp $\ell(\mathbf{x}) = \log \sum_j e^{x_j}$, whose gradient is the softmax; the plane map $\mathbf{f}(x, y) = (x + \sin y,\ y + x^2/2)$ from the previous section; and the polynomial expression $y = (uv + u)^2$, which is small enough to trace completely by hand.

We use the following imports throughout this section.

```
import numpy as np
import tensorflow as tf
```

34.5.1 Forward Mode and Dual Numbers

34.5.1.1 Dual Numbers

We want both the value of a program and its derivative from a single run, with no step size to tune and no symbolic formula for f' written down in advance. The trick is a remarkably small extension of the real numbers. We adjoin a new symbol ε that is nonzero, yet whose square vanishes:

$$\varepsilon^2 = 0, \qquad \varepsilon \neq 0. \tag{34.42}$$

With this single rule in place, we compute with expressions of the form $a + b\varepsilon$, called *dual numbers*, using the ordinary rules of algebra. Every differentiation rule in Section 34.1 works by discarding second-order terms, and setting $\varepsilon^2 = 0$ builds that discard directly into the arithmetic.

Let us see what happens when we apply this rule to $3+\varepsilon$. Squaring and cubing it yields

$$(3+\varepsilon)^2 = 9 + 6\varepsilon + \varepsilon^2 = 9 + 6\varepsilon, \qquad (3+\varepsilon)^3 = (9+6\varepsilon)(3+\varepsilon) = 27 + 27\varepsilon.$$

Look at the coefficients of ε: 6 and 27 are the derivatives of x^2 and x^3 at $x=3$. We did not invoke any differentiation rule; the derivatives fell straight out of multiplication. The same holds for any product. Multiplying two dual numbers and dropping the ε^2 term gives

$$(a+b\varepsilon)(c+d\varepsilon) = ac + (ad+bc)\,\varepsilon. \tag{34.43}$$

If b and d are the derivatives of two quantities whose values are a and c, then $ad+bc$ is the derivative of their product. Multiplication of dual numbers simply is the product rule.

A skeptical reader may object that no number can be nonzero and still have a zero square. No real number can, of course, but a matrix easily can. Take $\varepsilon = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$. Then $\varepsilon^2 = \mathbf{0}$, the dual number $a+b\varepsilon$ becomes the 2×2 matrix $\left(\begin{smallmatrix} a & b \\ 0 & a \end{smallmatrix}\right)$, and ordinary matrix multiplication $\left(\begin{smallmatrix} a & b \\ 0 & a \end{smallmatrix}\right)\left(\begin{smallmatrix} c & d \\ 0 & c \end{smallmatrix}\right) = \left(\begin{smallmatrix} ac & ad+bc \\ 0 & ac \end{smallmatrix}\right)$ reproduces Equation 34.43. Dual numbers are just as concrete as 2×2 matrices, much as complex numbers are as concrete as rotations and scalings of the plane.

Real programs also call elementary functions such as sin, exp, and log. For a function φ given by its Taylor series around a, substituting $a+b\varepsilon$ into the series kills every term from $(b\varepsilon)^2$ onward, leaving only the linear approximation:

$$\varphi(a+b\varepsilon) = \varphi(a) + \varphi'(a)\,b\,\varepsilon.$$

Thus $e^{a+b\varepsilon} = e^a + e^a b\,\varepsilon$ and $\sin(a+b\varepsilon) = \sin a + (\cos a)\,b\,\varepsilon$ are forced by the algebra itself. For a primitive that is merely differentiable at a rather than analytic, we adopt the formula above as the definition of its action on dual numbers. In either case, the ε-part obeys the chain rule: the incoming derivative b of the argument is multiplied by the local derivative $\varphi'(a)$.

Proposition (dual numbers compute derivatives). *Let f be an expression built from constants, the identity, sums, products, and primitives φ (such as* sin*,* exp*,* log*). Suppose each primitive is differentiable at the argument it receives when f is evaluated at x (for* log*, a positive argument). Then evaluating the same expression on the dual number $x+\varepsilon$ gives*

$$f(x+\varepsilon) = f(x) + f'(x)\,\varepsilon. \tag{34.44}$$

Proof. We proceed by structural induction on the expression. A constant c is represented as $c+0\varepsilon$ and the identity as $x+1\varepsilon$, so their ε-parts are their derivatives, 0 and 1. Now suppose two subexpressions satisfy $g(x+\varepsilon) = g(x) + g'(x)\varepsilon$ and $h(x+\varepsilon) = h(x) + h'(x)\varepsilon$. Their sum has ε-part $g'+h' = (g+h)'$. By Equation 34.43, their product has ε-part $g'h + gh' = (gh)'$. Finally, applying a primitive φ to g produces, by the rule above with $a = g(x)$ and $b = g'(x)$, the ε-part $\varphi'(g(x))\,g'(x) = (\varphi\circ g)'(x)$. Every way of combining subexpressions preserves the property, so the full expression satisfies Equation 34.44. ■

To differentiate a program, we therefore run it on $x+\varepsilon$ and read off the ε-part of the output. Programs with loops and branches are handled automatically as well: for any fixed input, the program executes a single concrete sequence of elementary operations, which is an

expression of this exact form, and the dual-number run differentiates that execution path (Section 1.5.3.1 demonstrates this in the frameworks). Note, however, that the result is the derivative of the executed path, which equals $f'(x)$ only if all nearby inputs take the same branches. A program that returns `x` if `x != 0` and `0.0` otherwise computes the identity, yet at $x = 0$ it executes the constant branch, and the dual-number run reports slope 0. This is the failure we met with $\mathrm{ReLU}(x) - \mathrm{ReLU}(-x)$ in Section 34.1.6.3. The input's ε-part, here 1, is called the *seed*. No symbolic expression for f' is ever constructed and no step size is chosen; the only error is floating-point rounding.

34.5.1.2 A Forward-Mode Engine

Operator overloading turns this algebra directly into code. The `Dual` class below stores a value a together with its derivative part b, which we call the *tangent* and write as $\dot{v}$ for a quantity v. It implements Equation 34.43 for $*$ and equips `sin`, `exp`, and `log` with the primitive rule. A class counter `ops` tallies how many primitive operations have executed, which we will use to measure cost in Section 34.5.2.4.

```
class Dual:
    """A dual number a + b*eps with eps^2 = 0; b carries the derivative."""
    ops = 0                                          # primitive operations run
    def __init__(self, a, b=0.0):
        self.a, self.b = a, b                        # value, tangent
    def __add__(self, o):
        o = o if isinstance(o, Dual) else Dual(o)
        Dual.ops += 1
        return Dual(self.a + o.a, self.b + o.b)
    __radd__ = __add__
    def __mul__(self, o):
        o = o if isinstance(o, Dual) else Dual(o)
        Dual.ops += 1
        return Dual(self.a * o.a, self.a * o.b + self.b * o.a)   # product rule
    __rmul__ = __mul__
    def sin(self):
        Dual.ops += 1
        return Dual(np.sin(self.a), np.cos(self.a) * self.b)     # chain rule
    def exp(self):
        Dual.ops += 1
        return Dual(np.exp(self.a), np.exp(self.a) * self.b)
    def log(self):
        Dual.ops += 1
        return Dual(np.log(self.a), self.b / self.a)
    def __repr__(self):
        return f'{np.round(self.a, 6)} + {np.round(self.b, 6)} eps'
```

Let us test `Dual` on $f(x) = \sin(x^2) + e^x$ at $x = 1.3$ by passing in $1.3 + \varepsilon$, and compare its ε-part against the hand-derived derivative $f'(x) = 2x\cos(x^2) + e^x$:

```
def f(x):
    return (x * x).sin() + x.exp()                   # sin(x^2) + e^x, in dual algebra

x0 = 1.3
```

```
out = f(Dual(x0, 1.0))                              # seed the derivative with 1
exact = 2 * x0 * np.cos(x0**2) + np.exp(x0)         # f'(x) by hand
print('dual result :', out)
print('value f(x)  :', np.sin(x0**2) + np.exp(x0))
print("derivative  : dual %.6f  vs  exact %.6f" % (out.b, exact))
```

```
dual result : 4.6622 + 3.360101 eps
value f(x)  : 4.662200318713363
derivative  : dual 3.360101  vs  exact 3.360101
```

A single run returns both the function value 4.6622 and the derivative 3.360101, matching the analytic formula to every printed digit.

A single-variable example, however, hides the main limitation of forward mode. Consider log-sum-exp at the three-dimensional input $\mathbf{x} = (1, -0.5, 2)$, whose gradient is the softmax $\partial \ell / \partial x_j = e^{x_j} / \sum_k e^{x_k} = p_j$. How many passes does forward mode need to obtain this full gradient? Seeding input j with 1 and all other inputs with 0 yields the single partial derivative $\partial \ell / \partial x_j$ in the output's ε-part, and nothing else.

```
def lse_dual(xs):                                   # log-sum-exp, in dual algebra
    total = 0.0
    for x in xs:
        total = total + x.exp()
    return total.log()

x_lse = [1.0, -0.5, 2.0]
p = np.exp(x_lse) / np.exp(x_lse).sum()             # softmax, the known gradient
for j in range(3):                                  # one pass per input direction
    out = lse_dual([Dual(x, 1.0 if k == j else 0.0) for k, x in enumerate(x_lse)])
    print(f'seed e{j + 1}: value {out.a:.6f}, partial {out.b:.6f}, '
          f'softmax {p[j]:.6f}')
```

```
seed e1: value 2.371539, partial 0.253716, softmax 0.253716
seed e2: value 2.371539, partial 0.056612, softmax 0.056612
seed e3: value 2.371539, partial 0.689672, softmax 0.689672
```

It takes three passes. Each pass recomputes the same value 2.371539 and recovers just one softmax entry: 0.253716, 0.056612, or 0.689672. More generally, a gradient over n inputs requires n passes. For the 10^8-parameter network from the opening, that puts us right back at 10^8 runs of the program. Forward mode eliminates the finite-difference step size, but not the number of runs.

34.5.1.3 Vector Tangents and Jacobian Columns

Now consider a vector-valued map $\mathbf{f} : \mathbb{R}^n \to \mathbb{R}^m$ with $m \times n$ Jacobian $\mathbf{J}$. What does a single forward pass compute? Suppose we seed the inputs with an arbitrary direction $\mathbf{v}$, setting input j to $x_j + v_j \varepsilon$. Applying our proposition to the one-dimensional slice $t \mapsto f_i(\mathbf{x} + t\mathbf{v})$ shows that output i emerges as $f_i(\mathbf{x}) + (\nabla f_i \cdot \mathbf{v})\, \varepsilon$. Collecting the ε-parts across all m outputs therefore produces the vector $\mathbf{J}\mathbf{v}$, known as the *Jacobian–vector product* (JVP). When $\mathbf{v}$ is the j-th standard basis vector $\mathbf{e}_j$, the JVP picks out column j of $\mathbf{J}$. One forward pass carries one input direction through the entire map.

Let us verify this on the plane map $\mathbf{f}(x, y) = (x + \sin y,\ y + x^2/2)$ at $(0.5, 0.5)$. Its Jacobian, whose row i holds the partial derivatives of output i, is

$$\mathbf{J} = \begin{pmatrix} 1 & \cos y \\ x & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0.877583 \\ 0.5 & 1 \end{pmatrix}.$$

Two forward passes, seeded first with $\mathbf{e}_1$ and then with $\mathbf{e}_2$, recover its two columns.

```
def plane_dual(x, y):
    return [x + y.sin(), y + 0.5 * (x * x)]        # (x + sin y, y + x^2/2)

z0 = (0.5, 0.5)
cols = []
for seed in ((1.0, 0.0), (0.0, 1.0)):              # e1, then e2
    out = plane_dual(Dual(z0[0], seed[0]), Dual(z0[1], seed[1]))
    cols.append([out[0].b, out[1].b])              # tangent = J @ seed, a column
J_fwd = np.array(cols).T                           # columns side by side
J_exact = np.array([[1.0, np.cos(0.5)], [0.5, 1.0]])
print('forward-mode J:\n', J_fwd.round(6))
print('matches the analytic Jacobian:', np.allclose(J_fwd, J_exact))
```

```
forward-mode J:
 [[1.       0.877583]
 [0.5      1.      ]]
matches the analytic Jacobian: True
```

Notice that nothing in `Dual` forces the tangent to be a scalar. If we give x the vector tangent $(1, 0)$ and y the vector tangent $(0, 1)$, every operation propagates both input directions simultaneously, and the tangent of output i becomes row i of $\mathbf{J}$. Can a single pass recover the entire matrix?

```
out = plane_dual(Dual(z0[0], np.array([1.0, 0.0])),     # identity seed:
                 Dual(z0[1], np.array([0.0, 1.0])))     # both directions at once
J_one = np.array([out[0].b, out[1].b])                  # row i = tangent of f_i
print('one-pass J:\n', J_one.round(6))
print('matches the analytic Jacobian:', np.allclose(J_one, J_exact))
```

```
one-pass J:
 [[1.       0.877583]
 [0.5      1.      ]]
matches the analytic Jacobian: True
```

It can, though the savings are illusory. Every tangent operation now acts on arrays of length n, so that single pass performs roughly n times as much arithmetic as a scalar pass. Counting passes and counting arithmetic are not the same thing, and we will measure arithmetic directly in Section 34.5.2.4. For a scalar loss with 10^8 inputs, forward mode demands either 10^8 scalar passes or one pass carrying tangents of length 10^8. Either way, its total work scales with n runs of the program.

34.5.2 Reverse Mode and the Tape

34.5.2.1 Two Orders of One Product

To eliminate the factor of n, we must multiply the chain of derivatives in the opposite order. In Section 34.4, we saw that the Jacobian of a K-step program $\mathbf{f} = \mathbf{f}_K \circ \cdots \circ \mathbf{f}_1$ is the product of the step Jacobians,

$$\mathbf{J} = \mathbf{J}_K \mathbf{J}_{K-1} \cdots \mathbf{J}_1, \tag{34.45}$$

and that the parenthesization of this product governs its cost: for three layers of width 1000 multiplied by a row vector on the left, associating from the left takes 3×10^6 multiplications, whereas associating from the right takes 2×10^9 (Figure 34.22). An automatic differentiation engine never materializes these Jacobian matrices explicitly. Instead, it propagates a seed vector through one step after another. Forward mode multiplies a column direction $\mathbf{v}$ in from the right; reverse mode multiplies a row vector $\mathbf{u}^\top$ in from the left:

$$\mathbf{J}\mathbf{v} = \mathbf{J}_K\Big(\cdots(\mathbf{J}_2(\mathbf{J}_1\mathbf{v}))\Big), \qquad \mathbf{u}^\top\mathbf{J} = \Big(((\mathbf{u}^\top\mathbf{J}_K)\mathbf{J}_{K-1})\cdots\Big)\mathbf{J}_1. \tag{34.46}$$

Because a seed vector is present from the start, every step is a matrix–vector product and never a matrix–matrix product. On the left, an input direction travels forward to produce the JVP $\mathbf{J}\mathbf{v}$. On the right, an output direction travels backward to produce the *vector–Jacobian product* (VJP) $\mathbf{u}^\top\mathbf{J}$, a linear combination of the rows of $\mathbf{J}$ weighted by $\mathbf{u}$. Setting $\mathbf{u} = \mathbf{e}_i$ extracts row i of $\mathbf{J}$.

From this symmetry comes the fundamental cost rule of automatic differentiation. Forward mode requires one sweep per input direction, while reverse mode requires one sweep per output direction, and each sweep costs only a small constant multiple of evaluating the program once. For programs built from $+, -, \times, \div$, Baur and Strassen proved that computing all partial derivatives together takes at most a fixed multiple of the program's own operation count, between three and five depending on which operations are counted (Baur and Strassen 1983). A scalar loss has a $1 \times n$ Jacobian, a single row, so one reverse sweep seeded with 1 returns the entire gradient at once. Figure 34.23 illustrates this rule in terms of matrix shapes.

The two modes evaluate the exact same matrix product from opposite ends. Which end wins depends solely on the shape of $\mathbf{J}$: the cheaper mode is the one whose number of seeds matches the shorter side. A neural network loss, with one scalar output and millions or billions of parameters, has the most lopsided Jacobian imaginable.

34.5.2.2 The Tape

Forward mode and reverse mode propagate fundamentally different quantities. In a program taking input x to output y, the tangent $\dot{v}$ of an intermediate variable v measures how fast v changes when the input moves in the direction $\dot{x}$. By contrast, the *adjoint* $\bar{v}$ introduced in Section 34.3 is the total derivative of the final output y with respect to v, summed over all paths from v to y. A tangent depends only on the steps *before* v, whereas an adjoint depends on the steps *after* v. In $y = v^2$ with $v = 3x$, for example, we have $\dot{v} = 3\dot{x}$ coming from below and $\bar{v} = 2v$ coming from above.

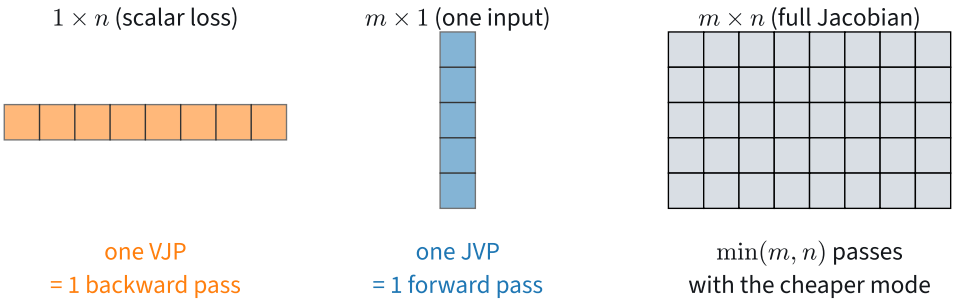

Figure 34.23: The shape of the Jacobian decides the cheaper mode. A scalar loss has a $1 \times n$ Jacobian: one row, one VJP, one backward pass. A map with one input has an $m \times 1$ Jacobian: one column, one JVP, one forward pass. A full $m \times n$ Jacobian costs $\min(m, n)$ passes with the cheaper mode.

This asymmetry dictates how each mode executes (Figure 34.24). Because tangents move in the same direction as the values, forward mode finishes in a single pass alongside the program itself; `Dual` never needs to remember past intermediates. Adjoints, however, travel against the flow of execution: computing the adjoint of a node requires the adjoints of every node that consumes it, and those exist only after the program has reached its output. Reverse mode therefore runs in two phases. First it executes the program forward while recording every elementary operation; then it replays that record in reverse. The record is called the *tape*, or Wengert list, after the list of elementary operations that Wengert (1964) introduced for forward mode; reversing the list yields reverse mode, introduced by Linnainmaa (1970) .

We can build a working reverse-mode engine in about forty lines of Python. Each node on the tape stores its forward value, its parent nodes, and a small backward closure. Given the node's own adjoint g, that closure adds the node's contribution to each parent's adjoint: for $c = a + b$ it adds g to both parents, while for $c = ab$ it adds $b\,g$ to $\bar{a}$ and $a\,g$ to $\bar{b}$. The function `backprop` topologically sorts the graph so that every node appears after its parents, seeds the output adjoint with 1, and invokes the closures in reverse order. Just like `Dual`, the class maintains an `ops` counter across both forward and backward steps.

```
class Var:
    """A scalar node on the autodiff tape; .grad accumulates the adjoint."""
    ops = 0                                          # recorded ops + backward steps
    def __init__(self, value, parents=(), backward=lambda g: None):
        self.value = value
        self.grad = 0.0
        self._parents = parents                      # nodes this one depends on
        self._backward = backward                    # pushes adjoint to parents
    def __add__(self, o):
        o = o if isinstance(o, Var) else Var(o)
        Var.ops += 1
        out = Var(self.value + o.value, (self, o))
        def back(g):                                 # d(a+b) = 1*g to each parent
            Var.ops += 1
```

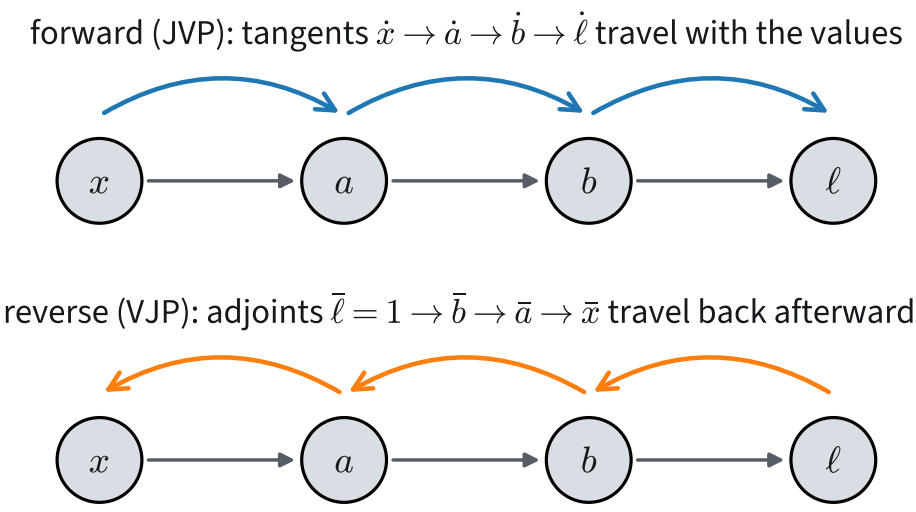

Figure 34.24: Forward and reverse mode on a chain $x \to a \to b \to \ell$. Both evaluate the chain from left to right (gray). Forward mode (top) carries the tangents $\dot{v}$ along with the values, one input direction per sweep. Reverse mode (bottom) runs the chain first and then carries the adjoints $\bar{v}$, the total derivatives of ℓ with respect to v, back from the seed $\bar{\ell} = 1$, one output direction per sweep, which for a scalar loss is the whole gradient.

```
            self.grad += g; o.grad += g
        out._backward = back
        return out
    __radd__ = __add__
    def __mul__(self, o):
        o = o if isinstance(o, Var) else Var(o)
        Var.ops += 1
        out = Var(self.value * o.value, (self, o))
        def back(g):                                # product rule, reversed
            Var.ops += 1
            self.grad += o.value * g; o.grad += self.value * g
        out._backward = back
        return out
    __rmul__ = __mul__

def backprop(node):
    """Topologically sort the tape and replay it backward from `node`."""
    order, seen = [], set()
    def visit(v):
        if v not in seen:
            seen.add(v)
            for p in v._parents:
                visit(p)
            order.append(v)
    visit(node)
```

```
    node.grad = 1.0                                 # seed the output adjoint
    for v in reversed(order):
        v._backward(v.grad)
```

Although `Var` implements only `+` and `*`, that is already enough for our third running example, $y = (uv + u)^2$. Before running the code, let us trace the entire backward sweep by hand at $u = 2$, $v = -3$. The forward pass records three elementary operations: $t = uv = -6$, then $r = t + u = -4$, and finally $y = r \cdot r = 16$. The backward sweep visits nodes in a reverse topological order such as y, r, t, u, v, ensuring that every node is processed only after all nodes that depend on it (`backprop` happens to visit v before u, which is equally valid). Each adjoint is the sum of contributions arriving along its outgoing edges, where each contribution multiplies the consumer's adjoint by the local derivative:

node	outgoing edges and their contributions	adjoint
y	none: the seed	$\bar{y} = 1$
r	both arguments of $y = r \cdot r$: $\bar{y}\, r + \bar{y}\, r$	$\bar{r} = -8$
t	$r = t + u$: $\bar{r} \cdot 1$	$\bar{t} = -8$
u	$r = t + u$ and $t = uv$: $\bar{r} \cdot 1 + \bar{t} \cdot v$	$\bar{u} = -8 + 24 = 16$
v	$t = uv$: $\bar{t} \cdot u$	$\bar{v} = -16$

Direct differentiation of $y = (uv+u)^2$ confirms both answers: $\partial y/\partial u = 2(uv+u)(v+1) = 2(-4)(-2) = 16$ and $\partial y/\partial v = 2(uv + u)\, u = 2(-4)(2) = -16$. Notice how crucial accumulation is at two places in the graph: r feeds both arguments of the final product, and u feeds both t and r (Figure 34.25). Overwriting instead of adding would leave $\bar{r} = -4$, and even with $\bar{r}$ fixed it would leave $\bar{u}$ as either -8 or 24, depending on which closure happened to run last. Because an adjoint sums over all outgoing edges (the chain rule's sum over paths), every backward closure must accumulate with `+=`.

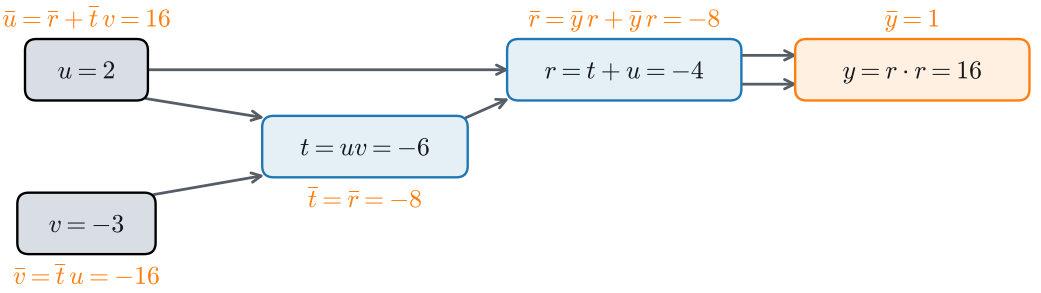

Figure 34.25: The tape of $y = (uv + u)^2$ at $u = 2$, $v = -3$. Each box shows the forward value of its node; the orange label shows its adjoint, the derivative of y with respect to that node. The graph is a diamond, not a chain: u feeds both $t = uv$ and $r = t + u$, and r feeds both arguments of $y = r \cdot r$, so the adjoints of r and u are sums of two contributions.

Recording the same expression with `Var` and running a single backward sweep gives:

```
u, v = Var(2.0), Var(-3.0)
r = u * v + u                                   # t = uv, then r = t + u
y = r * r                                       # r feeds both arguments
backprop(y)
print('our tape  : dy/du = %.4f  dy/dv = %.4f' % (u.grad, v.grad))
```

```
our tape  : dy/du = 16.0000  dy/dv = -16.0000
```

These match $\bar{u}$ and $\bar{v}$ from our hand trace. A production deep learning framework runs the exact same algorithm at tensor scale and produces the same two derivatives:

```
ut, vt = tf.Variable(2.0), tf.Variable(-3.0)
with tf.GradientTape() as tape:                 # framework autograd
    rt = ut * vt + ut
    yt = rt * rt
du, dv = tape.gradient(yt, [ut, vt])
print('tensorflow: dy/du = %.4f  dy/dv = %.4f' % (float(du), float(dv)))
```

```
tensorflow: dy/du = 16.0000  dy/dv = -16.0000
```

A production framework differs from our toy `Var` engine in three practical respects, none of which alters the underlying algorithm. First, its nodes hold entire tensors rather than scalars, so each backward closure implements the VJP of a whole tensor operation, such as $\bar{\mathbf{X}} = \bar{\mathbf{Y}}\mathbf{W}^\top$ and $\bar{\mathbf{W}} = \mathbf{X}^\top\bar{\mathbf{Y}}$ (Section 34.4.3.2) for matrix multiplication. Second, its library of primitives is much larger, each paired with a hand-tuned VJP rule. Third, frameworks construct the computation graph in one of two ways. An *eager tape* records operations dynamically as the program executes, just as `Var` does. A *tracer*, by contrast, runs the program once on abstract placeholder inputs to capture its sequence of operations, builds the linearized forward-mode rule for each step, and then transposes and reverses the sequence. Both routes produce the exact same backward sweep. Applied to a neural network, this reverse-mode sweep is what deep learning calls *backpropagation* (Rumelhart et al. 1986).

TensorFlow records eagerly inside a `GradientTape` context, and `tape.gradient` replays the tape in reverse.

The frameworks also inherit the hypothesis of the dual-number proposition: each primitive must be differentiable at the argument it receives. Masking is where this hypothesis fails most often in practice. Suppose that we sum $\log x_i$ over the real entries of a padded vector, and that a `where` sets the padded entries to zero. A `where` chooses between two values that have both been computed, so log still runs on the padding, here $x_2 = 0$. The forward pass is unharmed: the $-\infty$ is discarded and the loss is $\log 2 \approx 0.6931$. On the backward sweep, however, `where` sends the adjoint 0 into the discarded branch, and the VJP of log multiplies it by the local derivative $1/0 = \infty$. In floating-point arithmetic $0 \cdot \infty$ is not 0 but NaN.

```
x = tf.Variable([2.0, 0.0])                     # x[1] is padding
mask = tf.constant([True, False])
with tf.GradientTape(persistent=True) as tape:
    one = tf.reduce_sum(tf.where(mask, tf.math.log(x), 0.0))
    safe = tf.where(mask, x, 1.0)               # padding never reaches log
    two = tf.reduce_sum(tf.where(mask, tf.math.log(safe), 0.0))
g1, g2 = tape.gradient(one, x), tape.gradient(two, x)
```

```
print('one where   : loss = %.4f, grad =' % float(one), g1.numpy())
print('double where: loss = %.4f, grad =' % float(two), g2.numpy())
```

```
one where   : loss = 0.6931, grad = [0.5 nan]
double where: loss = 0.6931, grad = [0.5 0. ]
```

The first line reports the gradient $(0.5, \text{NaN})$, although the loss does not depend on the padded entry at all and the true derivative there is 0. A single NaN is not a local blemish: every parameter upstream of x_2 receives it. The second line shows the standard remedy, the *double where*. An inner `where` replaces the masked entries by a harmless value, here 1, before the primitive sees them, so that no infinite local derivative is ever formed and the gradient is $(0.5, 0)$. Clamping the argument away from the edge of the domain serves the same purpose. The same trap awaits $\sqrt{x}$ at 0, and with it a norm computed as $\sqrt{\sum_i x_i^2}$ at $\mathbf{x} = \mathbf{0}$.

34.5.2.3 Parameter Gradients

So far, the Jacobian product Equation 34.45 has tracked derivatives with respect to the network's input, whereas training needs derivatives with respect to its weights. Fortunately, the weight gradients drop out of the very same backward sweep via the layer VJP rule (Section 34.4.3.2). For a linear layer $\mathbf{h}_k = \mathbf{W}_k \mathbf{h}_{k-1}$ with weight matrix $\mathbf{W}_k$ of shape $d_k \times d_{k-1}$, that rule reads

$$\nabla_{\mathbf{W}_k} \ell = \bar{\mathbf{h}}_k \, \mathbf{h}_{k-1}^{\top}, \tag{34.47}$$

the outer product of the adjoint arriving from above and the activation stored from below. Intuitively, a weight matters in proportion to both how strongly its output affects the loss and how large its input activation was. What matters for our cost analysis is how much arithmetic this rule takes.

Forming the outer product $\bar{\mathbf{h}}_k \, \mathbf{h}_{k-1}^{\top}$ takes $d_k d_{k-1}$ multiplications, the same count as the forward matrix–vector product $\mathbf{W}_k \mathbf{h}_{k-1}$. Passing the adjoint down to the previous layer, $\bar{\mathbf{h}}_{k-1}^{\top} = \bar{\mathbf{h}}_k^{\top} \mathbf{W}_k$, takes another $d_k d_{k-1}$ multiplications. Measured in multiplications, the backward sweep therefore costs roughly twice a forward pass, so a forward pass plus a backward sweep costs about three forward passes, matching the 30 ms figure from the opening. Forward mode, by contrast, would have to treat every individual weight as its own input direction, requiring $d_k d_{k-1}$ passes for a single layer alone. That is why no framework trains neural networks in forward mode.

34.5.2.4 Cost of the Two Modes

Because we built both engines ourselves, we can measure their operation counts directly instead of relying on asymptotic arguments. Take $f(\mathbf{x}) = (\sum_j x_j^2)^2$ on $n = 200$ inputs $x_j = 0.01\, j$ for $j = 1, \dots, 200$. We choose a polynomial built solely from $+$ and $\times$ so that `Var` can record it without adding `exp` and `log` closures (which would mirror the methods of `Dual`). Its gradient is $\nabla f = 4(\sum_j x_j^2)\mathbf{x}$, and one plain evaluation runs $2n + 1 = 401$ primitive operations: n squares, n additions, and one final square. Forward mode will clearly need 200 passes of 401 operations each. Before reading the output below, pause and guess how many operations reverse mode will take.

```
n = 200
def f(xs):                          # f: R^n -> R, from + and * alone
    total = 0.0
    for x in xs:
        total = total + x * x
    return total * total            # (sum of squares)^2

xs0 = [0.01 * (j + 1) for j in range(n)]
Dual.ops = 0
grad_fwd = [f([Dual(x, 1.0 if k == j else 0.0) for k, x in enumerate(xs0)]).b
            for j in range(n)]   # forward mode: one pass per input direction
Var.ops = 0
xs = [Var(x) for x in xs0]          # reverse mode: one recorded pass...
backprop(f(xs))                     # ...and one backward sweep for all n partials
grad_rev = [x.grad for x in xs]

gap = max(abs(a - b) for a, b in zip(grad_fwd, grad_rev))
print(f'forward mode: {Dual.ops:,} operations ({n} passes of {2 * n + 1})')
print(f'reverse mode: {Var.ops:,} operations (one recorded pass, one sweep)')
print(f'ratio {Dual.ops / Var.ops:.1f}, largest gradient difference {gap:.1e}')
```

```
forward mode: 80,200 operations (200 passes of 401)
reverse mode: 802 operations (one recorded pass, one sweep)
ratio 100.0, largest gradient difference 0.0e+00
```

Forward mode executed $80{,}200 = n(2n+1)$ operations, whereas reverse mode executed only $802 = 2(2n+1)$: 401 recorded during the forward pass and 401 backward closures during the sweep. The ratio is $100 = n/2$, and the two gradients agree to every printed digit. For these engines, pass counts differ by a factor of n and operation counts by $n/2$; at $n = 10^8$, that recovers the factor from the opening up to the same small constant.

At first glance, the measured factor of two might seem to contradict the factor of three we quoted earlier. It does not: `Var.ops` counts each backward closure as a single operation, even though the closure for multiplication performs two multiplications of its own. Counting scalar multiplications directly gives 402 on the backward sweep against 201 on the forward pass, so computing the value and gradient together costs three times the value alone, just as it did for the linear layer. Including the additions that accumulate adjoints brings the backward sweep to 1204 operations and the total factor to four, still well within the Baur–Strassen bound.

Reverse mode trades memory for this speed. The tape must retain all 401 recorded intermediate values until the backward sweep consumes them, whereas forward mode, like the original program, holds only the current values alongside their tangents.

34.5.2.5 Gradient Checkpointing

A computation of T recorded steps keeps T intermediate values alive in memory until the backward sweep reaches them. In a deep neural network, those values are the activations of every layer for every example in the batch, and activation memory, rather than arithmetic, is often what caps the batch size or depth.

The simplest remedy divides the tape into segments of s steps. During the forward pass, we save only every s-th value, the T/s *checkpoints*, and discard everything in between. When

the backward sweep arrives at a segment, it recomputes that segment's s steps from its saved checkpoint onto a temporary tape, sweeps that short tape backward, and immediately frees it. At any instant, memory holds only the T/s checkpoints plus one active segment of length s. Choosing s to balance these two terms minimizes peak memory:

$$M(s) = \frac{T}{s} + s, \qquad \min_s M(s) = M(\sqrt{T}) = 2\sqrt{T}. \tag{34.48}$$

The minimum follows either from setting $M'(s) = 1 - T/s^2 = 0$ or directly from the AM–GM inequality $T/s + s \geq 2\sqrt{T}$. Peak memory now grows only as the square root of the computation length rather than linearly. Because each step is recomputed once, the extra compute is just one additional forward pass. For $T = 400$, segment lengths $s = 1, 5, 10, 20, 100, 400$ yield peak memory $M = 401, 85, 50, 40, 104, 401$, with the minimum at $s = 20 = \sqrt{400}$. At $T = 10^4$, segments of length $s = 100$ store just 200 values instead of 10,000 (Chen et al. 2016). Figure 34.26 illustrates this schedule.

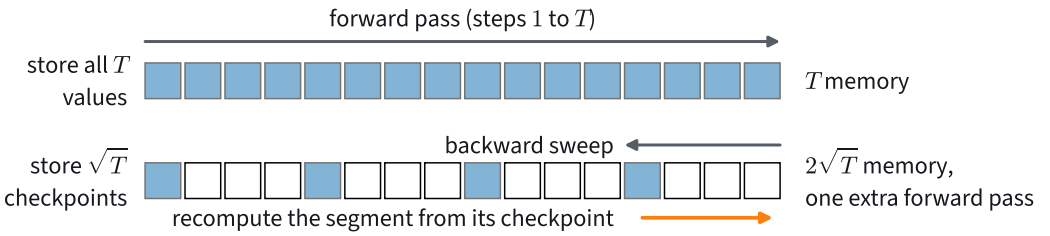

Figure 34.26: Gradient checkpointing on a tape of T steps. Plain reverse mode (top) keeps all T values until the backward sweep uses them. Checkpointing (bottom) keeps every s-th value; when the backward sweep reaches a segment, the segment is recomputed from its checkpoint and then swept. The memory is $T/s + s$, which is $2\sqrt{T}$ at $s = \sqrt{T}$, for one extra forward pass.

Importantly, checkpointing alters time and memory without changing the gradient at all, provided the recomputation is deterministic: the recomputed intermediates are then identical, so the resulting derivatives match plain reverse mode bit for bit. Deep learning frameworks expose this trade-off at the level of network blocks, storing only a checkpointed block's input and rerunning the block during backpropagation. There the proviso needs care. A rerun block draws a fresh dropout mask unless the state of the random number generator is restored, batch normalization updates its running statistics a second time, and nondeterministic GPU kernels need not reproduce the first run's bits. Applying the same idea recursively inside each segment pushes memory all the way down to $O(\log T)$ at the cost of $O(T \log T)$ recomputation.

34.5.3 Composing Jacobian Products

Automatic differentiation offers both linear operators our toy engines just built: the forward-mode JVP $\mathbf{J}\mathbf{v}$ and the reverse-mode VJP $\mathbf{u}^\top \mathbf{J}$. Once both are available as composable primitives, we can compute directional curvature, differentiate through numerical solvers, or assemble full Jacobians when needed.

34.5.3.1 Jacobian–Vector and Vector–Jacobian Products

In Section 1.5.4, we met the framework APIs for both products. Let us evaluate them on the plane map at $(0.5, 0.5)$ with $\mathbf{v} = \mathbf{u} = (1, 2)$. Using the Jacobian we computed earlier with `Dual`, we expect $\mathbf{J}\mathbf{v} = (1 + 2 \cdot 0.8776,\ 0.5 + 2) = (2.7552,\ 2.5)$ and $\mathbf{u}^\top \mathbf{J} = (1 + 2 \cdot 0.5,\ 0.8776 + 2) = (2,\ 2.8776)$, and the framework calls match these values directly.

```
def plane(z):                                       # (x + sin y, y + x^2/2)
    return tf.stack([z[0] + tf.sin(z[1]), z[1] + 0.5 * z[0]**2])

z0 = tf.constant([0.5, 0.5])
v, u = tf.constant([1.0, 2.0]), tf.constant([1.0, 2.0])
with tf.autodiff.ForwardAccumulator(z0, v) as acc:  # forward mode: J v
    y = plane(z0)
Jv = acc.jvp(y)
with tf.GradientTape(persistent=True) as tape:      # reverse mode: one tape
    tape.watch(z0)
    y = plane(z0)
uJ = tape.gradient(y, z0, output_gradients=u)       # u^T J
J = tape.jacobian(y, z0)                            # one VJP per row
print('J v   =', Jv.numpy().round(4))
print('u^T J =', uJ.numpy().round(4))
print('J     =', J.numpy().astype(float).round(4).tolist())
```

```
J v   = [2.7552 2.5   ]
u^T J = [2.     2.8776]
J     = [[1.0, 0.8776], [0.5, 1.0]]
```

Both a JVP and a VJP cost a single sweep and propagate only a vector of derivative information, though the VJP must also hold the forward intermediates on its tape. Assembling a dense $m \times n$ Jacobian takes $\min(m, n)$ sweeps in the cheaper mode plus mn numbers of storage. Materializing the full matrix is the right choice when n is small, as in this 2×2 example, or when an algorithm needs its determinant, as in normalizing flows that transform probability densities by $|\det \mathbf{J}|$.

34.5.3.2 Hessian–Vector Products

For a model with $n = 10^6$ parameters, the Hessian has 10^{12} entries, which would occupy 4 TB in float32. Yet second-order optimization methods rarely need the matrix itself. Newton's method uses the Hessian only to solve $\mathbf{H}\mathbf{d} = -\nabla \ell$ for the update step $\mathbf{d}$, and Newton–CG (or truncated Newton) solves that linear system by conjugate gradients, an iterative solver that accesses $\mathbf{H}$ solely through matrix–vector products $\mathbf{H}\mathbf{v}$ (Nocedal and Wright 2006; Martens 2010). Can we compute $\mathbf{H}\mathbf{v}$ without ever forming $\mathbf{H}$?

We can, by composing reverse mode and forward mode. Because the Hessian is the Jacobian of the gradient map $\nabla \ell$, the product $\mathbf{H}\mathbf{v}$ is simply a JVP of the gradient, measuring how fast the gradient changes along $\mathbf{v}$:

$$\mathbf{H}\mathbf{v} = \mathbf{J}_{\nabla \ell}\, \mathbf{v} = \left. \frac{d}{dt} \right|_{t=0} \nabla \ell(\mathbf{x} + t\mathbf{v}). \tag{34.49}$$

A reverse sweep evaluates $\nabla \ell$, and a forward-mode pass through that gradient computa-

tion, seeded with tangent $\mathbf{v}$, differentiates it along $\mathbf{v}$. This composition is called *forward over reverse* (Pearlmutter 1994). Regardless of the dimension n, its cost is only a small constant multiple of computing a single gradient.

Log-sum-exp gives us a clean test with a closed-form answer. Its gradient is the softmax $\mathbf{p}$, so its Hessian is the softmax Jacobian (Section 34.4, equivalently the covariance matrix of a one-hot vector $\mathbf{e}_J$ with J drawn from $\mathbf{p}$). Therefore,

$$\mathbf{H} = \operatorname{diag}(\mathbf{p}) - \mathbf{p}\mathbf{p}^\top, \qquad \mathbf{H}\mathbf{v} = \mathbf{p} \odot \mathbf{v} - \mathbf{p}\,(\mathbf{p}^\top \mathbf{v}), \tag{34.50}$$

where $\odot$ denotes entrywise multiplication. Evaluating the right-hand side requires just $3n$ multiplications and never builds an $n \times n$ matrix. At $\mathbf{x} = (1, -0.5, 2)$ and $\mathbf{v} = (1, 0.5, -1)$, we have $\mathbf{p} = (0.2537, 0.0566, 0.6897)$ and $\mathbf{p}^\top \mathbf{v} = -0.4077$, which gives

$$\mathbf{H}\mathbf{v} = (0.3571,\ 0.0514,\ -0.4085).$$

Notice that this is a genuine check, unlike testing on a quadratic $\frac{1}{2}\mathbf{x}^\top \mathbf{A}\mathbf{x}$. For a quadratic, the gradient at $\mathbf{v}$ happens to equal $\mathbf{H}\mathbf{v}$, so a buggy implementation could still pass; for log-sum-exp, $\mathbf{H}$ varies with $\mathbf{x}$, and the gradient at $\mathbf{v}$, $\operatorname{softmax}(\mathbf{v}) = (0.574, 0.348, 0.078)$, is nowhere near $\mathbf{H}\mathbf{v}$.

With both modes available, forward over reverse takes a single line of code.

```
x = tf.Variable([1.0, -0.5, 2.0])
v = tf.constant([1.0, 0.5, -1.0])
with tf.autodiff.ForwardAccumulator(x, v) as acc:   # forward over ...
    with tf.GradientTape() as tape:                 # ... reverse
        ell = tf.reduce_logsumexp(x)
    g = tape.gradient(ell, x)
Hv = acc.jvp(g)
p = tf.nn.softmax(x)
print('forward over reverse :', Hv.numpy().round(4))
print('p*v - p (p.v)        :', (p * v - p * tf.tensordot(p, v, 1)).numpy().round(4))
```

```
forward over reverse : [ 0.3571  0.0514 -0.4085]
p*v - p (p.v)        : [ 0.3571  0.0514 -0.4085]
```

The computed products match Equation 34.50 to full printed precision, without ever forming the 3×3 Hessian matrix. In Exercise 3, you will build the same product directly from our `Dual` and `Var` classes and compare forward-over-reverse with reverse-over-reverse.

34.5.3.3 Implicit Differentiation

Not every quantity of interest comes from an explicit formula. Many are defined implicitly as the solution to an equation and computed by an iterative solver: the fixed point of a recurrence, the equilibrium of a physical system, or the minimizer of an inner optimization problem. Recording twenty Newton iterations on a tape and backpropagating through all of them does work, but it stores every intermediate iterate and differentiates the particular trajectory the solver happened to follow. Can we obtain the derivative from the defining equation alone?

Start with the simplest possible case: a single equation in one unknown, $g(x, \theta) = x^2 - \theta = 0$, whose solution is $x^\star = \sqrt{\theta}$. Instead of differentiating the closed form, differentiate the identity $x^\star(\theta)^2 - \theta \equiv 0$ directly with respect to θ. That gives $2x^\star \, dx^\star/d\theta - 1 = 0$, and solving for the derivative yields

$$\frac{dx^\star}{d\theta} = \frac{1}{2x^\star} = \frac{1}{2\sqrt{\theta}},$$

which is indeed the derivative of $\sqrt{\theta}$ (equal to 0.25 at $\theta = 4$). Crucially, we never used an explicit formula for $x^\star$, only the equation $g(x, \theta) = 0$ and the value of the solution itself.

The general result is the *implicit function theorem* (Rudin 1976), which we state without proof. Let $\mathbf{g}(\mathbf{x}, \theta)$ map $\mathbb{R}^d \times \mathbb{R}^p$ to $\mathbb{R}^d$, suppose $\mathbf{g}$ is continuously differentiable near a solution $(\mathbf{x}^\star, \theta)$ of $\mathbf{g} = \mathbf{0}$, and suppose the Jacobian $\partial \mathbf{g}/\partial \mathbf{x}$ is invertible there. Then, in a neighborhood of θ, the solution is a differentiable function $\mathbf{x}^\star(\theta)$. Applying the chain rule to the identity $\mathbf{g}(\mathbf{x}^\star(\theta), \theta) \equiv \mathbf{0}$ gives $\frac{\partial \mathbf{g}}{\partial \mathbf{x}} \frac{\partial \mathbf{x}^\star}{\partial \theta} + \frac{\partial \mathbf{g}}{\partial \theta} = \mathbf{0}$, and therefore

$$\frac{\partial \mathbf{x}^\star}{\partial \theta} = -\left(\frac{\partial \mathbf{g}}{\partial \mathbf{x}}\right)^{-1} \frac{\partial \mathbf{g}}{\partial \theta}. \tag{34.51}$$

Both Jacobians on the right are evaluated solely at the solution $(\mathbf{x}^\star, \theta)$. Computing the full derivative matrix costs one linear solve with $\partial \mathbf{g}/\partial \mathbf{x}$ per parameter, regardless of how many iterations the solver took. Even better, in VJP form it takes just a single linear solve for all parameters combined: $\mathbf{u}^\top \partial \mathbf{x}^\star/\partial \theta = -\mathbf{a}^\top \partial \mathbf{g}/\partial \theta$, where the adjoint vector $\mathbf{a}$ solves $(\partial \mathbf{g}/\partial \mathbf{x})^\top \mathbf{a} = \mathbf{u}$.

This same principle powers several major techniques in machine learning: the adjoint method for differentiating through ODE solvers (Section 38.3.2), deep equilibrium models (Bai et al. 2019) that define an entire layer as a fixed point $\mathbf{z}^\star = \mathbf{f}(\mathbf{z}^\star, \theta)$ and train it via Equation 34.51, and gradient-based hyperparameter tuning through an inner minimization.

Let us test Equation 34.51 on a nonlinear 2×2 system, $g_1 = x_1^2 + \theta x_2 - 2 = 0$ and $g_2 = x_1 x_2 + \theta - 1 = 0$, solved with twenty Newton steps, and check the implicit gradient against a central difference of the solver's output.

```
# Implicit gradient dx*/dtheta = -(dg/dx)^{-1} dg/dtheta on a 2x2 system,
# checked against a finite difference of the solver output
def g(x, th):                          # g(x, theta) = 0 defines x*(theta)
    return np.array([x[0]**2 + th * x[1] - 2, x[0] * x[1] + th - 1])

def dg_dx(x, th):                      # Jacobian in x, evaluated at (x, th)
    return np.array([[2 * x[0], th], [x[1], x[0]]])

def solve(th):                         # Newton iteration, from a fixed start
    x = np.array([1.0, 1.0])
    for _ in range(20):
        x = x - np.linalg.solve(dg_dx(x, th), g(x, th))
    return x

th, h = 0.3, 1e-6
xs = solve(th)
```

```
    dg_dth = np.array([xs[1], 1.0])      # dg/dtheta at the solution
    implicit = -np.linalg.solve(dg_dx(xs, th), dg_dth)
    fd = (solve(th + h) - solve(th - h)) / (2 * h)
    print('implicit-function gradient:', implicit.round(8))
    print('finite-difference check   :', fd.round(8))
```

```
implicit-function gradient: [-0.11311451 -0.69322129]
finite-difference check   : [-0.11311451 -0.69322129]
```

The two vectors agree to the full precision of the finite difference, and none of the twenty Newton iterations ever appeared in the implicit formula. Because the derivative depends only on $\mathbf{g}$ and the solution $\mathbf{x}^\star$, any solver that converges to the same root produces the same gradient.

Like any theorem, the implicit function theorem has two clear boundaries, and both are easy to observe in practice. First, $\partial \mathbf{g}/\partial \mathbf{x}$ must be invertible at the solution. In our scalar example $x^2 = \theta$, at $\theta = 0$ we have $\partial g/\partial x = 2x^\star = 0$, so the formula divides by zero, reflecting the vertical tangent of $\sqrt{\theta}$ at the origin. Second, the formula assumes the solver has actually converged. To see what goes wrong when it has not, let us run Newton's method on $x^2 = 4$ starting from $x = 1$ and stop early after $k = 1, 2, 3$ steps, comparing the implicit formula $1/(2\tilde{x}_k)$ evaluated at the unconverged iterate $\tilde{x}_k$ with the derivative of the k-step unrolled solver itself (estimated by a central difference in θ).

```
    def newton(theta, k, x=1.0):                    # k Newton steps on x^2 = theta
        for _ in range(k):
            x = x - (x * x - theta) / (2 * x)
        return x

    theta, h = 4.0, 1e-6
    for k in (1, 2, 3):
        x_k = newton(theta, k)
        unrolled = (newton(theta + h, k) - newton(theta - h, k)) / (2 * h)
        print(f'k={k}: x = {x_k:.5f}, formula {1 / (2 * x_k):.4f}, '
              f'unrolled {unrolled:.4f}, exact 0.25')
```

```
k=1: x = 2.50000, formula 0.2000, unrolled 0.5000, exact 0.25
k=2: x = 2.05000, formula 0.2439, unrolled 0.2900, exact 0.25
k=3: x = 2.00061, formula 0.2499, unrolled 0.2509, exact 0.25
```

After one, two, and three steps, Newton's method reaches 2.5, 2.05, and 2.00061. Against the true derivative 0.25, the implicit formula returns 0.2000, 0.2439, and 0.2499, while the unrolled derivative gives 0.5000, 0.2900, and 0.2509. Both are inaccurate before convergence: the implicit formula inherits the solver's residual error, and the unrolled derivative, which differentiates the truncated iteration path, is even further off here. The remedy is straightforward: let the solver converge first.

One fundamental problem remains open. Automatic differentiation computes the product $\mathbf{J}_K \cdots \mathbf{J}_1$ accurately up to floating-point rounding, but it cannot alter the value of that product. Across many layers, a long product of Jacobians can still shrink or explode geometrically (Section 34.4), and an exact gradient of 10^{-20} is no more useful for training than zero. Controlling vanishing and exploding gradients requires careful initialization and architectural choices, which we take up starting in Section 4.4.

34.5.4 Summary

The derivative of a program is the product of the Jacobians of its elementary steps, and automatic differentiation evaluates that product against a seed vector so that every step is a matrix–vector product rather than a matrix–matrix product. Forward mode runs the program on dual numbers to compute one Jacobian–vector product (one input direction) per pass; reverse mode records a tape during the forward pass and replays it backward to compute one vector–Jacobian product (one output direction) per pass. The shape of the Jacobian determines which mode is cheaper. Because a scalar loss has a single output, one reverse sweep yields all parameter gradients at roughly three times the cost of evaluating the loss. On $(\sum_j x_j^2)^2$ with $n = 200$ inputs, reverse mode took 802 operations against $80{,}200$ for forward mode. The tape's memory grows linearly with the computation length T, and gradient checkpointing lowers peak memory to $2\sqrt{T}$ for one extra forward pass. Finally, composing forward mode over reverse mode computes Hessian–vector products at a small constant multiple of one gradient evaluation, and the implicit function theorem differentiates a solver's output with a single linear solve at the converged solution.

34.5.5 Exercises

1. code **Dual and complex steps.** Take $\mathbf{f}(x, y) = (x + \sin y,\ y + x^2/2)$ at $\mathbf{x}_0 = (0.5, 0.5)$ and the second column $\mathbf{J}\mathbf{e}_2 = (\cos 0.5,\ 1)$ of its Jacobian. The central difference $(\mathbf{f}(\mathbf{x}_0 + t\mathbf{e}_2) - \mathbf{f}(\mathbf{x}_0 - t\mathbf{e}_2))/(2t)$ has an error of order t^2 from truncation plus an error of order u/t from rounding, where $u \approx 10^{-16}$ is the float64 unit roundoff.

    1. Predict the best step and the smallest error, then check the prediction for $t = 10^{-1}, 10^{-2}, \dots, 10^{-12}$ (you should find about 2×10^{-11} near $t = 10^{-5}$). Compare with one pass of `Dual` seeded with $\mathbf{e}_2$. Why does no step size enter the dual computation?
    2. Repeat (a) for the first column $\mathbf{J}\mathbf{e}_1$, and explain why the central difference is exact there for every t, up to rounding. (Hint: $\mathbf{f}$ is a polynomial of degree two in x.)
    3. Replacing ε by the imaginary unit i gives the complex-step estimate $\operatorname{Im} \mathbf{f}(\mathbf{x}_0 + it\mathbf{e}_2)/t$ (Squire and Trapp 1998), valid for an $\mathbf{f}$ that extends analytically to complex arguments, as this one does. Expand $\mathbf{f}(\mathbf{x}_0 + it\mathbf{e}_2)$ to third order in t and show that the error of the estimate is $O(t^2)$. Why does the estimate subtract no nearly equal numbers?
    4. Evaluate the complex-step estimate with NumPy's complex arithmetic for $t = 10^{-1}, 10^{-2}, \dots, 10^{-20}$ and compare its errors with those of (a). Which difference between $\varepsilon^2 = 0$ and $i^2 = -1$ causes the $O(t^2)$ error of the complex step?

2. code **Hyperparameter gradient.** Ridge regression with one penalty $\lambda_j > 0$ per feature fits

$$\mathbf{w}^\star(\lambda) = \operatorname*{argmin}_{\mathbf{w}} \ \|\mathbf{X}\mathbf{w} - \mathbf{y}\|^2 + \sum_{j=1}^{d} \lambda_j w_j^2$$

    on training data $(\mathbf{X}, \mathbf{y})$, and its validation loss on data $(\mathbf{X}_\mathrm{v}, \mathbf{y}_\mathrm{v})$ is $V(\lambda) = \|\mathbf{X}_\mathrm{v}\mathbf{w}^\star(\lambda) - \mathbf{y}_\mathrm{v}\|^2$.

    1. Show that $\mathbf{w}^\star$ solves $\mathbf{g}(\mathbf{w}, \lambda) = (\mathbf{X}^\top\mathbf{X} + \operatorname{diag}(\lambda))\,\mathbf{w} - \mathbf{X}^\top\mathbf{y} = \mathbf{0}$, and use Equation 34.51 to derive $\partial\mathbf{w}^\star/\partial\lambda$.

2. Show that $\nabla_\lambda V = -\mathbf{a} \odot \mathbf{w}^\star$, where $\mathbf{a}$ solves one linear system with the matrix $\mathbf{X}^\top\mathbf{X} + \operatorname{diag}(\lambda)$, and give its right-hand side. How many linear solves does the forward route through $\partial \mathbf{w}^\star / \partial \lambda$ need for d penalties, and how many does this adjoint route need?
3. Implement V and the adjoint gradient in NumPy for random data with 50 training examples, 50 validation examples, and $d = 10$ features. Check the gradient against central differences of V.

Adapted from Alan Edelman and Steven G. Johnson, Matrix Calculus for Machine Learning and Beyond, problem set 2, MIT 18.S096, IAP 2023, Problem 1.

3. code **Hessian–vector product.** ● The function $f(\mathbf{x}) = \left(\sum_j x_j^2\right)^2$ of Section 34.5.2.4, evaluated at the inputs `xs0` with $n = 200$, is built from addition and multiplication alone, so both `Dual` and `Var` can evaluate it.

   1. Derive ∇f and the Hessian $\mathbf{H}$ of f, and write $\mathbf{Hv}$ in a form that never builds $\mathbf{H}$.
   2. Draw a random direction $\mathbf{v}$, wrap each input x_j as `Var(Dual(x_j, v_j))`, and run `backprop`. Show that the value parts of the resulting adjoints form ∇f and that their ε-parts form $\mathbf{Hv}$, and compare both with
      (a) and with the Hessian–vector product of Section 34.5.3.2 applied to the same f. Which operations of the backward closures run in dual arithmetic, and why does this make the computation forward over reverse in the sense of Equation 34.49?
   3. Nest the tape in itself instead. Wrap each input as `Var(Var(x_j))` and run `backprop`; the adjoints are now `Var` objects. Form $\sum_j (\nabla f)_j v_j$ from them and run `backprop` on it to obtain $\mathbf{Hv}$ by reverse over reverse. Count the `Var` objects that each method creates, for example with a counter in `Var.__init__`, and compare both counts with that of one plain gradient. Which method records the backward pass, and what does that cost in memory?

4. code **Checkpointing on the tape.** ● Let $x_k = x_{k-1} - 0.01\, x_{k-1}^2$ for $k = 1, \dots, T$ with $T = 400$ and $x_0 = 1$, and differentiate x_T with respect to x_0. `Var` has no subtraction, so record each step as `x + (-0.01) * x * x`.

   1. Record the chain on the tape with plain `backprop` and count the nodes that the tape holds when the backward sweep starts.
   2. `backprop` seeds the output adjoint with 1. Generalize it to accept any seed. Show that recording a segment $x_i \mapsto x_j$ from a fresh leaf for x_i and running the generalized `backprop` from x_j with the seed $\partial x_T / \partial x_j$ returns $\partial x_T / \partial x_i$ in the adjoint of the leaf.
   3. Implement the schedule of Figure 34.26 with segments of s steps: a forward pass in plain floats that stores $x_0, x_s, x_{2s}, \dots$, followed by a backward pass that re-records one segment at a time, from the last to the first, and applies (b). Check that the result equals the gradient of (a).
   4. For $s \in \{1, 5, 10, 20, 100, 400\}$, report the number of stored checkpoints, the largest tape in steps, and the number of evaluations of the step $x \mapsto x - 0.01x^2$, the first forward pass included. Confirm the memory $T/s + s$ of Equation 34.48, that is $401, 85, 50, 40, 104, 401$, and its minimizer $s = \sqrt{T} = 20$. Repeat the sweep for $T = 100$ and $T = 1600$ over the divisors $s \le 800$ of T (a single segment of 1600 steps exceeds Python's default recursion limit in `backprop`). How does the minimizing s scale with T, and how many step evaluations does the best

schedule need?

5. [extended] **Equilibrium layer.** ●● A deep equilibrium layer (Bai et al. 2019) outputs the fixed point

$$\mathbf{z}^\star = \tanh(\mathbf{W}\mathbf{z}^\star + \mathbf{c}), \tag{34.52}$$

where $\mathbf{c}$ depends on the layer's input. Let the loss be $\ell = \tfrac{1}{2}\|\mathbf{z}^\star - \mathbf{y}\|^2$, and write $\mathbf{D} = \operatorname{diag}(1-(z_1^\star)^2, \dots, 1-(z_d^\star)^2)$ for the derivative of tanh at the fixed point.

   1. Show that the map $\mathbf{z} \mapsto \tanh(\mathbf{W}\mathbf{z} + \mathbf{c})$ is a contraction when $\|\mathbf{W}\|_2 < 1$, so that the fixed point exists and is unique, and that $\mathbf{I} - \mathbf{D}\mathbf{W}$ is then invertible. Use Equation 34.51 to derive $\nabla_{\mathbf{W}}\ell$, and show that it equals $(\mathbf{D}\mathbf{a})(\mathbf{z}^\star)^\top$ for the adjoint $\mathbf{a}$ that solves $(\mathbf{I} - \mathbf{D}\mathbf{W})^\top \mathbf{a} = \mathbf{z}^\star - \mathbf{y}$.
   2. Take $d = 20$, a standard normal $\mathbf{G} \in \mathbb{R}^{d\times d}$, $\mathbf{S} = \mathbf{G} + \mathbf{G}^\top$, and $\mathbf{W} = \rho\,\mathbf{S}/\|\mathbf{S}\|_2$ for $\rho \in \{0.5, 0.9, 0.99\}$, and draw the entries of $\mathbf{c}$ and $\mathbf{y}$ independently from $\mathcal{N}(0, 0.1^2)$. In NumPy, compute $\mathbf{z}^\star$ by fixed-point iteration and the gradient of (a) with one linear solve. Check a few of its entries against central differences of ℓ.
   3. Unrolled differentiation runs K iterations from $\mathbf{z}_0 = \mathbf{0}$ and backpropagates through all of them. Implement this backward sweep by hand, one VJP per iteration. Plot against K the error of the unrolled gradient relative to the gradient of (b), together with the forward error $\|\mathbf{z}_K - \mathbf{z}^\star\|$. Compare the decay rate of both errors with the spectral radius of $\mathbf{D}\mathbf{W}$. How does the ratio of the two errors behave as K grows, and why? How does the memory of each gradient scale with K?
   4. Replace the linear solve by m steps of the iteration $\mathbf{a} \leftarrow (\mathbf{z}^\star - \mathbf{y}) + (\mathbf{D}\mathbf{W})^\top \mathbf{a}$ from $\mathbf{a} = \mathbf{0}$, a truncated Neumann series that Geng et al. (2021) use as a *phantom gradient*. Show that this truncated adjoint gives the same gradient as backpropagation through m iterations started at $\mathbf{z}^\star$. Plot the cosine between the truncated and the exact gradient against m for each ρ. The gradient for $m = 1$ needs no linear solve and is the Jacobian-free backpropagation of Wu Fung et al. (2022) . Is it still a descent direction for ℓ?

6. code **Second derivatives in one forward pass.** Adjoin ε with $\varepsilon^3 = 0$ (but $\varepsilon^2 \neq 0$), and write $a + b\varepsilon + c\varepsilon^2$ as a triple (a, b, c).

   1. Derive the product $(a,b,c)(a',b',c') = (aa',\ ab' + ba',\ ac' + bb' + ca')$, and show that for an analytic φ, $\varphi(a + b\varepsilon + c\varepsilon^2) = \varphi(a) + \varphi'(a)\,b\,\varepsilon + (\varphi'(a)\,c + \tfrac{1}{2}\varphi''(a)\,b^2)\varepsilon^2$.
   2. Implement `Dual2` with `__add__`, `__mul__`, `sin`, and `exp`, and evaluate $f(x) = \sin(x^2) + e^x$ on $(1.3, 1, 0)$. Show that the result is $(f(1.3),\ f'(1.3),\ \tfrac{1}{2}f''(1.3))$, and check $f''(1.3) \approx -3.2806$ against the hand formula $f''(x) = 2\cos x^2 - 4x^2 \sin x^2 + e^x$.
   3. For $\ell : \mathbb{R}^n \to \mathbb{R}$ with inputs seeded by a direction $\mathbf{v}$, what does the ε^2-part return? (Answer: $\tfrac{1}{2}\mathbf{v}^\top \mathbf{H}\mathbf{v}$, a number.) How many such passes give the vector $\mathbf{H}\mathbf{v}$ by polarization, against one forward-over-reverse pass?
   4. Write ε as a 3×3 matrix with $\varepsilon^3 = \mathbf{0}$ and verify the product of (a) by matrix multiplication.

34.6 Integral Calculus

Earlier chapters used continuous random variables without asking how their probabilities are computed. We described a normal distribution by its density (Section 2.1.3), wrote an expected loss as an average over that density, and treated both as given. In this section we ask how to add up a quantity that is spread continuously over an interval.

The standard normal distribution, the familiar bell curve, shows why continuous summation requires care. A standard normal random variable Z has density $p(z) = e^{-z^2/2}/\sqrt{2\pi}$. At $z = 0$ the curve reaches height $p(0) \approx 0.40$, yet the probability of landing on zero is $P(Z = 0) = 0$, and the same is true for every other single point. Intervals, on the other hand, do carry probability: $P(-1 \le Z \le 1) \approx 0.68$. Geometrically, that number is the area under p between -1 and 1, and $1/\sqrt{2\pi}$ is the constant that makes the total area under the curve equal to 1. Where does $\sqrt{2\pi}$ come from, and how do we compute 0.68?

These questions reach well beyond the bell curve. Every probability and every expected loss over a continuous variable is an area of this kind. Training a model through random sampling, as variational autoencoders and policy-gradient methods do, also requires differentiating such an area with respect to a model parameter.

Our strategy is simple: cut the area into thin slices, add their areas, and let the slices shrink to zero. The limit is the integral. The fundamental theorem of calculus then replaces this infinite addition with the reverse of differentiation, which settles most integrals in a single line. It does not settle the bell curve, whose normalizing constant $\sqrt{2\pi}$ requires a detour through two dimensions. Three results anchor the section: the fundamental theorem Equation 34.55, the multivariable change-of-variables formula Equation 34.63, and the Gaussian integral Equation 34.65. If you already have first-year calculus at hand, you can skim through to Section 34.6.2.2. Differentiating an integral with respect to a parameter builds on all of these tools and has a section of its own in Section 34.7. We leave out measure theory and the Lebesgue integral, pointing interested readers to Section 34.8.

34.6.1 The Definite Integral

34.6.1.1 Riemann Sums

A probability density gives probability per unit length, so over a short interval of width ϵ the probability is approximately density times width. Over a longer interval, we cut it into thin slices, multiply height by width on each slice, and add the results. Nothing in this idea is specific to densities: the same recipe works for any function.

Let us start with a case we can work out by hand. Take $f(x) = x^2$ on $[0, 1]$ and divide the interval into N slices of equal width $\epsilon = 1/N$. On the i-th slice $[i/N, (i+1)/N]$, we approximate the area by a rectangle whose height is the value of f at the left endpoint, $(i/N)^2$. Adding all N rectangles gives

$$\sum_{i=0}^{N-1} \frac{1}{N}\Big(\frac{i}{N}\Big)^2 = \frac{1}{N^3}\sum_{i=0}^{N-1} i^2 = \frac{(N-1)N(2N-1)}{6N^3} = \frac{1}{3} - \frac{1}{2N} + \frac{1}{6N^2},$$

where the middle step uses the classical identity $\sum_{i=0}^{N-1} i^2 = (N-1)N(2N-1)/6$. As N grows, the rectangle sums converge to $\frac{1}{3}$, missing the limit by roughly $\frac{1}{2N}$, an error of first order in the slice width ϵ.

The helper function `left_sum` implements this **left-endpoint rule** for any function f: divide $[a, b]$ into slices of width ϵ and evaluate f at the left end of each slice, as shown in Figure 34.27. We will use `left_sum` for every grid sum in this section, starting with a quick check on x^2.

```
def left_sum(f, a, b, eps):
    """Left-endpoint Riemann sum of f on [a, b] with slices of width eps."""
    x = a + eps * np.arange(round((b - a) / eps))   # left ends of the slices
    return float(np.sum(eps * f(x)))

for N in [10, 100, 1000]:
    print(f'N={N:<5} left sum={left_sum(lambda x: x**2, 0, 1, 1 / N):.6f}  '
          f'formula={1/3 - 1/(2*N) + 1/(6*N**2):.6f}')
```

```
N=10    left sum=0.285000  formula=0.285000
N=100   left sum=0.328350  formula=0.328350
N=1000  left sum=0.332834  formula=0.332834
```

The numerical sums match the closed-form formula to every printed digit.

The definition. Nothing in this construction requires equal slice widths or left endpoints. More generally, a *partition* $P : a = x_0 < x_1 < \cdots < x_N = b$ cuts $[a, b]$ into subintervals, a *tag* $\xi_i \in [x_{i-1}, x_i]$ picks one sample point inside each slice, and the *mesh* $\|P\| = \max_i (x_i - x_{i-1})$ measures the width of the widest slice. A bounded function f is **Riemann integrable** on $[a, b]$ if there is a single number I that every tagged sum approaches as the mesh shrinks to zero, regardless of how the tags are chosen:

$$\int_a^b f(x)\,dx = I = \lim_{\|P\| \to 0} \sum_{i=1}^{N} f(\xi_i)(x_i - x_{i-1}). \tag{34.53}$$

In short, the definite integral is the common limit of the slice sums as the slices become arbitrarily thin. Our hand calculation above establishes $\int_0^1 x^2\,dx = \frac{1}{3}$. Every continuous function on $[a, b]$ is Riemann integrable, and so is every bounded function with finitely many jump discontinuities (Rudin 1976). Some pathological bounded functions, such as the indicator of the rational numbers, fail to have a Riemann integral; the Lebesgue integral (Section 34.8) extends integration to them while agreeing with the Riemann integral whenever the latter exists.

Two elementary properties follow straight from the definition and will power the proofs below. First, the integral is **monotone**: if $f \le g$ everywhere on $[a, b]$, then every tagged sum of f is no larger than the corresponding tagged sum of g, and taking limits preserves the inequality, giving $\int_a^b f\,dx \le \int_a^b g\,dx$. Second, it is **additive over subintervals**: for any $a \le b \le c$, $\int_a^c f\,dx = \int_a^b f\,dx + \int_b^c f\,dx$, because any partition that includes the point b splits cleanly into a partition of $[a, b]$ and a partition of $[b, c]$.

The running example. Until we reach the Gaussian integral, we will carry one concrete example through the section:

$$\int_0^2 \frac{x}{1+x^2}\,dx = \tfrac{1}{2}\log 5 \approx 0.80472.$$

We will see why its value is $\frac{1}{2}\log 5$ once we establish the evaluation rule Equation 34.56. Figure 34.27 illustrates left-endpoint rectangles under this curve at three slice widths.

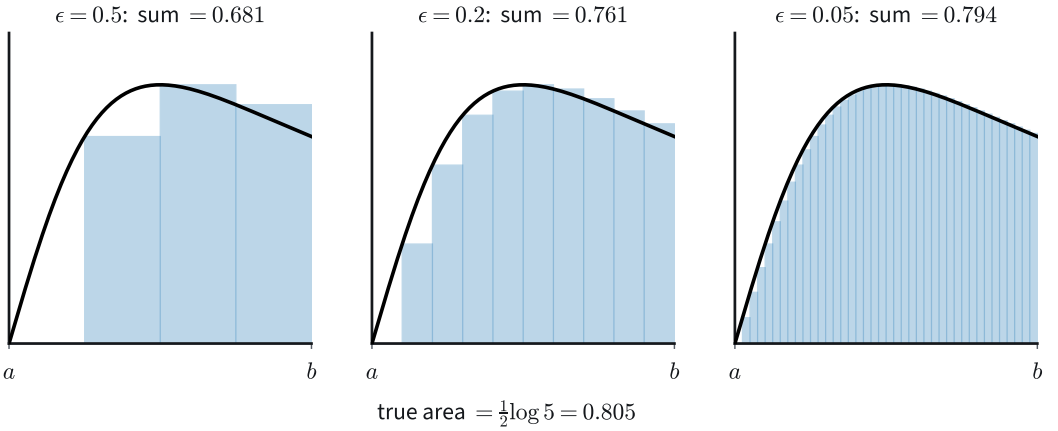

Figure 34.27: Left-endpoint rectangles under $f(x) = x/(1+x^2)$ on $[0, 2]$ for slice widths $\epsilon = 0.5, 0.2$, and 0.05. Each slice takes the height of f at its left endpoint, and the rectangle sums approach the area $\frac{1}{2}\log 5$ as $\epsilon \to 0$.

How quickly do the left sums converge to $\frac{1}{2}\log 5$? For x^2 on $[0, 1]$ the error was $\frac{1}{2N} = \frac{\epsilon}{2}$. If first-order convergence is typical, making the slices ten times thinner should reduce the error by a factor of ten. Let us check by printing the error alongside $0.2\,\epsilon$.

```
f = lambda x: x / (1 + x**2)
truth = math.log(5) / 2
for eps in [1e-1, 1e-2, 1e-3, 1e-4]:
    s = left_sum(f, 0, 2, eps)
    print(f'eps={eps:.0e}  sum={s:.6f}  truth-sum={truth - s:.2e}  '
          f'0.2*eps={0.2 * eps:.0e}')
print(f'truth = (1/2) log 5 = {truth:.6f}')
```

```
eps=1e-01  sum=0.783785  truth-sum=2.09e-02  0.2*eps=2e-02
eps=1e-02  sum=0.802710  truth-sum=2.01e-03  0.2*eps=2e-03
eps=1e-03  sum=0.804519  truth-sum=2.00e-04  0.2*eps=2e-04
eps=1e-04  sum=0.804699  truth-sum=2.00e-05  0.2*eps=2e-05
truth = (1/2) log 5 = 0.804719
```

Each time ϵ shrinks by a factor of ten, the error shrinks by ten as well, and every sum sits below the true value. The constant 0.2 happens to be half of $f(2) - f(0) = 0.4$. This is no coincidence, and we will derive the formula behind it as soon as the fundamental theorem is in place.

34.6.1.2 Signed Area

Rectangles below the horizontal axis have negative height $f(\xi_i) < 0$ and enter the Riemann sum with a minus sign. The integral therefore measures *signed* area: regions where $f < 0$ contribute negatively, as in $\int_0^1 (-1)\,dx = -1$. By convention, integrating from right to left also negates the result, $\int_b^a f\,dx = -\int_a^b f\,dx$. This convention ensures that additivity holds regardless of how a, b, and c are ordered. Figure 34.28 illustrates both conventions on a single curve.

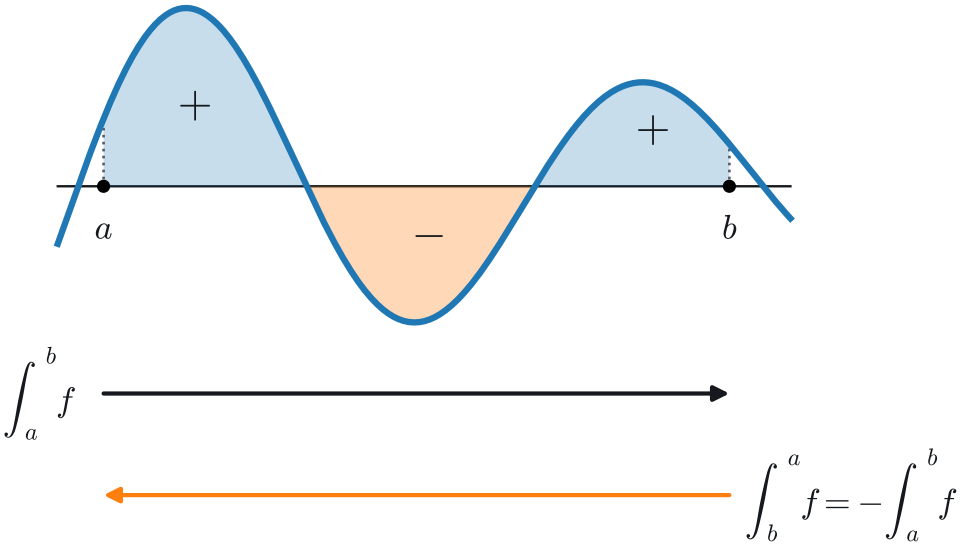

Figure 34.28: Signed area. Lobes above the axis count positively and the lobe below counts negatively, so $\int_a^b f$ totals the shaded regions with their signs; reversing the limits traverses the same area from right to left and negates the total.

34.6.2 The Fundamental Theorem

34.6.2.1 The Theorem

Adding slices gave $\frac{1}{3}$ for x^2 only because $\sum i^2$ happens to have a closed form. For our running example, the left sum is $\sum_i \epsilon \cdot i\epsilon/(1+i^2\epsilon^2)$, and no algebraic identity collapses it. We need a way to evaluate integrals without adding slices at all.

The breakthrough comes from treating the upper limit as a variable. Fix a base point a and define the **area-so-far function**

$$F(x) = \int_a^x f(y)\,dy, \tag{34.54}$$

which records the signed area accumulated from a out to x. This single function encodes every definite integral of f: by additivity, the area over any interval $[x_1, x_2]$ is simply the

difference of two accumulated areas,

$$\int_{x_1}^{x_2} f(x)\,dx = F(x_2) - F(x_1),$$

as shown in Figure 34.29. Finding F therefore solves the whole problem.

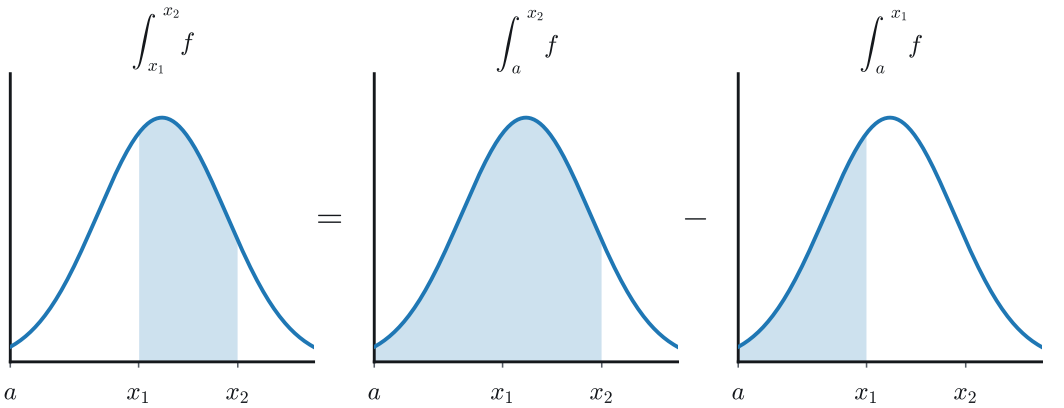

Figure 34.29: The area under f from x_1 to x_2 as the difference of two areas accumulated from the base point a at the plot's left edge: $\int_{x_1}^{x_2} f\,dx = \int_a^{x_2} f\,dx - \int_a^{x_1} f\,dx$.

How does F change when we nudge x slightly to the right? Figure 34.30 shows the accumulated area up to x alongside the thin strip of width ϵ added by moving to $x+\epsilon$. That strip is nearly a rectangle of height $f(x)$, so $F(x+\epsilon) - F(x) \approx \epsilon f(x)$. Dividing by ϵ suggests that $F'(x) = f(x)$.

Theorem (Fundamental theorem of calculus). *Let f be Riemann integrable on $[a,b]$, let $F(x) = \int_a^x f(y)\,dy$, and let f be continuous at a point $x \in (a,b)$. Then F is differentiable at x and*

$$\frac{dF}{dx}(x) = f(x). \tag{34.55}$$

In words, the rate at which area accumulates equals the current height of the curve.

Proof. Nudge x by $\epsilon > 0$ and look at the added area. By Equation 34.54 and additivity, the change is a single sliver,

$$F(x+\epsilon) - F(x) = \int_x^{x+\epsilon} f(y)\,dy.$$

Let $m_\epsilon = \inf_{[x,x+\epsilon]} f$ and $M_\epsilon = \sup_{[x,x+\epsilon]} f$ be the tightest constant bounds on f over this sliver; both are finite because an integrable function is bounded. Since $m_\epsilon \le f \le M_\epsilon$ throughout $[x, x+\epsilon]$, monotonicity of the integral traps the sliver's area between two rectangles of width ϵ:

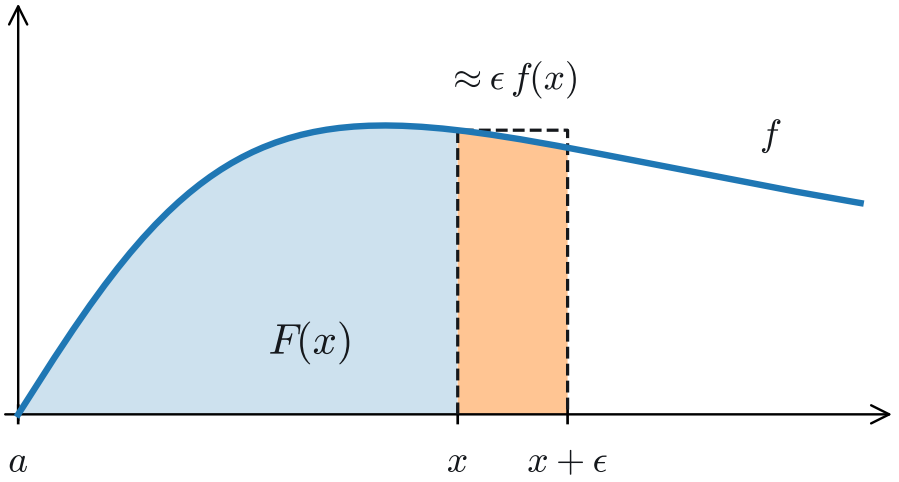

Figure 34.30: The area-so-far $F(x)$ under $f(y) = y/(1+y^2)$ from $a = 0$ to $x = 1.2$ (light), and the strip added by moving to $x + \epsilon$ (dark). The strip is close to the dashed rectangle of height $f(x)$, so $F(x+\epsilon) - F(x) \approx \epsilon f(x)$.

$$\epsilon\, m_\epsilon \;\le\; F(x+\epsilon) - F(x) \;\le\; \epsilon\, M_\epsilon .$$

Now divide through by ϵ. Because f is continuous at x, for any $\delta > 0$ the entire interval $[x, x+\epsilon]$ eventually lies inside the region where $|f(y) - f(x)| < \delta$. Both m_ϵ and M_ϵ therefore converge to $f(x)$ as $\epsilon \to 0$, and the squeeze forces $\lim_{\epsilon\to 0} \frac{F(x+\epsilon)-F(x)}{\epsilon} = f(x)$. When $\epsilon < 0$, the sliver sits to the left of x, and the same bounds hold with both sign flips canceling in the difference quotient. That limit is $F'(x)$. ■

Notice that the proof used only monotonicity and additivity, the two properties we read off the definition. The theorem turns the problem of finding an area into the problem of finding an **antiderivative**, a function G satisfying $G' = f$, which we can often read straight off the derivative table in Section 34.1.2. Any antiderivative yields the definite integral via the **evaluation rule**: *if f is continuous on $[a,b]$ and $G' = f$ on all of $[a,b]$, then*

$$\int_a^b f(x)\,dx = G(b) - G(a). \tag{34.56}$$

Why does any antiderivative work, not just F? Because F and G share the same derivative f on (a,b), so their difference $G - F$ has derivative zero and must be constant by the mean value theorem (Section 34.1.3). That additive constant cancels out in $G(b) - G(a) = F(b) - F(a) = \int_a^b f\,dx$.

The requirement "on all of $[a,b]$" is essential. Since $(-1/x)' = x^{-2}$, blindly applying the rule gives $\int_{-1}^{1} x^{-2}\,dx = [-1/x]_{-1}^{1} = -2$, a negative answer for a strictly positive integrand. The rule does not apply here because $G' = f$ breaks down at $x = 0$, where neither function is defined; in fact the integral diverges (Section 34.6.2.2).

Read backwards, every derivative formula becomes an integral: $(y^3)' = 3y^2$ gives $\int_0^1 y^2\,dy = \frac{1}{3}$ without a single slice, and $(e^t)' = e^t$ gives $\int_0^x e^t\,dt = e^x - 1$. For our running example, try $G(x) = \frac{1}{2}\log(1+x^2)$. By the chain rule, $G'(x) = \frac{1}{2}\cdot\frac{2x}{1+x^2} = \frac{x}{1+x^2}$, so

$$\int_0^2 \frac{x}{1+x^2}\,dx = G(2) - G(0) = \tfrac{1}{2}\log 5 - \tfrac{1}{2}\log 1 = \tfrac{1}{2}\log 5,$$

confirming the limit our Riemann sums were approaching.

The error of the left rule. The evaluation rule also explains where the constant 0.2 in the left-sum error came from. On the slice starting at x_i, a first-order expansion gives $f(x) \approx f(x_i) + f'(x_i)(x - x_i)$. Integrating over $[x_i, x_i + \epsilon]$ shows that the true area of the slice exceeds its rectangle $\epsilon f(x_i)$ by roughly $\frac{\epsilon^2}{2} f'(x_i)$. Summing these triangular excesses across all slices yields $\frac{\epsilon}{2}$ times a left sum of f', which approximates $\frac{\epsilon}{2}\int_a^b f'\,dx = \frac{\epsilon}{2}(f(b) - f(a))$. To first order in ϵ,

$$\text{left sum} - \int_a^b f(x)\,dx \approx \frac{\epsilon}{2}(f(a) - f(b)).$$

For x^2 on $[0,1]$ this gives $-\frac{\epsilon}{2} = -\frac{1}{2N}$, matching the leading error term we found by hand. For the running example, $f(0) = 0$ and $f(2) = 0.4$ give $-0.2\,\epsilon$. This estimate is numerical analysis rather than pure calculus, yet it accounts for the residual error in three more experiments in this section and serves as the baseline against which random sampling is judged in Section 36.5.1.7.

The fundamental theorem actually tells us more than $\int_0^2 f = G(2) - G(0)$: the area-so-far function $F(x)$ must equal $G(x) - G(0)$ at every x. Let us verify this by computing F as a cumulative left sum across $[0, 2]$ and comparing it with $G(x) - G(0)$ at every grid point. The two will not match to machine precision, because the left sum on $[0, x]$ carries the bias $\frac{\epsilon}{2}(f(0) - f(x))$. That bias is largest where f peaks, at $x = 1$ where $f(1) = \frac{1}{2}$, so the maximum discrepancy across the interval should be $\frac{\epsilon}{4}$.

```
G = lambda x: np.log(1 + x**2) / 2            # antiderivative of f
for eps in [1e-2, 1e-3, 1e-4]:
    x = eps * np.arange(round(2 / eps))       # left ends of the slices of [0, 2]
    F = np.cumsum(eps * f(x))                 # F[k]: left sum on [0, x_k + eps]
    gap = np.abs(F - (G(x + eps) - G(0))).max()
    print(f'eps={eps:.0e}  max over x of |F(x) - (G(x) - G(0))| = {gap:.2e}')
```

```
eps=1e-02  max over x of |F(x) - (G(x) - G(0))| = 2.51e-03
eps=1e-03  max over x of |F(x) - (G(x) - G(0))| = 2.50e-04
eps=1e-04  max over x of |F(x) - (G(x) - G(0))| = 2.50e-05
```

At every slice width, the maximum discrepancy is $\frac{\epsilon}{4}$, just as predicted. The cumulative sum tracks the antiderivative across the entire interval, not only at the right endpoint $x = 2$.

34.6.2.2 Improper Integrals

The normal, exponential, and many other probability densities live on unbounded domains, whereas Equation 34.53 defines integrals only over a finite interval $[a, b]$. We extend the definition the same way we built it, by taking a limit. The **improper integral** over $[a, \infty)$ is

$$\int_a^{\infty} f(x)\,dx = \lim_{b\to\infty} \int_a^{b} f(x)\,dx, \tag{34.57}$$

the area accumulated out to b in the limit of large b. If this limit exists and is finite, the integral *converges*; otherwise it *diverges*. To integrate over the entire real line, we split $\int_{-\infty}^{\infty} f\,dx$ at any convenient point into two one-sided improper integrals, and *both* must converge independently. A symmetric limit is not enough: $\int_{-b}^{b} x\,dx = 0$ for every b, yet $\int_0^{\infty} x\,dx = \infty$, so $\int_{-\infty}^{\infty} x\,dx$ does not exist.

The power law x^{-s} (with exponent $s > 0$) is the standard benchmark for deciding whether a tail decays fast enough to enclose finite area. Applying the evaluation rule on $[1, b]$ and taking $b \to \infty$ gives

$$\begin{aligned}\int_1^{b} x^{-s}\,dx &= \frac{b^{1-s} - 1}{1-s} \\ &\xrightarrow{b\to\infty} \begin{cases} \dfrac{1}{s-1}, & s > 1 \text{ (converges)}, \\ \infty, & s \le 1 \text{ (diverges)}. \end{cases}\end{aligned}$$

(At $s = 1$ the expression reads $0/0$; the definite integral is $\log b$, which is the limit of the formula as $s \to 1$ and diverges as $b \to \infty$.) Thus $\int_1^{\infty} x^{-2}\,dx = 1$ whereas $\int_1^{\infty} x^{-1}\,dx = \infty$: the dividing line between finite and infinite area lies right at $s = 1$.

Power laws are the canonical **heavy-tailed** distributions (Section 36.1, which also examines how heavy tails affect averages). For a density with tail $p(x) \propto x^{-s}$, the normalizing constant is finite only when $s > 1$, and the mean, tested by applying the same criterion to $x \cdot x^{-s} = x^{1-s}$, is finite only when $s > 2$.

The same limiting device handles an integrand that blows up at an endpoint: $\int_0^1 f\,dx = \lim_{a\to 0^+} \int_a^1 f\,dx$. For the power law x^{-s}, the condition reverses:

$$\int_0^1 x^{-s}\,dx = \lim_{a\to 0^+} \frac{1 - a^{1-s}}{1-s} = \frac{1}{1-s} \quad \text{for } s < 1,$$

while the integral diverges for $s \ge 1$. At $s = \frac{1}{2}$, for instance, $x^{-1/2}$ shoots to infinity at 0, yet the area under it is only 2. Near infinity, a power law must fall faster than $1/x$ to have finite area; near zero, it must grow more slowly than $1/x$.

When we approximate an improper integral numerically, two distinct errors enter: we cut off the domain at a finite b, and we sum slices of finite width ϵ. For $\int_0^{\infty} e^{-x}\,dx = 1$, we can

separate the two. Below we print the exact partial integral $\int_0^b e^{-x}\,dx = 1 - e^{-b}$ (from the antiderivative $-e^{-x}$) next to a left sum with $\epsilon = 10^{-3}$.

```
for b in [1, 2, 5, 10, 20]:
    left = left_sum(lambda x: np.exp(-x), 0, b, 1e-3)
    print(f'b={b:<3}  left sum={left:.6f}  exact 1-e^-b={1 - math.exp(-b):.6f}')
```

```
b=1    left sum=0.632437  exact 1-e^-b=0.632121
b=2    left sum=0.865097  exact 1-e^-b=0.864665
b=5    left sum=0.993759  exact 1-e^-b=0.993262
b=10   left sum=1.000455  exact 1-e^-b=0.999955
b=20   left sum=1.000500  exact 1-e^-b=1.000000
```

The exact partial integrals converge to 1 rapidly: the *truncation error* from stopping at b is e^{-b}, already below the sixth decimal place by $b = 20$. The left sums, however, settle near 1.0005 rather than 1. That residual is *discretization error*, our left-rule bias $\frac{\epsilon}{2}(f(0) - f(b)) \to \frac{\epsilon}{2} = 0.0005$. To leading order the two errors simply add: pushing b higher removes truncation error, while shrinking ϵ removes discretization error.

34.6.2.3 Integration by Parts

Every differentiation rule, read through the evaluation rule, yields a matching integration rule. The product rule becomes integration by parts.

For continuously differentiable functions u and v on $[a, b]$,

$$\int_a^b u(x)\,v'(x)\,dx = \Big[\,u(x)\,v(x)\,\Big]_a^b - \int_a^b u'(x)\,v(x)\,dx, \tag{34.58}$$

where $[\,h(x)\,]_a^b$ is shorthand for $h(b) - h(a)$. The proof takes one line: by the product rule, uv is an antiderivative of $u'v + uv'$, so Equation 34.56 gives $\int_a^b (u'v + uv')\,dx = [\,u(x)v(x)\,]_a^b$, and subtracting $\int_a^b u'v\,dx$ from both sides yields Equation 34.58.

What this formula does is shift a derivative from one factor onto the other at the cost of a boundary term. It pays off whenever the new integrand $u'v$ is simpler than uv'. Choosing $u(x) = x$ and $v'(x) = e^{-x}$ (so $u' = 1$ and $v = -e^{-x}$), applying Equation 34.58 on $[0, b]$, and letting $b \to \infty$ gives

$$\int_0^\infty x\,e^{-x}\,dx = \Big[-x\,e^{-x}\Big]_0^\infty + \int_0^\infty e^{-x}\,dx = 0 + 1 = 1.$$

The boundary term vanishes because $xe^{-x} \to 0$ at both endpoints, leaving the improper integral we just evaluated. This integral is the mean of the exponential distribution (Section 36.3).

Because expectations are integrals of products, a recurring trick in probability and machine learning is to shift a derivative off an intractable factor and onto a tractable one. The bell curve shows this technique at its cleanest. Consider the unnormalized bell weight $w(z) = e^{-z^2/2}$, which satisfies $w'(z) = -z\,w(z)$. Let g be continuously differentiable with

$g(z)w(z) \to 0$ as $z \to \pm\infty$, and suppose the two integrals below converge. Integrating by parts on $[-a, b]$ and then taking $a \to \infty$ and $b \to \infty$ separately yields

$$\int_{-\infty}^{\infty} g'(z)\, w(z)\, dz = \Big[\, g(z)\, w(z) \,\Big]_{-\infty}^{\infty} - \int_{-\infty}^{\infty} g(z)\, w'(z)\, dz = \int_{-\infty}^{\infty} z\, g(z)\, w(z)\, dz. \tag{34.59}$$

Under the bell weight, multiplying by z has the same effect as differentiating g. Both hypotheses hold for every polynomial g. Taking $g(z) = z$ gives $\int z^2 w\, dz = \int w\, dz$: the mean of z^2 under the bell weight is 1, regardless of what the normalizing constant $\int w\, dz$ turns out to be (we will show it is $\sqrt{2\pi}$ in Equation 34.66). Taking $g(z) = z^3$ gives $\int z^4 w\, dz = 3\int z^2 w\, dz = 3\int w\, dz$, so the mean of z^4 is 3. Once w is normalized into the standard normal density $p = w/\sqrt{2\pi}$, this becomes $\mathbb{E}[g'(Z)] = \mathbb{E}[Z\, g(Z)]$, known as Stein's identity for the standard normal. Shifting a derivative from an unknown factor onto a known one is also the key step behind score matching (Section 38.6, (Hyvärinen 2005)). In $\mathbb{R}^d$, the corresponding rule moves a divergence instead of a one-dimensional derivative; Section 38.5.2.1 introduces the divergence, the Laplacian, and that multivariable identity where they are first needed.

34.6.2.4 Substitution

Reading the chain rule backwards through the evaluation rule produces the substitution rule. Suppose u is continuously differentiable on $[a, b]$ and f is continuous on an interval containing $u([a, b])$, with antiderivative G. By the chain rule, $(G \circ u)'(x) = f(u(x))\, u'(x)$, so

$$\int_a^b f(u(x))\, u'(x)\, dx = \int_a^b (G \circ u)'(x)\, dx = G(u(b)) - G(u(a)) = \int_{u(a)}^{u(b)} f(y)\, dy.$$

Read from right to left, this is the **change-of-variables formula**

$$\int_{u(a)}^{u(b)} f(y)\, dy = \int_a^b f(u(x))\, \frac{du}{dx}\, dx. \tag{34.60}$$

In words, an integral over y can be rewritten as an integral over x provided we multiply the integrand by the local stretch factor du/dx. Note that u does not even need to be monotone.

A single thin slice makes the stretch factor transparent. Partition $[a, b]$ into slices of width ϵ. The map u carries the slice at x to a slice of width approximately $\epsilon\, u'(x)$ at $y = u(x)$, where the curve has height $f(y) = f(u(x))$. Its area is therefore $f(u(x))\, u'(x)\, \epsilon$, which is the quantity the x-integral sums (Figure 34.31).

In practice, substitution works by spotting the pattern $f(u(x))\, u'(x)$ inside an integrand. In $\int_0^1 x\, e^{-x^2}\, dx$, set $u(x) = x^2$ so $u'(x) = 2x$: the integrand is $\frac{1}{2} e^{-u(x)} u'(x)$, and

$$\int_0^1 x\, e^{-x^2}\, dx = \frac{1}{2}\int_0^1 e^{-y}\, dy = \frac{1 - e^{-1}}{2} \approx 0.316.$$

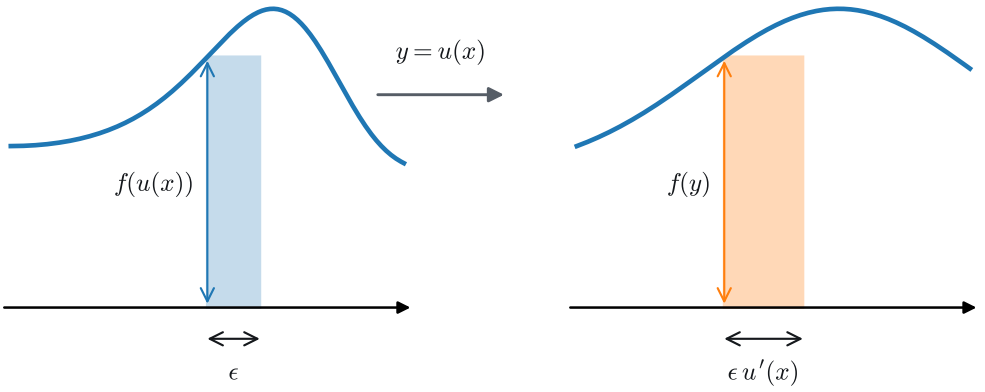

Figure 34.31: A thin sliver under the substitution $y = u(x)$. Left, the x side (the right-hand side of the formula): a sliver of width ϵ at x and height $f(u(x))$. Right, the y side: its image, of width $\epsilon\, u'(x)$ and the same height. Matching the two areas requires the factor du/dx.

Here the factor x supplied the $u'(x)$ that substitution needs. Remove that x and we are left with $\int e^{-x^2}\,dx$, which has no elementary antiderivative and is the very integral behind the bell curve's normalizer $1/\sqrt{2\pi}$. To evaluate it in Equation 34.65, we will obtain the missing factor by moving to two dimensions and switching to polar coordinates.

34.6.3 Multiple Integrals

From this point on we quote two standard theorems without proof, both from (Folland 1999): Fubini's theorem and the multivariable change-of-variables formula.

34.6.3.1 Double Integrals and Fubini's Theorem

Because our route to $\int e^{-x^2}\,dx$ passes through two dimensions, we first extend integration from intervals to regions of the plane. Consider the two-dimensional bell surface $f(x,y) = e^{-x^2-y^2}$ over the square $[-2,2]^2$, which encloses a volume above the base plane. We approximate that volume just as we approximated areas: tile the base with $\epsilon \times \epsilon$ squares, erect on each square a column of height f, and sum the column volumes (Figure 34.32). For a function f on a rectangle $R = [a,b] \times [c,d]$, the limit of these box sums as $\epsilon \to 0$ is the **double integral** $\iint_R f(x,y)\,dx\,dy$, the signed volume beneath the surface.

How can we compute such a volume using our one-dimensional tools? Any finite sum can be totaled in whatever order we like. Indexing the grid squares by i along x and j along y, we can sum the boxes column by column (Figure 34.33):

$$\sum_{i,j} \epsilon^2 f(a+\epsilon i, c+\epsilon j) = \sum_{i} \epsilon \Big(\sum_{j} \epsilon\, f(a+\epsilon i, c+\epsilon j) \Big).$$

The inner sum is the left-endpoint approximation to $\int_c^d f(a+\epsilon i, y)\,dy$, the cross-sectional area of the surface at $x = a + \epsilon i$ (the highlighted column in Figure 34.32), and the outer

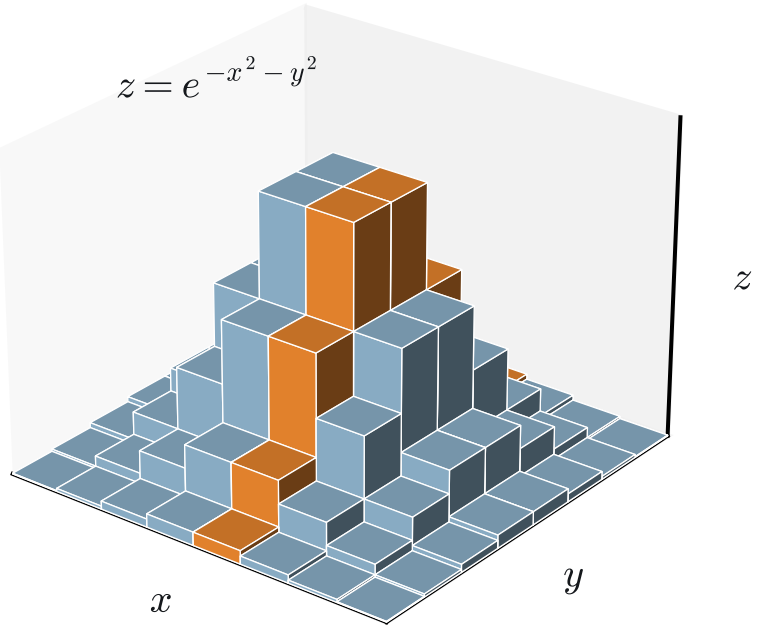

Figure 34.32: The bell surface $z = e^{-x^2-y^2}$ over the square $[-2, 2]^2$. Tiling the base with $\epsilon \times \epsilon$ squares ($\epsilon = 0.5$) and placing a box of height f on each approximates the volume under the surface; the highlighted column of boxes at a fixed x corresponds to one inner sum in Fubini's theorem.

sum integrates that slice area across x.

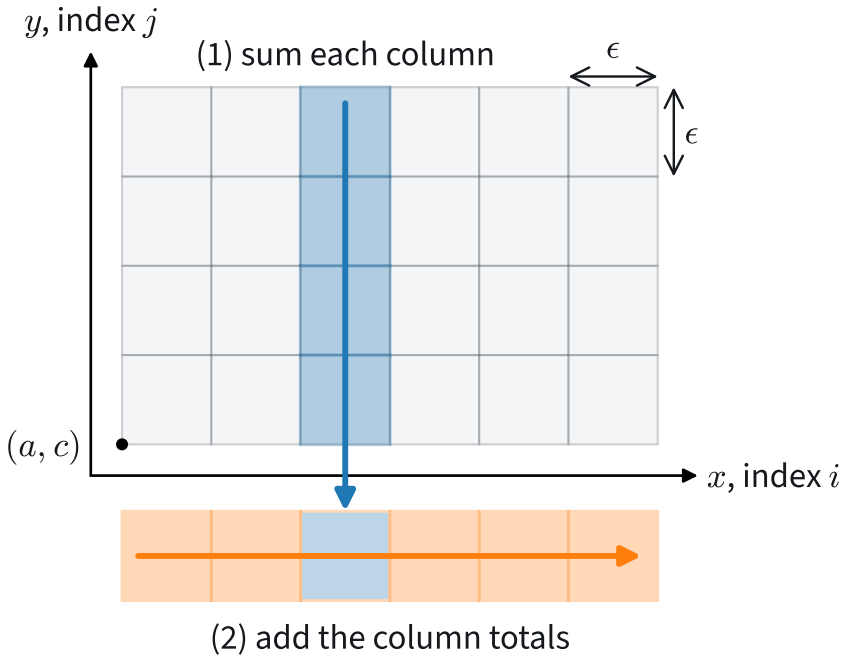

Figure 34.33: Totalling a grid of $\epsilon \times \epsilon$ cells with corner (a, c), indexed by i along x and j along y. (1) Sum each column, at fixed i, over j. (2) Add the column totals from left to right. Reordering a finite sum changes nothing; this discrete fact underlies iterated integration.

Reordering a finite grid sum is elementary, but ensuring that the equality survives the limit $\epsilon \to 0$ requires a theorem and a condition. **Fubini's theorem** states that if f is **absolutely integrable** on R, meaning $\iint_R |f(x,y)|\,dx\,dy < \infty$, then the double integral equals either iterated integral:

$$\iint_R f(x,y)\,dx\,dy = \int_c^d \left(\int_a^b f(x,y)\,dx \right) dy = \int_a^b \left(\int_c^d f(x,y)\,dy \right) dx. \tag{34.61}$$

In geometric terms, a volume can be computed slice by slice in either direction. When $f \geq 0$, the same equality holds with no integrability check at all, allowing all three sides to equal $+\infty$ (*Tonelli's theorem*). Probability densities, squared losses, and other nonnegative integrands therefore require no verification; for a signed integrand, however, we must check $\iint |f| < \infty$ first. Fubini's theorem is at work whenever we marginalize a variable out of a joint density or swap an expectation with another integral.

The most common special case is a product integrand $f(x,y) = g(x)h(y)$. Because $g(x)$ is constant with respect to y, it pulls straight out of the inner integral, $\int_c^d g(x)h(y)\,dy = g(x)\int_c^d h(y)\,dy$, leaving

$$\iint_R g(x)\,h(y)\,dx\,dy = \int_a^b g(x)\,dx \int_c^d h(y)\,dy. \tag{34.62}$$

A product integrand integrates factor by factor. Crucially, the two-dimensional bell factors in this way, $e^{-x^2-y^2} = e^{-x^2}e^{-y^2}$, and our evaluation of the Gaussian integral below rests on this observation.

The absolute-integrability hypothesis is not a mere formality. Consider $f(x,y) = (x^2 - y^2)/(x^2+y^2)^2$ on $[0,1]^2$. A quick differentiation shows that $\partial_y(y/(x^2+y^2)) = f(x,y)$, so the evaluation rule gives $\int_0^1 f(x,y)\,dy = \frac{1}{1+x^2}$ for $x > 0$, and integrating over x yields $\int_0^1 \frac{dx}{1+x^2} = \arctan 1 = \frac{\pi}{4}$. Yet $f(x,y) = -f(y,x)$, so integrating in the reverse order gives $-\frac{\pi}{4}$. The two orders disagree because $\iint |f| = \infty$: near the origin, $|f|$ grows like the inverse square of the distance, and its total volume diverges.

When the domain D is not a rectangle, $\int_D f(\mathbf{x})\,d\mathbf{x}$ is defined by *zero-extension*: set f to 0 outside D and integrate over any rectangle that contains D.

34.6.3.2 Change of Variables in Many Dimensions

The one-dimensional stretch factor du/dx generalizes naturally to higher dimensions, and linear maps already show the form it must take. A linear map scales every area or volume by the absolute value of its determinant (Section 33.2), while the sign of the determinant merely tracks orientation. For example, the map $\phi(u,v) = (au, bv)$ with $a, b > 0$ has determinant ab and stretches the unit disc (of area π) into the ellipse $x^2/a^2 + y^2/b^2 \le 1$, whose area is therefore πab.

Locally, a smooth nonlinear map looks linear, with its Jacobian matrix serving as the linear approximation; the volume scale factor simply varies from point to point. Let $\Omega \subseteq \mathbb{R}^n$ be open and let $\phi : \Omega \to \mathbb{R}^n$ be a C^1**-diffeomorphism** onto its image: ϕ is continuously differentiable and injective, and its Jacobian $\mathbf{J}_\phi$ (the matrix of partial derivatives from Section 34.4) satisfies $\det \mathbf{J}_\phi(\mathbf{x}) \neq 0$ everywhere on Ω. Injectivity prevents the map from folding space onto itself, and a nonzero determinant prevents it from flattening a region to a lower dimension. Under these conditions, for any absolutely integrable f,

$$\int_{\phi(\Omega)} f(\mathbf{y})\,d\mathbf{y} = \int_\Omega f(\phi(\mathbf{x}))\,\bigl|\det \mathbf{J}_\phi(\mathbf{x})\bigr|\,d\mathbf{x}. \tag{34.63}$$

An infinitesimal cube of volume $d\mathbf{x}$ at $\mathbf{x}$ maps to an infinitesimal parallelepiped of volume $|\det \mathbf{J}_\phi(\mathbf{x})|\,d\mathbf{x}$ at $\mathbf{y} = \phi(\mathbf{x})$, and the Jacobian determinant adjusts the integrand for that local distortion. Figure 34.34 places the one- and two-dimensional pictures side by side.

Why does Equation 34.63 carry the absolute value $|\det \mathbf{J}_\phi|$ rather than $\det \mathbf{J}_\phi$? Because the left-hand side integrates over an unoriented set, not between ordered endpoints. In one dimension, the order of the limits carries the sign: if u is decreasing, the limits in Equation 34.60 run backwards while $u' < 0$, so the two minus signs cancel and we can equivalently integrate over the image interval with $|u'|$. Regions in $\mathbb{R}^n$ have no natural ordering, so only this unsigned form generalizes.

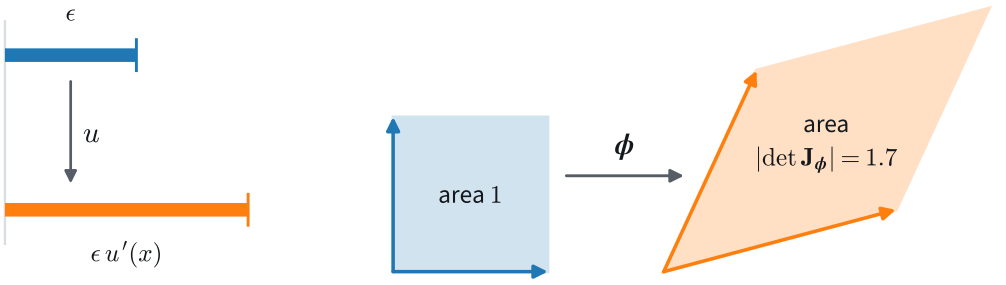

Figure 34.34: Left: one-dimensional substitution scales a segment of length ϵ by $u'(x)$. Right: in two dimensions, a linear map ϕ sends the unit square to a parallelogram whose area is the volume factor $|\det \mathbf{J}_\phi|$.

When f is a probability density, Equation 34.63 tells us how a density transforms under a smooth invertible map, which is how a normalizing flow computes the density of its output (Section 36.2).

34.6.3.3 The Gaussian Integral

The normalizing constant $1/\sqrt{2\pi}$ of the bell curve comes from the one-dimensional integral $\int_{-\infty}^{\infty} e^{-x^2}\,dx$. Here the fundamental theorem cannot give us a closed form: an antiderivative certainly exists because e^{-x^2} is continuous, but it is a fundamentally new function that cannot be written in terms of elementary ones. Surprisingly, the integral over the entire real line can still be evaluated in closed form by taking a detour through two dimensions. The argument takes three steps and is the most elegant calculation in the section. (Normalized, the antiderivative is the **error function** $\operatorname{erf}(x) = \frac{2}{\sqrt{\pi}}\int_0^x e^{-t^2}\,dt$, which tends to 1 as $x \to \infty$ by the result we are about to prove; standard libraries provide it as `math.erf`.)

I. Square and factor. On the square $[-b, b]^2$, the product rule Equation 34.62 gives $\iint_{[-b,b]^2} e^{-x^2-y^2}\,dx\,dy = \left(\int_{-b}^{b} e^{-x^2}\,dx\right)^2$. Letting $b \to \infty$ on both sides yields

$$\left(\int_{-\infty}^{\infty} e^{-x^2}\,dx\right)^2 = \lim_{b\to\infty} \iint_{[-b,b]^2} e^{-x^2-y^2}\,dx\,dy = \iint_{\mathbb{R}^2} e^{-x^2-y^2}\,dx\,dy. \tag{34.64}$$

The square of our one-dimensional integral is simply the volume under the two-dimensional bell, and that surface is rotationally symmetric around the origin.

II. Polar coordinates. Rotational symmetry invites polar coordinates, $\phi(r, \theta) = (r\cos\theta, r\sin\theta)$, on the open set $\Omega = (0, \infty) \times (0, 2\pi)$, where the map is injective. Its Jacobian determinant is

$$|\det \mathbf{J}_\phi| = \left|\det \begin{bmatrix} \cos\theta & -r\sin\theta \\ \sin\theta & r\cos\theta \end{bmatrix}\right| = r(\cos^2\theta + \sin^2\theta) = r.$$

Geometrically, a polar cell with radial side dr and arc length $r\,d\theta$ has area approximately $r\,dr\,d\theta$ (Figure 34.35), reflecting the fact that cells farther from the origin are

wider. Crucially, this factor r supplies the missing factor x from our substitution example $\int_0^1 x\,e^{-x^2}\,dx$.

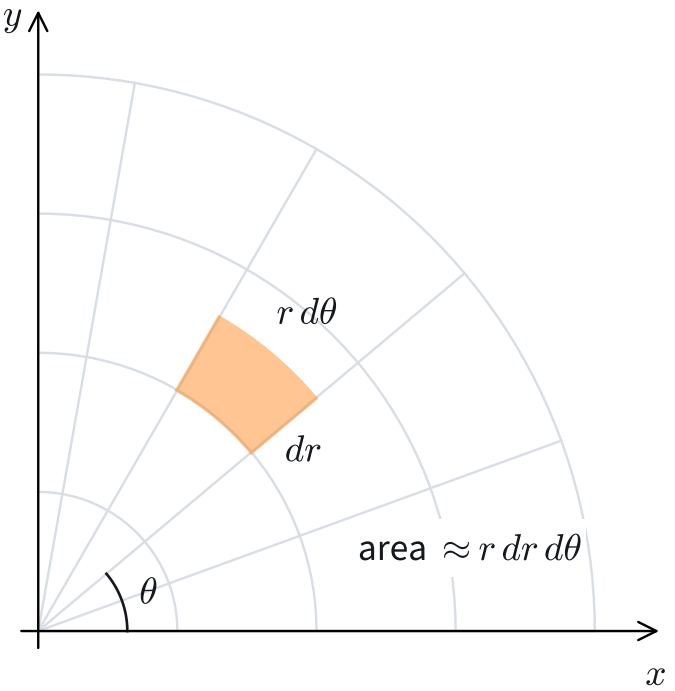

Figure 34.35: A polar grid with one cell shaded: radial side dr and arc side $r\,d\theta$, giving an area of approximately $r\,dr\,d\theta$. Switching to polar coordinates multiplies the integrand by $|\det \mathbf{J}_\phi| = r$.

III. Integrate. Applying Equation 34.63 and using the antiderivative $-\frac{1}{2}e^{-r^2}$ of re^{-r^2}, we obtain

$$\iint_{\mathbb{R}^2} e^{-x^2-y^2}\,dx\,dy = \int_0^{2\pi}\int_0^{\infty} r\,e^{-r^2}\,dr\,d\theta = 2\pi\cdot\frac{1}{2} = \pi.$$

Taking the positive square root of Equation 34.64 gives

$$\int_{-\infty}^{\infty} e^{-x^2}\,dx = \sqrt{\pi}. \tag{34.65}$$

Thus the total area under e^{-x^2} is $\sqrt{\pi} \approx 1.7725$.

Three technical points make this argument completely rigorous. First, because the integrand is nonnegative, integrals over expanding squares and over expanding discs converge to the same limit: every disc fits inside some square and every square inside some disc, so

the shape of the growing region does not matter. Second, the polar map omits the nonnegative ray $\theta = 0$, which has zero area and contributes nothing to the integral. Third, we apply the change of variables on the bounded rectangles $(0, b) \times (0, 2\pi)$, where the integrand is bounded and continuous, and let $b \to \infty$ afterward.

The normalizing constant of the standard normal now follows from a single substitution. Setting $z = \sqrt{2}\,x$ in Equation 34.60 gives

$$\int_{-\infty}^{\infty} e^{-z^2/2}\,dz = \sqrt{2}\int_{-\infty}^{\infty} e^{-x^2}\,dx = \sqrt{2\pi}. \tag{34.66}$$

Dividing the bell $e^{-z^2/2}$ by $\sqrt{2\pi} \approx 2.5066$ scales its total area to 1, which is where the constant in the standard normal density comes from.

Let us check step I numerically: do the expanding squares $[-b, b]^2$ really exhaust the plane and converge to π? The code below computes the two-dimensional grid sum over $[-b, b]^2$ at $\epsilon = 0.01$ alongside the exact square volume $\left(\int_{-b}^{b} e^{-x^2}\,dx\right)^2 = \pi\,\mathrm{erf}(b)^2$ and the limiting value π.

```
eps = 0.01
for b in [1, 2, 3, 6]:
    g = -b + eps * np.arange(round(2 * b / eps))    # left ends of the slices
    x, y = np.meshgrid(g, g, indexing='ij')
    grid = np.sum(eps**2 * np.exp(-x**2 - y**2))
    print(f'b={b}  grid sum={grid:.6f}  pi*erf(b)^2={math.pi * math.erf(b)**2:.6f}'
          f'  pi={math.pi:.6f}')
```

```
b=1  grid sum=2.230949  pi*erf(b)^2=2.230985  pi=3.141593
b=2  grid sum=3.112266  pi*erf(b)^2=3.112270  pi=3.141593
b=3  grid sum=3.141454  pi*erf(b)^2=3.141454  pi=3.141593
b=6  grid sum=3.141593  pi*erf(b)^2=3.141593  pi=3.141593
```

The grid sums track $\pi\,\mathrm{erf}(b)^2$ closely and climb to π; by $b = 3$, the volume left outside the square is only about 10^{-4}. Agreement to four or more decimal places at $\epsilon = 0.01$ has a simple explanation: for an even integrand on a symmetric interval, the left rule's first-order bias $\frac{\epsilon}{2}(f(-b) - f(b))$ vanishes identically.

We can now compute the standard normal probability $P(-1 \le Z \le 1) \approx 0.68$ as well. Substituting $z = \sqrt{2}\,t$ turns the area under $p(z) = e^{-z^2/2}/\sqrt{2\pi}$ into an error function:

$$P(-1 \le Z \le 1) = \frac{1}{\sqrt{2\pi}}\int_{-1}^{1} e^{-z^2/2}\,dz = \frac{1}{\sqrt{\pi}}\int_{-1/\sqrt{2}}^{1/\sqrt{2}} e^{-t^2}\,dt = \mathrm{erf}(1/\sqrt{2}) \approx 0.683.$$

Both questions we asked about the bell curve are now answered, and the apparent paradox that $p(0) \approx 0.40$ while $P(Z = 0) = 0$ disappears: a density measures probability per unit length, and a single point is an interval of length zero.

One question from the opening remains open. Training a model through random sampling requires knowing how an area of this kind changes when a parameter of the density moves, and for that we need to differentiate an integral.

34.6.4 Summary

The definite integral is the limit of sums of thin slices, measuring signed area under a curve. The fundamental theorem of calculus replaces that limit with antidifferentiation: because the area-so-far function satisfies $F' = f$, any antiderivative G gives $\int_a^b f\,dx = G(b) - G(a)$. Integration by parts and substitution are the product and chain rules read backwards. In multiple dimensions, Fubini's theorem reduces volume integrals to iterated one-dimensional integrals, and the change-of-variables stretch factor becomes $|\det \mathbf{J}_\phi|$, the local volume distortion; combined with polar coordinates, this yields $\int_{-\infty}^{\infty} e^{-x^2}\,dx = \sqrt{\pi}$ and the standard normal normalizing constant $\sqrt{2\pi}$.

34.6.5 Exercises

1. **Activations as accumulated areas.** Let H be the unit step, with $H(t) = 1$ for $t > 0$ and $H(t) = 0$ for $t \le 0$. Let $\phi(t) = e^{-t^2/2}/\sqrt{2\pi}$ be the standard Gaussian density and $\Phi(x) = \int_{-\infty}^{x} \phi(t)\,dt$ its distribution function.
   1. Show that $\int_{-\infty}^{x} H(t)\,dt = \mathrm{ReLU}(x)$. Which hypothesis of the fundamental theorem Equation 34.55 fails at $x = 0$? What are the one-sided derivatives of the integral there?
   2. Write $\Phi(x) = \Phi(0) + \int_0^x \phi(t)\,dt$ to conclude that $\Phi' = \phi$. Then substitute $t = \sqrt{2}\,s$ to show that $\Phi(x) = \frac{1}{2}(1 + \mathrm{erf}(x/\sqrt{2}))$.
   3. The GELU activation of Section 4.1 is $x\Phi(x)$. Derive its derivative, find the points where the derivative is largest and smallest, and evaluate it there with `math.erf`. In which interval does the slope of GELU lie, and how does that interval compare with the slopes 0 and 1 of ReLU?
2. **Heavy tails.** The *Pareto density* with tail index $\alpha > 0$ is $p(x) = \alpha x^{-\alpha-1}$ for $x \ge 1$ and $p(x) = 0$ otherwise. The *Cauchy density* is $p(x) = \frac{1}{\pi(1+x^2)}$ on $\mathbb{R}$.
   1. Show that the Pareto density is normalized for every $\alpha > 0$. For which α are $\mathbb{E}[X]$ and $\mathbb{E}[X^2]$ finite? Compute $\mathbb{E}[X]$ where it is finite.
   2. Show that the Cauchy density is normalized, using the antiderivative $\arctan x$ of $\frac{1}{1+x^2}$.
   3. Show that $\int_{-b}^{b} x\,p(x)\,dx = 0$ for the Cauchy density and every $b > 0$. Why does the Cauchy density nevertheless have no mean under the definition of $\int_{-\infty}^{\infty}$ that follows Equation 34.57? How fast does $\int_0^b x\,p(x)\,dx$ grow with b?
3. **Gamma function by parts.** The *Gamma function* is $\Gamma(t) = \int_0^\infty u^{t-1}e^{-u}\,du$. For $t < 1$ the integrand is unbounded at $u = 0$, and the integral near 0 is defined by a limit, $\int_0^1 = \lim_{a\to 0^+} \int_a^1$, as in Section 34.6.2.2.
   1. For which t does the integral converge at $u = 0$? Compare the condition with the test for $\int_0^1 x^{-s}\,dx$ in Section 34.6.2.2.
   2. Integrate by parts Equation 34.58 at a general $t > 0$ to show that $\Gamma(t+1) = t\,\Gamma(t)$, and conclude that $\Gamma(n+1) = n!$ for every integer $n \ge 0$. Where does the argument use $t > 0$? Use the result to compute the variance of the exponential density e^{-u} on $u \ge 0$, whose mean we computed in Section 34.6.2.3.
   3. Substitute $u = x^2$ and use the Gaussian integral Equation 34.65 to evaluate $\Gamma(\frac{1}{2})$.

4. The product rule Equation 34.62, applied d times, gives $\int_{\mathbb{R}^d} e^{-\|\mathbf{x}\|^2}\, d\mathbf{x} = \pi^{d/2}$. In polar form the same integral is $S_{d-1}\int_0^\infty r^{d-1}e^{-r^2}\, dr$, where S_{d-1} is the surface area of the unit sphere in $\mathbb{R}^d$. Show that the radial integral is $\frac{1}{2}\Gamma(d/2)$ and deduce $S_{d-1} = 2\pi^{d/2}/\Gamma(d/2)$. Integrate $S_{d-1}r^{d-1}$ over $r \in [0,1]$ to show that the unit ball has volume $V_d = \pi^{d/2}/\Gamma(d/2+1)$. Evaluate V_d for $d \in \{1,2,3,5,10,20\}$ and explain why $V_d \to 0$. A midpoint grid with three points per axis on the cube $[-1,1]^{10}$ has 3^{10} points; what fraction of them lies inside the unit ball, and what does that say about grids in high dimensions?

4. **Swapping the order.** Fubini's theorem Equation 34.61, together with zero-extension for regions that are not rectangles, lets us choose the order of integration.
   1. The inner integral of $\int_0^1 (\int_y^1 e^{-x^2}\, dx)\, dy$ has no elementary antiderivative. Sketch the triangular region of integration, reverse the order, and evaluate the integral in closed form.
   2. Let $X \ge 0$ have density p. Write $x = \int_0^x dt$ inside $\mathbb{E}[X] = \int_0^\infty x\, p(x)\, dx$ and swap the two integrals to show that $\mathbb{E}[X] = \int_0^\infty P(X > t)\, dt$. Why is the swap valid even when $\mathbb{E}[X] = \infty$? Check the formula on the density $\lambda e^{-\lambda x}$ for $x \ge 0$.
5. **Gaussian normalizers and moments.** The text normalizes the standard normal and computes its moments with the Stein identity Equation 34.59 for the bell weight. Let $p(x) = \frac{1}{\sqrt{2\pi\sigma^2}}\exp\!\big(-\frac{(x-\mu)^2}{2\sigma^2}\big)$ with $\sigma > 0$.
   1. Substitute $x = \mu + \sigma z$ and use Equation 34.66 to show that p is normalized. Which μ and σ^2 does the density $\frac{1}{\sqrt{\pi}}e^{-x^2}$ have?
   2. Let X have density p, and let g be continuously differentiable with $g(x)\,p(x) \to 0$ as $x \to \pm\infty$. Use $p'(x) = -\frac{x-\mu}{\sigma^2}\,p(x)$ and integration by parts to show that
   $$\mathbb{E}\big[(X-\mu)\,g(X)\big] = \sigma^2\,\mathbb{E}\big[g'(X)\big]. \tag{34.67}$$
   Deduce that $\mathbb{E}[(X-\mu)^2] = \sigma^2$ and $\mathbb{E}[(X-\mu)^4] = 3\sigma^4$.
   3. Let $\Sigma = \mathbf{L}\mathbf{L}^\top$ be a $d \times d$ covariance matrix with invertible $\mathbf{L}$. Use the change of variables $\mathbf{x} = \mathbf{L}\mathbf{z}$ in Equation 34.63 and the product rule Equation 34.62 to show that
   $$\int_{\mathbb{R}^d} \exp\!\big(-\tfrac{1}{2}\mathbf{x}^\top\Sigma^{-1}\mathbf{x}\big)\, d\mathbf{x} = (2\pi)^{d/2}\,(\det\Sigma)^{1/2}. \tag{34.68}$$

34.7 Expectations and Their Gradients

Almost every loss we have minimized so far is an average: over a minibatch of examples, over random dropout masks, or over noise injected into an input. As long as the source of randomness does not depend on the model parameters, differentiating such an average is straightforward. The derivative of an average equals the average of the derivatives, so minibatch gradient descent computes it directly without any extra machinery. The difficulty arises when the parameters control the probability distribution itself. A variational autoencoder draws its latent code from a distribution whose mean and variance are produced by its encoder; a policy-gradient agent (Section 14.7) samples actions from the very policy it is trying to improve. In both cases, the objective is an expectation over samples whose distribution shifts with the parameters, yet a sample, once drawn, is just a number. It carries no memory of the parameter that generated it.

Consider the simplest problem of this kind. Let $X \sim \mathcal{N}(\theta, 1)$ be a normal random variable with mean θ and unit variance, and take the expected squared loss

$$\ell(\theta) = \mathbb{E}\big[X^2\big] = \theta^2 + 1.$$

The closed form follows immediately by writing $X = \theta + Z$ with Z standard normal: $\mathbb{E}[(\theta + Z)^2] = \theta^2 + 2\theta\,\mathbb{E}[Z] + \mathbb{E}[Z^2]$, where $\mathbb{E}[Z] = 0$ by symmetry and $\mathbb{E}[Z^2] = 1$ (Section 34.6.2.3). At $\theta = 1.5$, the exact derivative is $\ell'(1.5) = 3$. In practice, however, a model can draw samples of X but cannot evaluate $\ell(\theta)$ in closed form. How, then, can we estimate $\ell'(\theta)$ from samples alone?

Calculus offers two fundamentally different answers. Both express the expectation as an integral (Section 34.6) and pass the derivative inside it. From there they diverge: the *score-function* estimator differentiates the probability density while leaving the samples untouched, whereas the *pathwise* estimator differentiates the samples while leaving the noise density untouched. Neither method dominates in every setting, and comparing them (Section 34.7.3) is the central goal of this section. First, we briefly recall how expectations are written as integrals and establish when passing a derivative inside an integral is valid, because that step is where subtle errors can creep in.

34.7.1 Expectations as Integrals

Before differentiating anything, let us fix our notation for densities and expectations. The probability chapter develops both notions in detail (Section 36.1); here we restate them in the integral language of the preceding section. A probability **density** on a domain $\mathcal{X}$ is a nonnegative function whose total integral equals 1:

$$p(x) \geq 0, \qquad \int_{\mathcal{X}} p(x)\,dx = 1. \tag{34.69}$$

The probability that a random variable X with density p lands in an interval $[a, b]$ is the area under p over that interval, $P(a \leq X \leq b) = \int_a^b p(x)\,dx$ (Section 36.1). Because a density measures probability per unit length rather than probability itself, its value can exceed 1; for example, the uniform density on $[0, \frac{1}{2}]$ equals 2 everywhere on its support. Our main running example is the **standard normal** distribution $\mathcal{N}(0, 1)$, whose density $p(z) = e^{-z^2/2}/\sqrt{2\pi}$ is normalized by the Gaussian integral of Section 34.6.

An **expectation** computes the weighted average of X, or of a function $g(X)$, weighting each outcome by its probability density:

$$\mathbb{E}[X] = \int_{\mathcal{X}} x\,p(x)\,dx, \qquad \mathbb{E}[g(X)] = \int_{\mathcal{X}} g(x)\,p(x)\,dx. \tag{34.70}$$

The expectation $\mathbb{E}[g(X)]$ is well defined whenever the integral converges absolutely, $\int_{\mathcal{X}} |g(x)|\,p(x)\,dx < \infty$. Heavy-tailed distributions can violate this condition; the Cauchy density in exercise 2, for instance, has no finite mean.

In deep learning, expectations rarely have closed-form expressions, and they often live in thousands of dimensions where numerical quadrature on a grid is out of the question.

Instead, we draw independent samples $x_1, \dots, x_n$ from p and form the sample average $\frac{1}{n}\sum_{i=1}^{n} g(x_i)$, known as the *Monte Carlo* estimate. If a single sample $g(X)$ has standard deviation σ, the Monte Carlo average has root-mean-square error $\sigma/\sqrt{n}$, regardless of the dimension (Section 36.5.1.7). Both gradient estimators in this section are Monte Carlo averages of this form. Because both are unbiased for the same true gradient, they differ only in the spread of a single sample, making the single-sample standard deviation σ the natural yardstick for comparing them.

34.7.2 Differentiation under the Integral Sign

34.7.2.1 The Swap

Our toy loss $\ell(\theta) = \mathbb{E}[X^2]$ is an integral that varies with a parameter θ. In general, a parameter can affect an integral in two places: through the limits of integration, which the fundamental theorem of calculus (Section 34.6) handles, or through the integrand itself.

When the limits of integration are fixed and only the integrand depends on θ, we differentiate by passing the derivative inside the integral:

$$\frac{d}{d\theta}\int f(x,\theta)\,dx = \int \frac{\partial f}{\partial \theta}(x,\theta)\,dx. \tag{34.71}$$

Geometrically, the rate of change of the total area equals the integral of the pointwise rate of change of the height. We will refer to this exchange of derivative and integral as the *swap*; both gradient estimators depend on it. At first glance the identity looks harmless, since a derivative is a limit of difference quotients, an integral is a limit of sums, and finite sums and differences always commute. Yet exchanging two limits is never automatic and requires regularity conditions. On a bounded interval of x, continuity of $\partial_\theta f$ in both variables is enough. On an unbounded domain, we also need an integrable function of x that dominates $|\partial_\theta f(x,\theta')|$ for all θ' near θ (an immediate consequence of the dominated convergence theorem, quoted without proof from (Folland 1999)). For our running example $f(x,\theta) = x^2 p_\theta(x)$ with a normal density, such a dominating bound always exists because the Gaussian tail decays faster than any polynomial grows.

34.7.2.2 The Leibniz Rule

When the limits of integration also move with θ, the plain swap is incomplete and gives the wrong answer. The Leibniz rule supplies the missing boundary terms: the interior change and the sweeping boundaries simply add (Figure 34.36).

Proposition (Leibniz rule). *Let f and $\partial_\theta f$ be continuous on a region containing $\{(x,\theta) : x \in [a(\theta), b(\theta)]\}$ for θ in an open interval, and let a and b be differentiable. Then*

$$\frac{d}{d\theta}\int_{a(\theta)}^{b(\theta)} f(x,\theta)\,dx = \int_{a(\theta)}^{b(\theta)} \frac{\partial f}{\partial \theta}(x,\theta)\,dx + f\big(b(\theta),\theta\big)\,b'(\theta) - f\big(a(\theta),\theta\big)\,a'(\theta). \tag{34.72}$$

Proof. Define $H(\alpha,\beta,\theta) = \int_\alpha^\beta f(x,\theta)\,dx$. By the fundamental theorem of calculus, $\partial_\beta H = f(\beta,\theta)$ and $\partial_\alpha H = -f(\alpha,\theta)$, while the swap on the bounded interval $[\alpha,\beta]$ gives

$\partial_\theta H = \int_\alpha^\beta \partial_\theta f \, dx$. Since all three partial derivatives are continuous, the multivariable chain rule (Section 34.3) applies to the composition $\theta \mapsto H(a(\theta), b(\theta), \theta)$ and combines the three terms weighted by $a'(\theta)$, $b'(\theta)$, and 1. ■

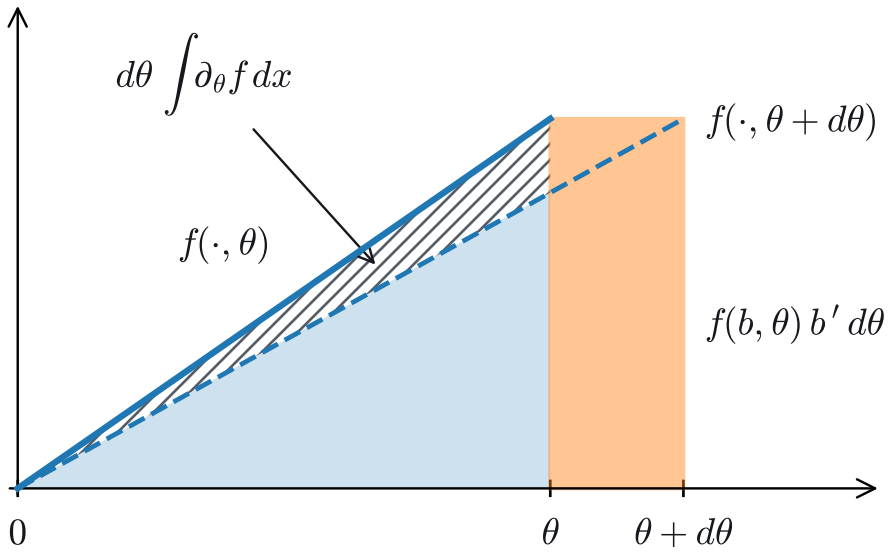

Figure 34.36: The Leibniz rule for $f(x, \theta) = x/\theta$ on $[0, \theta]$, the uniform example. When θ increases by $d\theta$, the integrand curve shifts to $f(\cdot, \theta + d\theta)$ (dashed; here it drops, so the hatched region represents lost area), while the right boundary moves outward and sweeps in a strip of height $f(b, \theta)$ and width $b'\, d\theta$.

Ignoring the boundary term is not a minor inaccuracy; it can flip the sign of the derivative. Suppose X is uniform on $[0, \theta]$, with density $1/\theta$ on that interval. Its mean is $\mathbb{E}[X] = \int_0^\theta \frac{x}{\theta}\, dx = \frac{\theta}{2}$, whose derivative is $+\frac{1}{2}$. Differentiating only the integrand gives $\int_0^\theta -\frac{x}{\theta^2}\, dx = -\frac{1}{2}$, which has the wrong sign. Adding the upper boundary contribution $f(\theta, \theta)\, b'(\theta) = \frac{\theta}{\theta} \cdot 1 = 1$ restores the true derivative, $-\frac{1}{2} + 1 = +\frac{1}{2}$. Whenever the support of a distribution depends on the parameter, the plain swap alone is not valid (exercise 1 works out $\mathbb{E}[X^2]$).

34.7.2.3 Log-Integral-Exp

The swap also produces the continuous counterpart of the log-sum-exp function. Applying the chain rule and Equation 34.71 to $\log \int e^{\theta x} p(x)\, dx$ yields

$$\frac{d}{d\theta} \log \int e^{\theta x} p(x)\, dx = \frac{\int x\, e^{\theta x} p(x)\, dx}{\int e^{\theta x} p(x)\, dx}.$$

The right-hand side is the mean of x under the exponentially *tilted* density proportional to $e^{\theta x} p(x)$. For the standard normal density, completing the square via $\theta z - \frac{1}{2} z^2 = \frac{1}{2}\theta^2 - \frac{1}{2}(z - \theta)^2$ shows that the tilted density is $\mathcal{N}(\theta, 1)$ and that $\log \mathbb{E}[e^{\theta Z}] = \theta^2/2$, whose

derivative θ is indeed the tilted mean. Just as the gradient of log-sum-exp is the softmax vector, the gradient of log-integral-exp is an expectation. We will encounter this identity again as the derivative $A'(\eta)$ of the log-partition function in Section 36.4.

34.7.3 Score-Function and Pathwise Gradients

Applying the swap to an expected loss gives the integral $\int g(x)\,\partial_\theta p_\theta(x)\,dx$. Unfortunately, we cannot estimate this integral directly by Monte Carlo sampling: $\partial_\theta p_\theta$ is not a probability density (it takes both positive and negative values and integrates to zero), so we cannot draw samples from it. Two simple identities rewrite this integral back into an expectation that samples can estimate.

34.7.3.1 The Score-Function Estimator

Let p_θ be a density parameterized by θ. Applying the chain rule to $\log p_\theta(x)$ yields the **log-derivative identity**:

$$\nabla_\theta\, p_\theta(x) = p_\theta(x)\,\nabla_\theta \log p_\theta(x). \tag{34.73}$$

In words, the gradient of a density equals the density itself multiplied by the gradient of its logarithm, a vector known as the **score** $\nabla_\theta \log p_\theta$. Whenever the swap is valid and the support of p_θ does not move with θ, the score has expectation zero: $\mathbb{E}[\nabla_\theta \log p_\theta(X)] = \int \nabla_\theta p_\theta\,dx = \nabla_\theta \int p_\theta\,dx = \nabla_\theta 1 = \mathbf{0}$. The uniform density on $[0,\theta]$ shows why fixed support is essential: its score is $\partial_\theta \log(1/\theta) = -1/\theta$, whose expectation is $-1/\theta \neq 0$, because differentiating $\int_0^\theta p_\theta(x)\,dx = 1$ also picks up the boundary term $p_\theta(\theta) = 1/\theta$. The mean-zero property of the score is also the starting point for Fisher information (Section 36.6).

Multiplying Equation 34.73 by a function $g(x)$ that does not depend on θ and integrating gives the **score-function identity**:

$$\nabla_\theta\, \mathbb{E}_{X\sim p_\theta}[g(X)] = \int g(x)\,\nabla_\theta p_\theta(x)\,dx = \mathbb{E}\big[g(X)\,\nabla_\theta \log p_\theta(X)\big]. \tag{34.74}$$

This identity turns the gradient of an expected loss back into an expectation under p_θ: each sample's loss $g(x)$ is weighted by how strongly θ increases that sample's log-probability. To estimate it by Monte Carlo, we draw samples $x_i \sim p_\theta$ and average $g(x_i)\nabla_\theta \log p_\theta(x_i)$. In reinforcement learning, this is the REINFORCE estimator of policy-gradient methods (Section 14.7) (Williams 1992). (If g also depends directly on θ, the product rule simply adds the term $\mathbb{E}[\nabla_\theta g(X,\theta)]$.)

Because the score has mean zero, we may subtract any constant **baseline** b (independent of x) from $g(X)$ without biasing the estimator (Section 14.8): $\mathbb{E}[(g(X)-b)\nabla_\theta \log p_\theta(X)] = \mathbb{E}[g(X)\nabla_\theta \log p_\theta(X)]$. Choosing b well can substantially reduce the variance of the estimate.

34.7.3.2 The Pathwise Estimator

The second identity restores the sample's memory of θ. Often, a sample from p_θ can be generated by applying a deterministic transformation $x = T_\theta(\mathbf{z})$ to an auxiliary noise variable $\mathbf{z} \sim q$ whose distribution does not depend on θ. A normal random variable $\mathcal{N}(\mu,\sigma^2)$, for

instance, is simply $\mu + \sigma z$ with $z \sim \mathcal{N}(0,1)$. Rewriting the expectation as an integral over $\mathbf{z}$ removes θ from the density entirely, so the swap yields the **pathwise identity**:

$$\nabla_\theta \, \mathbb{E}_{X \sim p_\theta}[g(X)] = \nabla_\theta \int g(T_\theta(\mathbf{z}))\, q(\mathbf{z})\, d\mathbf{z} = \mathbb{E}_{\mathbf{z}\sim q}\Big[\nabla_\theta \, g(T_\theta(\mathbf{z}))\Big]. \tag{34.75}$$

Instead of differentiating the density, this estimator differentiates right through the sample: automatic differentiation traces the path from θ through T_θ into g. Known as the *reparameterization trick*, this is how variational autoencoders backpropagate through Gaussian latent variables (Kingma and Welling 2014; Rezende et al. 2014). The estimator itself is older: the simulation literature had long used it under the names pathwise and infinitesimal-perturbation derivative (Mohamed et al. 2020). Valid use requires T_θ to be differentiable in θ, g to be differentiable along the path (a Lipschitz g suffices when X has a continuous density), and an integrable dominating bound for the swap. Notice that no boundary term ever appears, even if the support of X moves with θ, because the integral is taken over $\mathbf{z}$ whose density q stays fixed.

The differentiability requirement on g is not a technicality we can ignore. Consider the step function $g(x) = \mathbf{1}(x > 0)$, which equals 1 for positive x and 0 otherwise, with $X = \theta + z$. The true expectation $\mathbb{E}[g(X)] = P(z > -\theta)$ has derivative $\varphi(\theta) = e^{-\theta^2/2}/\sqrt{2\pi}$, which evaluates to about 0.13 at $\theta = 1.5$. Yet the pathwise sample $\partial_\theta \mathbf{1}(\theta + z > 0)$ is 0 for every z except the single point $z = -\theta$ (an event of probability zero), so the pathwise estimator returns 0 with probability 1. By contrast, the score-function sample $\mathbf{1}(x > 0)\, z$ has expectation $\int_{-\theta}^{\infty} z\,\varphi(z)\, dz = \big[-\varphi(z)\big]_{-\theta}^{\infty} = \varphi(\theta)$, recovering the exact derivative. Because the score-function estimator never differentiates through g or the sampling step, it applies equally well to discontinuous losses and to discrete distributions such as Bernoulli or categorical choices, where no differentiable path from θ to the sample exists.

34.7.3.3 The Two Estimators Compared

We now have two unbiased estimators of the same derivative, and our running example $\ell(\theta) = \mathbb{E}[X^2]$ with $X = \theta + z$ is simple enough to compute the variance of both by hand. For the pathwise estimator, a single sample contributes $\partial_\theta (\theta + z)^2 = 2X$, whose variance is $\mathrm{Var}(2X) = 4$. For the score-function estimator, the score of the normal location family is $\partial_\theta \log p_\theta(X) = X - \theta = z$, so one sample contributes $X^2 z$, or $(X^2 - b)z$ when using a baseline b. To find the variance of $X^2 z$, we use the standard normal moments $\mathbb{E}[z^2] = 1$, $\mathbb{E}[z^4] = 3$, and $\mathbb{E}[z^6] = 15$, all of which follow from Stein's identity $\mathbb{E}[g'(Z)] = \mathbb{E}[Z\, g(Z)]$ (Section 34.6.2.3). By symmetry, all odd powers of z vanish in the second moment:

$$\mathbb{E}\big[(\theta + z)^4 z^2\big] = \theta^4\, \mathbb{E}[z^2] + 6\theta^2\, \mathbb{E}[z^4] + \mathbb{E}[z^6] = \theta^4 + 18\theta^2 + 15.$$

Subtracting the squared mean $(2\theta)^2$ leaves a variance of $\theta^4 + 14\theta^2 + 15$. The variance-minimizing constant baseline turns out to be $b^\star = \theta^2 + 3$, reducing the variance to $8\theta^2 + 6$ (exercise 2). At $\theta = 1.5$, the three single-sample standard deviations are 2 for the pathwise estimator, 7.18 for the plain score-function estimator, and 4.90 for the score-function estimator with the optimal baseline. Although the baseline helps noticeably, it cannot close the gap for this loss, since $8\theta^2 + 6 > 4$ for every θ.

Let us test all three closed-form predictions in a single Monte Carlo simulation. Because the pathwise derivative is simply $2x_i$, we do not even need automatic differentiation here.

If our algebra is right, the three sample standard deviations should land near 2, 7.18, and 4.90, and each sample mean should fall within a few standard errors $\mathrm{sd}/\sqrt{n}$ of the true derivative 3.

```
theta, n = 1.5, 200_000
z = np.random.default_rng().standard_normal(n)     # noise, independent of theta
x = theta + z                                      # samples of N(theta, 1)
pathwise = 2 * x                                   # d/dtheta (theta + z_i)^2
score = x**2 * z                                   # g(x) times the score x - theta
baseline = (x**2 - (theta**2 + 3)) * z             # with the optimal baseline
exact_sd = {'pathwise': 2, 'score': math.sqrt(theta**4 + 14 * theta**2 + 15),
            'score+baseline': math.sqrt(8 * theta**2 + 6)}
print(f'true derivative 2*theta = {2 * theta}')
for name, s in zip(exact_sd, [pathwise, score, baseline]):
    print(f'{name:15s} mean={s.mean():.4f}  sd={s.std():.3f} '
          f'(exact {exact_sd[name]:.3f})  se={s.std() / math.sqrt(n):.4f}')
```

```
true derivative 2*theta = 3.0
pathwise        mean=3.0086  sd=1.997 (exact 2.000)  se=0.0045
score           mean=3.0114  sd=7.137 (exact 7.181)  se=0.0160
score+baseline  mean=2.9887  sd=4.852 (exact 4.899)  se=0.0108
```

In typical runs, all three means lie within a couple of standard errors of 3, and the empirical standard deviations match the closed-form predictions to within a few percent. For a fixed sample budget, the pathwise estimate is about 3.6 times more accurate than the plain score-function estimate; equivalently, the plain score-function estimator needs roughly thirteen times as many samples to reach the same precision.

It would be a mistake, however, to conclude that the pathwise estimator always has lower variance. Consider an oscillating loss $g(x) = \sin(\omega x)$, for which the true derivative of the expectation is $\omega \cos(\omega\theta) e^{-\omega^2/2}$. The pathwise sample $\omega \cos(\omega X)$ scales with the frequency ω and has standard deviation close to $\omega/\sqrt{2}$, whereas the score-function sample $\sin(\omega X)\, z$ has standard deviation at most $\sqrt{\mathbb{E}[z^2]} = 1$ because $|\sin| \le 1$. Whenever an integrand oscillates rapidly, its derivative can be huge even while its values remain bounded. Let us compare the two estimators at $\omega = 1$ and $\omega = 3$, reusing the samples already drawn.

```
for omega in [1, 3]:
    true = omega * math.cos(omega * theta) * math.exp(-omega**2 / 2)
    path, score = omega * np.cos(omega * x), np.sin(omega * x) * z
    print(f'omega={omega}  true={true:+.4f}  pathwise {path.mean():+.4f} '
          f'(sd {path.std():.2f})  score {score.mean():+.4f} (sd {score.std():.2f})')
```

```
omega=1  true=+0.0429  pathwise +0.0403 (sd 0.66)  score +0.0429 (sd 0.54)
omega=3  true=-0.0070  pathwise -0.0026 (sd 2.12)  score -0.0083 (sd 0.70)
```

Even at $\omega = 1$, the score-function estimator already has the smaller spread (about 0.5 versus 0.7), and at $\omega = 3$ it wins by a factor of three (about 0.7 versus 2.1). Both sample means agree with the exact derivatives within a few standard errors.

Neither estimator dominates in every problem. The pathwise estimator differentiates g, so its variance grows whenever g' is large; the score-function estimator multiplies g by the score, so its variance grows whenever g itself is large. In both cases, the single-sample stan-

dard deviation σ governs how many samples are needed for a given accuracy. Because σ also depends on the distribution from which we draw samples, choosing a proposal distribution that makes σ small leads directly to importance sampling, which we take up in Section 36.8.

34.7.4 Summary

When a model's parameters govern the distribution of its samples, the gradient of an expected loss must be rewritten as an expectation before Monte Carlo sampling can estimate it. Both ways of doing so pass the derivative inside the integral, a step that requires an integrable dominating bound and, whenever the limits of integration move with the parameter, the boundary terms of the Leibniz rule. The score-function identity differentiates the log-density; it works for arbitrary losses g and discrete random variables, though its samples scale with the magnitude of g and can be noisy without a good baseline. The pathwise identity differentiates through a reparameterized sample; it requires a differentiable g and often, though not always, achieves much lower variance. Because both estimators have root-mean-square error $\sigma/\sqrt{n}$ (Section 36.5.1.7), the single-sample standard deviation σ decides which one is preferable for a given problem.

34.7.5 Exercises

1. **A moving support.** Let X be uniform on $[0, \theta]$ with $\theta > 0$, so that $\ell(\theta) = \mathbb{E}[X^2] = \int_0^\theta \frac{x^2}{\theta}\, dx = \frac{\theta^2}{3}$ and $\ell'(\theta) = \frac{2\theta}{3}$.
   1. Differentiate ℓ with the Leibniz rule Equation 34.72. Which part of the result does the plain swap Equation 34.71 produce, and which part does it miss?
   2. On the support, $\log p_\theta(x) = -\log\theta$. Compute the expectation of the score-function estimator $X^2\, \partial_\theta \log p_\theta(X)$ of Equation 34.74. Then let g be continuous on $[0, \infty)$. Show that the mean of $g(X)\, \partial_\theta \log p_\theta(X)$ equals the plain swap Equation 34.71 applied to $\mathbb{E}[g(X)] = \int_0^\theta g(x)\, p_\theta(x)\, dx$. What is its bias as an estimate of $\frac{d}{d\theta}\mathbb{E}[g(X)]$, in terms of $g(\theta)$ and θ?
   3. Write $X = \theta U$ with U uniform on $[0, 1]$ and compute the expectation of the pathwise estimator of Equation 34.75. Why does it need no boundary term, although the support of X moves with θ?
2. code **Estimator variance for a quartic.** ● Let $X \sim \mathcal{N}(\theta, 1)$, write $X = \theta + z$, and let $s(X) = \partial_\theta \log p_\theta(X) = z$ be the score.
   1. Take $g(X) = X^4$, so that $\frac{d}{d\theta}\mathbb{E}[X^4] = 4\theta^3 + 12\theta$. Derive the single-sample pathwise estimator from Equation 34.75 and the single-sample score-function estimator from Equation 34.74. Use the identity of exercise 5 (b) to show that both have mean $4\theta^3 + 12\theta$.
   2. For a constant baseline b, show that the variance of $(g(X) - b)\, s(X)$ is minimized by $b^\star = \mathbb{E}[g(X)s(X)^2]/\mathbb{E}[s(X)^2]$. For $g(X) = X^2$ show that $b^\star = \theta^2 + 3$, and use $\mathbb{E}[z^2] = 1$, $\mathbb{E}[z^4] = 3$, $\mathbb{E}[z^6] = 15$ to derive the three variances 4, $\theta^4 + 14\theta^2 + 15$ and $8\theta^2 + 6$ that the text quotes.
   3. Evaluate $b^\star$ for $g(X) = X^4$. With 10^6 samples at $\theta \in \{0, 1, 2\}$, estimate the standard deviations of the pathwise estimator, the score-function estimator, and the score-function estimator with the baseline. For which θ is the baseline's gain largest, and does it ever close the gap to the pathwise estimator? Explain the ordering from the sizes of g' and of g.

4. Take $g(x) = \mathbf{1}(x > 0)$ at $\theta = 1.5$. The text shows that the pathwise estimator is 0 for almost every sample, while the score-function estimator $\mathbf{1}(x > 0)\, z$ has the correct mean $\varphi(\theta) = 0.1295$. Verify both by simulation.

3. [extended] **Gradients through a coin flip.** ●● When x is a discrete choice there is no differentiable path from θ to the sample, so the pathwise estimator does not exist. Continuous relaxations such as Gumbel-softmax (Jang et al. 2017; Maddison et al. 2017) create a differentiable surrogate, and straight-through estimators (Bengio, Léonard, et al. 2013) use the hard sample in the forward pass and the surrogate in the backward pass; both are biased for the original objective. This problem measures that bias. Tucker et al. (2017) illustrate it on a toy problem. A single Bernoulli variable $b \in \{0, 1\}$ has $P(b = 1) = \sigma(\theta)$ for a logit θ, and the objective is $\ell(\theta) = \mathbb{E}[(b - t)^2]$ with target $t = 0.45$. Let U be uniform on $(0, 1)$, let $\zeta = \log U - \log(1 - U)$, and, for a temperature $\tau > 0$, let $z = \sigma\big((\theta + \zeta)/\tau\big)$, the two-class case of the Gumbel-softmax relaxation.
   1. Compute $\ell(\theta)$ and $\ell'(\theta)$ in closed form. Which probability $\sigma(\theta)$ minimizes ℓ, and does a finite θ attain it?
   2. Show that $b = \mathbf{1}(z > \frac{1}{2})$ satisfies $P(b = 1) = \sigma(\theta)$ for every τ.
   3. Implement three single-sample estimators of $\ell'(\theta)$: REINFORCE Equation 34.74 with the baseline $\ell(\theta)$; the relaxed estimator $\frac{d}{d\theta}(z - t)^2$; and the straight-through estimator $2(b - t)\frac{dz}{d\theta}$, which uses the hard sample in the loss and the relaxed sample in the derivative. Tabulate the mean and the standard deviation of each estimator against $\ell'(\theta)$ for $\theta \in \{-2, 0, 2\}$ and $\tau \in \{1, 0.5, 0.1\}$. How does the bias of each estimator depend on θ and τ?
   4. Run stochastic gradient descent on θ from $\theta = 0$ with step size 1 for 5000 steps with REINFORCE and with the relaxed and straight-through estimators at each τ, replacing the REINFORCE baseline by an exponential moving average of past losses. Plot $\ell(\theta)$ along each run. Compute the relaxed objective $R_\tau(\theta) = \mathbb{E}[(z - t)^2]$ by quadrature over U, and compare its minimizer with the values of θ at which the relaxed runs settle. How does lowering τ trade the bias of the relaxed estimator against its variance?

34.8 Further Reading

Throughout this chapter, we proved our main results under clean assumptions that deep learning practice routinely bends: a ReLU network is full of sharp kinks, a reverse-mode tape can easily outgrow GPU memory, and a thousand-dimensional integral cannot be placed on a grid. The short notes below summarize what happens when those assumptions break down, followed by a curated list of textbooks, courses, and tutorials covering the chapter's core material. Two topics bear directly on everyday training and are worth reading first: conservative fields, which explain in what sense backpropagation through kinks is still valid, and recursive checkpointing, which keeps memory manageable on long computations. Nothing elsewhere in the book depends on this section.

34.8.1 Derivatives at Kinks

34.8.1.1 Conservative Fields

As Section 34.1 illustrates, adopting the standard convention $\mathrm{ReLU}'(0) = 0$ leads to a curious anomaly: if we write the identity function as $\mathrm{ReLU}(x) - \mathrm{ReLU}(-x) = x$, backprop-

agation returns slope 0 at $x = 0$, a number that is neither the true derivative nor even a valid subgradient of x. Classical subdifferentials cannot explain this behavior, because their sum and chain rules hold only as set inclusions once the constituent functions are no longer convex. To close this gap, Bolte and Pauwels (2021) introduce *conservative fields*, set-valued generalizations of the derivative that obey the chain rule by construction and agree with the ordinary gradient everywhere outside a set of measure zero. Backpropagation with any fixed choice of slope at each kink always returns an element of such a field. And why is the exceptional set of kinks harmlessly small? By Rademacher's theorem (Rademacher 1919), every Lipschitz function on $\mathbb{R}^n$ is differentiable almost everywhere, so the kinks of a ReLU network's loss occupy a set of measure zero.

The same work settles the practical question of whether stochastic gradient descent driven by these backpropagation values still converges. For losses built from standard neural network layers, assuming bounded iterates and the usual conditions on step sizes and gradient noise, the iterates converge to the set of critical points where the conservative field contains zero. That guarantee holds in exact arithmetic, whereas in finite-precision floating point, iterates actually land on kinks. Section 34.1 reports how often this occurs across three numerical precisions, as measured by Bertoin et al. (2021) and corrected in their 2023 erratum, and shows how little the choice of $\mathrm{ReLU}'(0)$ ends up affecting training.

34.8.1.2 Subgradient Methods

Smooth optimization relies on the descent lemma, which guarantees that a small step against the gradient lowers the objective. Nonsmooth functions break that guarantee: at the minimum of $|x|$, the valid subgradient $\frac{1}{2}$ actually points uphill, as shown in Section 34.1. Remarkably, the subgradient method converges anyway, because its analysis tracks the Euclidean distance to a minimizer rather than the objective value itself. With diminishing step sizes satisfying $\sum_t \eta_t = \infty$ and $\sum_t \eta_t^2 < \infty$, the best objective value seen so far converges to the minimum. Obtaining the optimal convergence rate calls for a different schedule: for a convex function whose subgradients have norm at most G, starting at distance R from a minimizer, a constant step size $R/(G\sqrt{T})$ brings the best of T iterates within $RG/\sqrt{T}$ of the minimum. When the dimension exceeds T, no method relying solely on subgradients can improve on this rate by more than a constant factor (Nesterov 2018). For a systematic development of subdifferential calculus, including exact conditions under which the sum rule holds with equality, see Rockafellar (1970) .

34.8.2 Derivatives of Vector and Matrix Maps

34.8.2.1 The Mean Value Theorem for Vector-Valued Maps

In one dimension, the mean value theorem of Section 34.1 guarantees an intermediate point ξ such that $f(b) - f(a) = f'(\xi)(b - a)$. It is tempting to assume the same equality holds for vector-valued curves $\gamma : \mathbb{R} \to \mathbb{R}^n$, but it fails completely. Take the unit circle $\gamma(t) = (\cos t, \sin t)$: after a full turn at $t = 2\pi$, the curve returns to its starting point so $\gamma(2\pi) - \gamma(0) = \mathbf{0}$, yet the velocity $\gamma'(\xi)$ has unit length and is never $\mathbf{0}$ for any ξ. What survives in higher dimensions is only the *mean value inequality*, $\|\gamma(b) - \gamma(a)\| \le \sup_{\xi} \|\gamma'(\xi)\|\, |b - a|$ (Theorem 5.19 of Rudin (1976)). Fortunately, the Taylor bounds in Section 34.2 never need a vector version of the theorem, because they restrict a scalar-valued loss to a line segment, where the ordinary one-variable theorem applies directly.

34.8.2.2 Jacobians of Matrix-Valued Maps

In Section 34.4, we differentiate scalar losses, so every gradient conveniently has the same shape as its matrix variable. Once we differentiate a matrix-valued function with respect to a matrix input, however, the full derivative becomes a four-index array. A standard way to keep the algebra linear and familiar is to flatten both matrices with the column-stacking operator vec, turning the four-index tensor into an ordinary Jacobian matrix. Under this flattening, a matrix differential $d\mathbf{F} = \mathbf{A}\, d\mathbf{X}\, \mathbf{B}$ becomes $d\,\mathrm{vec}\,\mathbf{F} = (\mathbf{B}^\top \otimes \mathbf{A})\, d\,\mathrm{vec}\,\mathbf{X}$, and the chain rule simply multiplies Kronecker products. Mike B. Giles (2008) provides a handy catalog of forward and reverse differentiation rules for matrix products, inverses, determinants, and standard matrix decompositions.

34.8.3 Automatic Differentiation

34.8.3.1 Optimal Jacobian Accumulation

As Section 34.4 shows, simply changing the order in which we multiply a chain of Jacobians can alter the computational cost by roughly a factor of the layer width. For a straight chain of K factors, finding the cheapest parenthesization is the classical matrix-chain multiplication problem, which dynamic programming solves in $O(K^3)$ time. A general computation graph with branches and skip connections opens up a much larger space of elimination orders: each intermediate node can be eliminated by multiplying the partial derivatives on its incoming and outgoing edges, in any sequence. Finding the elimination order with the fewest multiplications turns out to be NP-complete (Naumann 2008). Deep learning frameworks therefore do not attempt global optimization of the elimination order; instead, they provide forward mode, reverse mode, and their compositions, leaving the choice of mode to the user. Griewank and Walther (2008) develop vertex, edge, and face elimination in full generality and review the heuristics used by derivative compilers.

34.8.3.2 Recursive Checkpointing

The one-level checkpointing scheme in Section 34.5 reduces peak activation memory to $T/s + s$ stored states, reaching $2\sqrt{T}$ at the optimal block size s at the cost of one extra forward pass (Chen et al. 2016). For very long sequences or unrolled iterative solvers, even $O(\sqrt{T})$ memory can be too much. Applying the same idea recursively inside each recomputed segment brings memory all the way down to $O(\log T)$ while requiring $O(T \log T)$ recomputation (Griewank 1992). When every step has the same cost, Griewank's binomial checkpointing schedule is provably optimal for any fixed memory budget (Griewank and Walther 2008). In practice, checkpointing utilities implement one level of checkpointing per marked block.

TensorFlow provides `tf.recompute_grad`.

34.8.3.3 Taylor Mode

Computing a k-th directional derivative by nesting forward-mode automatic differentiation k times is wasteful, because each nesting doubles the state and carries 2^k components per value. *Taylor mode* avoids this exponential blow-up by replacing dual numbers with truncated power series $a_0 + a_1\varepsilon + \cdots + a_k\varepsilon^k$ subject to $\varepsilon^{k+1} = 0$. Each elementary operation propagates all $k+1$ coefficients in a single pass: multiplication convolves the two coefficient sequences in $O(k^2)$ operations, and transcendental functions such as exp, log, and sin

follow from recurrences of the same $O(k^2)$ cost (Griewank and Walther 2008). The exercise on computing second derivatives in one forward pass in Section 34.5 is the $k = 2$ case.

34.8.3.4 Forward Gradients

Reverse-mode differentiation requires storing a tape of intermediate values, whereas forward mode avoids the tape but requires one pass per input parameter. Baydin et al. (2022) sidestep both costs by running a single forward pass along a random Gaussian tangent $\mathbf{v} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ and taking $(\nabla \ell^\top \mathbf{v})\,\mathbf{v}$ as a stochastic gradient estimate. Because $\mathbb{E}[\mathbf{v}\mathbf{v}^\top] = \mathbf{I}$, the estimate is unbiased, and for n parameters its mean squared error is $(n+1)\|\nabla \ell\|^2$. The memory tape disappears completely, but the trade-off is stark: the typical estimation error is roughly $\sqrt{n}$ times the norm of the true gradient, which is manageable for small models yet prohibitive at modern neural network scales.

34.8.4 Integration

34.8.4.1 The Lebesgue Integral

The Riemann integral partitions the domain into intervals, a strategy that breaks down on wildly discontinuous functions: as shown in Section 34.6, the indicator of the rational numbers has tagged sums that never settle, and even a pointwise limit of Riemann-integrable functions need not remain Riemann integrable. Lebesgue's insight is to slice the range instead of the domain: measure the size of the set where f exceeds each height level, and add up those measures. Sets of measure zero, such as the rational numbers or the ray $\theta = 0$ in polar coordinates, contribute nothing at all, so the indicator of the rationals cleanly integrates to 0. Both Section 34.6 and Section 34.7 invoke three workhorse theorems of this theory without proof: Fubini–Tonelli, the n-dimensional change of variables, and differentiation under an integral over an infinite domain. All three rest on the monotone and dominated convergence theorems, which specify when a limit may be swapped with an integral: if $f_k \to f$ pointwise and $|f_k| \le g$ for a single integrable function g, then $\int f_k \to \int f$ (Folland 1999).

34.8.4.2 Quasi-Monte Carlo

In Section 36.5.1.7, we compared a second-order grid, whose error decays as $N^{-2/d}$, with Monte Carlo integration, whose error decays as $N^{-1/2}$ regardless of dimension. Purely random samples, however, inevitably leave accidental clumps and empty gaps. *Low-discrepancy* point sets (such as Sobol sequences, Halton sequences, and lattice rules) are constructed to fill the unit cube far more evenly, achieving an error of $O(N^{-1}(\log N)^d)$ for integrands of bounded variation (in the sense of Hardy and Krause). Taken purely as a worst-case guarantee, this bound is sobering: ignoring constants, it drops below $N^{-1/2}$ only past several thousand points for $d = 2$ and past 10^{15} points for $d = 5$. In practice, quasi-Monte Carlo still frequently outperforms ordinary Monte Carlo even in high dimensions, usually because real integrands depend primarily on a small number of effective coordinates at a time. Because a deterministic point set provides no built-in error bar, *randomized quasi-Monte Carlo* randomly shifts or scrambles the points so that independent replicates yield an unbiased variance estimate. Owen (2013) covers both deterministic and randomized methods in Chapters 15–17.

34.8.4.3 Gradient Estimators beyond Score and Pathwise

In Section 34.7, we derived the score-function and pathwise estimators and reduced the variance of the score-function estimator using a constant baseline. More sophisticated control variates exploit the structure of the model itself: REBAR (Tucker et al. 2017) subtracts the pathwise gradient of a continuous relaxation from the score-function estimator and adds back its analytic expectation, lowering variance while keeping the estimator unbiased for discrete random variables. The continuous relaxations themselves, such as Gumbel-softmax (Jang et al. 2017; Maddison et al. 2017) and straight-through estimators (Bengio, Léonard, et al. 2013), offer low variance at the cost of introducing bias relative to the original discrete objective. A third approach, *measure-valued derivatives*, expresses the derivative of a probability density as a scaled difference of two densities and estimates the gradient by sampling from both. Mohamed et al. (2020) unite all three families in a single framework and spell out the conditions under which each applies.

34.8.5 Books, Courses, and Tutorials

Books

- Mathematics for Machine Learning by Deisenroth, Faisal, and Ong: Chapter 5 ("Vector Calculus") covers gradients, Jacobians, and the chain rule for machine learning (Section 34.1 and Section 34.2).
- Calculus by Gilbert Strang (MIT OpenCourseWare): a free textbook whose chapters on integrals, the fundamental theorem, and multiple integrals accompany Section 34.6.
- The Matrix Cookbook by Petersen and Pedersen: a reference table of matrix-derivative identities useful for checking results derived by the differential method (Section 34.4).
- Evaluating Derivatives: Principles and Techniques of Algorithmic Differentiation by Griewank and Walther, and The Art of Differentiating Computer Programs by Naumann: the standard monographs on forward and reverse mode, VJPs and JVPs, checkpointing, and derivative compilers (Section 34.5).

Courses and Tutorials

- Essence of Calculus by 3Blue1Brown, Single Variable Calculus (18.01SC), and Multivariable Calculus (18.02SC) on MIT OpenCourseWare.
- Matrix Calculus for Machine Learning and Beyond (18.S096) by Edelman and Johnson (MIT OCW), The Matrix Calculus You Need For Deep Learning by Parr and Howard, and matrixcalculus.org by Laue, Mitterreiter, and Giesen.
- Calculus on Computational Graphs: Backpropagation by Christopher Olah, Automatic Differentiation in Machine Learning: a Survey by Baydin et al., The Autodiff Cookbook and Autodidax in the JAX documentation (Section 34.5), and Monte Carlo Gradient Estimation in Machine Learning by Mohamed et al. for the score-function (REINFORCE) estimator, pathwise reparameterization, and variance reduction with control variates (Section 34.7).

Chapter 35

Optimization

Every neural network in this book is trained by the same basic loop: compute the gradient of the loss, take a step in the opposite direction, and repeat. In Chapter 9, we saw empirically what momentum, adaptive step sizes, and learning-rate schedules do for that loop on real networks, leaving three questions open. Why is there a hard ceiling on the learning rate? Why can a step safely below that ceiling still make painfully slow progress? And why does gradient noise keep a training run from settling down?

Optimization theory ties each question to the geometry of the objective. The steepest curvature sets the largest safe step size; the ratio of the steepest curvature to the flattest sets the iteration count; and convexity decides whether a stationary point is globally optimal. Throughout this chapter, we return to the narrow bowl $\frac{1}{2}(x_1^2 + 1000\, x_2^2)$, which is a thousand times steeper in one direction than in the other: a step size that stays safe along the steep wall barely nudges the iterate along the flat valley. While Chapter 9 focuses on practice and measurement, this chapter supplies the self-contained proofs and underlying geometry.

The chapter unfolds in three parts. Under exact gradients, Section 35.1 proves the step-size ceiling and iteration count and shows how momentum replaces the curvature ratio with its square root, while Section 35.3 establishes when stationary points are global minima; between them, Section 35.2 covers Newton, quasi-Newton, and trust-region methods that actively model curvature. Turning to noisy gradients, Section 35.4 shows why fixed-step SGD stalls at a noise floor proportional to the step size, and Section 35.5 tests per-coordinate scaling and AdamW against heavy-ball momentum. Finally, Section 35.6 and Section 35.7 develop KKT conditions, projections, proximal steps, and duality behind norm budgets (Section 2.7), and Section 35.8 analyzes floating-point precision, cancellation, and conditioning (Section 5.5).

We assume familiarity with gradients and Hessians (Section 34.2) and eigendecompositions (Section 33.3). Because deep-network losses are neither globally smooth nor convex, our theorems serve as local models whose limits each section notes explicitly; interior-point and operator-splitting methods are surveyed in Section 35.9.

Notation

Throughout this chapter, we follow the conventions summarized in Table 35.1. Each section restates the symbols it uses most, and notation specific to a single section is introduced where it first appears.

Table 35.1: Symbols of the optimization chapter. A star $\star$ marks an optimum and an asterisk $*$ a convex conjugate. Matrices are bold.

Symbol	Meaning
f, $\ell(\mathbf{w})$	objective; training loss as a function of the weights
$\mathbf{x}^\star$, $f^\star$	a minimizer and the minimum value
∇f, $\nabla^2 f$, $\mathbf{g}_k$	gradient, Hessian; the gradient (or a stochastic gradient) used at step k
L, μ	smoothness and strong-convexity constants, $\mu\mathbf{I} \preceq \nabla^2 f \preceq L\mathbf{I}$
$\kappa = L/\mu$; $\kappa(\mathbf{A})$	condition number of the problem; of a matrix, $\sigma_{\max}(\mathbf{A})/\sigma_{\min}(\mathbf{A})$
λ_i, $\lambda_{\max}(\mathbf{A})$	eigenvalues of a Hessian or of a quadratic's matrix $\mathbf{A}$
η, β	step size (learning rate); momentum coefficient
k, t	iteration index; optimizer step in the adaptive methods
ϵ	target accuracy; in Adam, the constant that keeps a division finite
n, d, $\mathcal{B}$, b	number of examples; number of variables; a minibatch and its size
Σ	covariance of a per-example gradient
$\mathbf{m}_t$, $\mathbf{v}_t$; β_1, β_2	Adam's first- and second-moment estimates; their decay rates
$\mathbf{P}$	preconditioner: the step is $-\eta\,\mathbf{P}^{-1}\mathbf{g}$
g_i, h_j	inequality constraints $g_i(\mathbf{x}) \le 0$; equality constraints $h_j(\mathbf{x}) = 0$
λ, ν	multipliers of inequality and equality constraints; λ also weights the decay term $\frac{\lambda}{2}\lVert\mathbf{w}\rVert^2$
$\mathcal{L}$, q	Lagrangian; dual function
$p^\star$, $d^\star$	optimal values of the primal and the dual problem
f^*	convex conjugate of f
Π_C, prox_ψ	Euclidean projection onto a set C; proximal operator of ψ
u, $\varepsilon_{\text{mach}}$	unit roundoff and machine epsilon of a floating-point format, $u = \varepsilon_{\text{mach}}/2$

35.1 Gradient Descent and Curvature

In practice, a learning rate is usually chosen by trial and error: we pick a value, watch the loss, and turn it down if training blows up. Because every step moves opposite the gradient of the loss, the gradient fixes the direction and the learning rate sets only the distance. Yet a poor choice of distance turns training either painfully slow or unstable. How far can we trust a step along the gradient, and how many iterations does that limit force upon us?

A function of just two variables already exposes the difficulty. Consider the elliptical bowl $f(x, y) = \frac{1}{2}(x^2 + 10\,y^2)$, which curves ten times more steeply along y than along x, and start at $(2, 1)$, where $f = 7$ and $\nabla f = (2, 10)$. Taking a step of size η against the gradient lands at $(2 - 2\eta,\ 1 - 10\eta)$. With $\eta = 0.01$, the loss barely budges, dropping to 6.01. With $\eta = 0.1$, it falls sharply to 1.62. With $\eta = 0.25$, it *rises* to 12.4. Every one of those steps pointed downhill; only the step length changed.

The culprit is curvature. A step short enough to stay safe along the steep y-axis creeps along the flat x-axis. Even the best fixed learning rate needs 69 iterations to shrink the error by a factor of 10^6 (six digits of accuracy). Stretch the curvature ratio to 1000—our chapter's running example $\frac{1}{2}(x_1^2 + 1000\,x_2^2)$—and gradient descent needs $6{,}908$ steps. Adding momentum brings that count down to 315. We will work by hand on the gentler bowl, whose Hessian $\mathrm{diag}(1, 10)$ keeps every number easy to check, and quote the corresponding counts for the stiffer running example.

We build the analysis in three stages. First, we formalize smoothness to turn the local linear approximation of Section 34.2 into a guarantee on finite steps, yielding the descent lemma Equation 35.5. Next, we solve gradient descent exactly on quadratics, where the ratio of curvatures emerges as the condition number and fixes the optimal step Equation 35.10. Finally, we introduce momentum and derive its $\sqrt{\kappa}$ convergence law Equation 35.15. Throughout this section, our methods only respect curvature without modeling it; methods that model curvature directly, such as Newton's method, appear in Section 35.2. We also assume exact gradients here, leaving the noisy gradients of minibatch training to Section 35.4. All code below is plain NumPy, so each update can be read directly against its equation.

35.1.1 Descent Directions and Smoothness

Every gradient step settles two questions: which way to move, and how far. The first has an immediate answer from the first-order Taylor expansion. The second requires knowing how quickly the gradient itself can change—an assumption that turns a local linear approximation into a guarantee for steps of finite length.

35.1.1.1 The Steepest Direction

In our opening example, we stepped along $-\nabla f$ without asking whether another direction might be better. To see why the negative gradient is the natural choice, expand $f : \mathbb{R}^d \to \mathbb{R}$ to first order. A small step of size $\eta > 0$ along a direction $\mathbf{d}$ changes the function value by

$$f(\mathbf{x} + \eta\,\mathbf{d}) = f(\mathbf{x}) + \eta\,\nabla f(\mathbf{x})^{\top}\mathbf{d} + o(\eta).$$

To first order, the change is simply η times the directional derivative $\nabla f(\mathbf{x})^{\top}\mathbf{d}$. We call $\mathbf{d}$ a **descent direction** at $\mathbf{x}$ whenever $\nabla f(\mathbf{x})^{\top}\mathbf{d} < 0$.

Proposition (descent directions, and the steepest one). *Let f be differentiable at $\mathbf{x}$ with $\nabla f(\mathbf{x}) \neq \mathbf{0}$.*

1. *If $\nabla f(\mathbf{x})^{\top}\mathbf{d} < 0$, then $f(\mathbf{x} + \eta\,\mathbf{d}) < f(\mathbf{x})$ for every sufficiently small $\eta > 0$.*
2. *Among all unit vectors, the directional derivative is minimized uniquely by the normalized negative gradient:*

$$\min_{\|\mathbf{d}\|=1} \nabla f(\mathbf{x})^{\top}\mathbf{d} = -\|\nabla f(\mathbf{x})\|, \qquad \text{attained only at } \mathbf{d} = -\frac{\nabla f(\mathbf{x})}{\|\nabla f(\mathbf{x})\|}. \tag{35.1}$$

Proof. For the first claim, define $\varphi(\eta) = f(\mathbf{x}+\eta\,\mathbf{d})$. By the chain rule, $\varphi'(0) = \nabla f(\mathbf{x})^{\top}\mathbf{d} < 0$, so the difference quotient $(\varphi(\eta)-\varphi(0))/\eta$ is strictly negative for all sufficiently small $\eta > 0$; hence $\varphi(\eta) < \varphi(0)$. For the second claim, the Cauchy–Schwarz inequality gives $\nabla f(\mathbf{x})^{\top}\mathbf{d} \geq -\|\nabla f(\mathbf{x})\|\,\|\mathbf{d}\| = -\|\nabla f(\mathbf{x})\|$ for every unit vector $\mathbf{d}$, with equality if and only if $\mathbf{d}$ is a negative scalar multiple of $\nabla f(\mathbf{x})$. The unique such unit vector is $-\nabla f(\mathbf{x})/\|\nabla f(\mathbf{x})\|$, and it attains the bound. ■

On our opening bowl, the steepest unit direction at $(2,1)$ is $-(2,10)/\sqrt{104} = (-0.196,-0.981)$, with slope $-\|\nabla f\| = -10.198$. The coordinate direction $(-1,0)$ also points downhill, but with a much gentler slope of -2. In fact, descent directions fill the entire open half-space of vectors making an acute angle with $-\nabla f$; the negative gradient simply picks out the steepest one. Because this result governs slopes (the limit of vanishingly short steps), we next check how faithfully those slopes predict the actual decrease over a small finite step, $\eta = 0.01$, across four unit directions.

```
def f(v):
    return 0.5 * (v[0]**2 + 10 * v[1]**2)

def grad(v):
    return np.array([v[0], 10 * v[1]])

x = np.array([2.0, 1.0])
g = grad(x)
steepest = -g / np.linalg.norm(g)
candidates = [('steepest -grad/|grad|', steepest),
              ('diagonal -(1,1)/sqrt(2)', -np.ones(2) / np.sqrt(2)),
              ('axis     (-1,0)', np.array([-1.0, 0.0])),
              ('uphill   +(1,1)/sqrt(2)', np.ones(2) / np.sqrt(2))]
eta = 0.01
for name, d in candidates:
    print(f'{name}:  slope = {g @ d:+8.4f},  '
          f'f(x + eta d) - f(x) = {f(x + eta * d) - f(x):+.6f}')
```

```
steepest -grad/|grad|:  slope = -10.1980,  f(x + eta d) - f(x) = -0.101498
diagonal -(1,1)/sqrt(2):  slope =  -8.4853,  f(x + eta d) - f(x) = -0.084578
axis     (-1,0):  slope =  -2.0000,  f(x + eta d) - f(x) = -0.019950
uphill   +(1,1)/sqrt(2):  slope =  +8.4853,  f(x + eta d) - f(x) = +0.085128
```

At $\eta = 0.01$, each actual change matches η times the directional slope to within one percent, so the first-order model is a reliable guide for short steps. Differentiability promises nothing beyond that: a decrease for sufficiently small steps. How small is "sufficiently small" is the question we turn to next.

35.1.1.2 Smoothness and the Descent Lemma

Gradient descent repeats the steepest-descent step with a fixed **step size** (or learning rate) $\eta > 0$:

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \eta \nabla f(\mathbf{x}_k). \tag{35.2}$$

Throughout this section, k indexes iterations and we abbreviate $\mathbf{g}_k = \nabla f(\mathbf{x}_k)$. The first-order Taylor expansion justified the direction $-\mathbf{g}_k$, but it says nothing about how far to trust it: once the iterate moves far enough that the gradient changes significantly, $\mathbf{g}_k$ no longer describes f. To certify a finite step size, we need a bound on how fast the gradient can vary.

Definition (L-smoothness). A differentiable function f is **L-smooth** if its gradient changes by at most L per unit of distance:

$$\|\nabla f(\mathbf{x}) - \nabla f(\mathbf{y})\| \;\le\; L\,\|\mathbf{x} - \mathbf{y}\| \qquad \text{for all } \mathbf{x}, \mathbf{y}. \tag{35.3}$$

When f is twice continuously differentiable, L-smoothness is equivalent to requiring every eigenvalue of its Hessian to lie in $[-L, L]$. Bounded eigenvalues imply Equation 35.3 by integrating the Hessian along the line segment from $\mathbf{y}$ to $\mathbf{x}$, and the converse follows by taking a difference-quotient limit (exercise 2a). In short, L caps the curvature in every direction. Our opening bowl has constant Hessian $\operatorname{diag}(1, 10)$, so $L = 10$. By contrast, a function whose curvature grows without bound has no global smoothness constant: $\tfrac{1}{4}x^4$ has $f''(x) = 3x^2$, so no finite global L exists. We will handle that case shortly using backtracking line search.

Smoothness upgrades the local tangent plane into a global upper bound—a quadratic ceiling:

$$f(\mathbf{y}) \;\le\; f(\mathbf{x}) + \nabla f(\mathbf{x})^{\top}(\mathbf{y} - \mathbf{x}) + \tfrac{L}{2}\,\|\mathbf{y} - \mathbf{x}\|^2. \tag{35.4}$$

Geometrically, the graph of f can never rise above its tangent plane at $\mathbf{x}$ by more than $\tfrac{L}{2}$ times the squared distance. Before we prove this inequality, plug in a gradient step $\mathbf{y} = \mathbf{x} - \eta\,\mathbf{g}$ and watch the two terms compete. The linear first-order decrease $\eta\,\|\mathbf{g}\|^2$ grows proportionally to η, whereas the quadratic curvature penalty $\tfrac{L}{2}\eta^2\|\mathbf{g}\|^2$ grows as η^2. For small η, the linear decrease wins; at $\eta = 2/L$, the two terms exactly cancel.

Proposition (descent lemma). *If f is L-smooth, then the gradient step Equation 35.2 satisfies*

$$f(\mathbf{x}_{k+1}) \;\le\; f(\mathbf{x}_k) - \eta\left(1 - \tfrac{L\eta}{2}\right)\|\mathbf{g}_k\|^2. \tag{35.5}$$

In particular, f strictly decreases whenever $0 < \eta < 2/L$ and $\mathbf{g}_k \neq \mathbf{0}$. The guaranteed decrease is maximized at $\eta = 1/L$, where $f(\mathbf{x}_{k+1}) \le f(\mathbf{x}_k) - \tfrac{1}{2L}\|\mathbf{g}_k\|^2$.

Proof. We first establish the quadratic ceiling Equation 35.4. Restrict f to the line segment between $\mathbf{x}$ and $\mathbf{y}$ via $\psi(t) = f(\mathbf{x} + t(\mathbf{y} - \mathbf{x}))$ for $t \in [0, 1]$, so that $\psi'(t) = \nabla f(\mathbf{x} + t(\mathbf{y} - \mathbf{x}))^{\top}(\mathbf{y} - \mathbf{x})$. Applying the fundamental theorem of calculus, Cauchy–Schwarz, and the Lipschitz condition Equation 35.3 yields

$$
\begin{aligned}
f(\mathbf{y}) - f(\mathbf{x}) - \nabla f(\mathbf{x})^{\top}(\mathbf{y}-\mathbf{x}) &\\
&= \int_0^1 \big(\nabla f(\mathbf{x} + t(\mathbf{y}-\mathbf{x})) - \nabla f(\mathbf{x})\big)^{\top}(\mathbf{y}-\mathbf{x})\, dt \\
&\le \int_0^1 L\, t\, \|\mathbf{y}-\mathbf{x}\|^2\, dt = \tfrac{L}{2}\|\mathbf{y}-\mathbf{x}\|^2 .
\end{aligned}
$$

Substituting the gradient step $\mathbf{y} = \mathbf{x}_k - \eta\,\mathbf{g}_k$ gives

$$
f(\mathbf{x}_{k+1}) \;\le\; f(\mathbf{x}_k) - \eta\,\|\mathbf{g}_k\|^2 + \tfrac{L}{2}\,\eta^2\,\|\mathbf{g}_k\|^2 .
$$

The factor $\eta(1 - L\eta/2)$ is strictly positive if and only if $0 < \eta < 2/L$, and it reaches its maximum at $\eta = 1/L$. ■

Notice that the proof only compares gradients between $\mathbf{x}_k$ and points along the segment to $\mathbf{x}_{k+1}$, so it suffices for ∇f to be L-Lipschitz on that segment. Let us test the lemma on our opening bowl, where $\|\mathbf{g}\|^2 = 104$ and $L = 10$. At $\eta = 1/L = 0.1$, the bound guarantees $f \le 7 - 104/20 = 1.8$. At $\eta = 0.01$, it guarantees $f \le 7 - 104 \cdot 0.01 \cdot 0.95 = 6.012$. At $\eta = 0.25 > 2/L$, the factor $1 - L\eta/2$ turns negative and the bound rises above the starting value, offering no guarantee at all. How tight are these bounds compared with the values the three steps actually reach?

```
x, L = np.array([2.0, 1.0]), 10.0
g = grad(x)
for eta in (0.01, 0.1, 0.25):
    bound = f(x) - eta * (1 - L * eta / 2) * (g @ g)
    print(f'eta = {eta:4.2f}:  bound {bound:7.4f},  actual {f(x - eta * g):7.4f}')
```

```
eta = 0.01:  bound  6.0120,  actual  6.0102
eta = 0.10:  bound  1.8000,  actual  1.6200
eta = 0.25:  bound 13.5000,  actual 12.3750
```

For the two stable steps, the bounds are remarkably tight: 6.0102 lies just under 6.012, and 1.62 sits cleanly below 1.8. At $\eta = 0.25$, the bound 13.5 lies well above the starting value $f = 7$, and indeed the step overshoots to 12.375. Figure 35.1 plots both curves as functions of η. Along the search direction, $\mathbf{g}^{\top}\mathrm{diag}(1, 10)\,\mathbf{g} = 1004$, so the true objective is the parabola $7 - 104\,\eta + 502\,\eta^2$, while the quadratic ceiling is $7 - 104\,\eta + 520\,\eta^2$. The two parabolas hug each other so closely because this gradient points almost along the stiff axis, where the directional curvature is nearly L.

In short, the step $\eta = 1/L$ minimizes the quadratic ceiling, and f is guaranteed to lie beneath that ceiling. Section 34.1 develops the same geometric argument in one variable.

35.1.1.3 Stationary Points Without Convexity

Surprisingly, the descent lemma alone, without any convexity assumption, already places a quantitative limit on a long run: the gradient cannot stay large forever.

Proposition (gradient descent finds approximate stationary points). *Let f be L-smooth and bounded below by f_{low}, and run Equation 35.2 with $\eta = 1/L$. Then for every $K \ge 1$,*

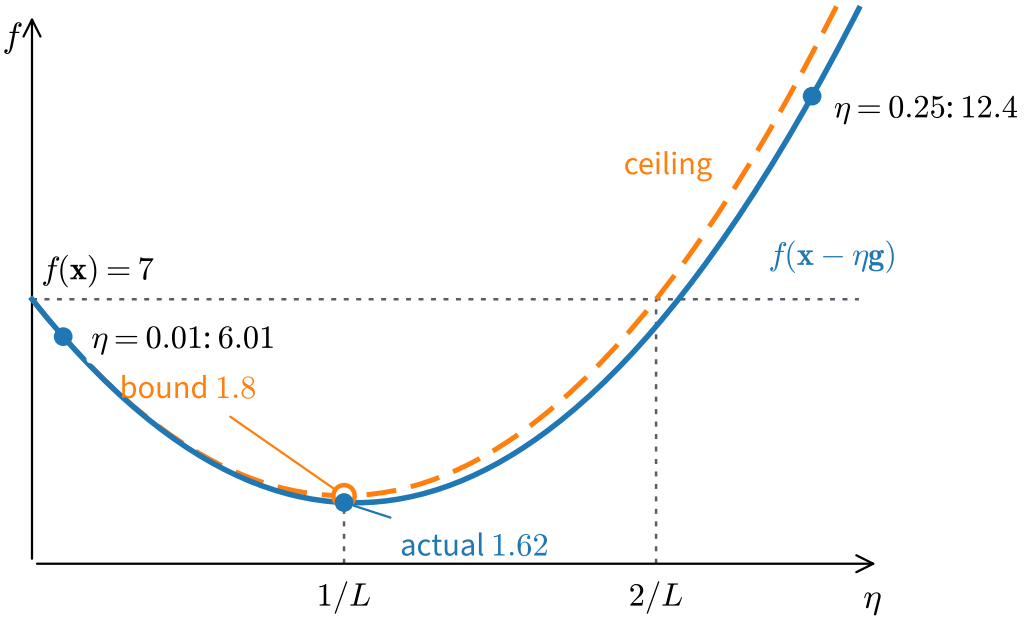

Figure 35.1: The descent lemma on the opening example. Along $-\mathbf{g}$ from $(2, 1)$, the true objective is the lower parabola and the quadratic ceiling $f - \eta\|\mathbf{g}\|^2 + \frac{L}{2}\eta^2\|\mathbf{g}\|^2$ is the upper one, tangent at $\eta = 0$. Minimizing the ceiling at $\eta = 1/L = 0.1$ guarantees $f \le 1.8$, and the step achieves 1.62. Beyond $2/L = 0.2$ the ceiling rises above the starting value and promises nothing; at $\eta = 0.25$ the objective climbs to 12.4.

$$\min_{0 \le k < K} \|\nabla f(\mathbf{x}_k)\|^2 \;\le\; \frac{2L\,(f(\mathbf{x}_0) - f_{\text{low}})}{K}. \tag{35.6}$$

Proof. At $\eta = 1/L$, the descent lemma rearranges to $\|\mathbf{g}_k\|^2 \le 2L\,(f(\mathbf{x}_k) - f(\mathbf{x}_{k+1}))$. Summing over $k = 0, \dots, K-1$, the right-hand side telescopes to $2L\,(f(\mathbf{x}_0) - f(\mathbf{x}_K)) \le 2L\,(f(\mathbf{x}_0) - f_{\text{low}})$. Because the minimum of K numbers is at most their average, dividing by K gives the bound. ■

Thus, among the first K iterates, at least one has squared gradient norm $O(1/K)$, using nothing beyond a lower bound on f and a smoothness constant. Keep in mind that this result assumes a global L; ReLU networks are not smooth, so for them the bound serves as an idealized model rather than a formal guarantee.

A small gradient, however, does not guarantee a minimum. Consider $f(x, y) = \tfrac{1}{2}x^2 + \cos y$, which is bounded below by -1 and 1-smooth (its Hessian $\operatorname{diag}(1, -\cos y)$ has eigenvalues in $[-1, 1]$). Starting gradient descent with $\eta = 1$ at $(1, 0)$ drives x to 0 in a single step and never changes y, since $\partial f/\partial y = -\sin y$ vanishes at $y = 0$. The algorithm halts at $(0, 0)$ with $f = 1$—a saddle point where f curves upward along x and downward along y, far from the true minimum value -1 at $(0, \pi)$. The theorem still holds, because the gradient vanishes at the saddle, yet it cannot tell us which kind of stationary point we reached. The stall itself is an accident of the starting point. Start at $(1, y_0)$ with any small $y_0 \neq 0$ instead, and each step $y \leftarrow y + \eta \sin y$ moves y further from 0 until the run settles at a minimum. In general, the starting points from which gradient descent converges to a saddle with a direction of negative curvature form a set of measure zero (Section 9.1.2), so a random initialization avoids it, although the iterates can linger nearby for a long time. For convex objectives, the question does not arise: every stationary point is automatically a global minimum (Section 35.3).

35.1.1.4 Backtracking Line Search

Using $\eta = 1/L$ presupposes that we know L. In practice we rarely do, and even when a global L exists, the local curvature varies across the loss landscape, making a single global constant overly conservative. A **line search** adapts the step size at run time. Given a candidate step η, it accepts the step only if the actual decrease achieves at least a fixed fraction $c \in (0, 1)$ of the decrease predicted by the first-order model—the **Armijo condition** (or sufficient decrease condition) (Armijo 1966):

$$f\big(\mathbf{x} - \eta\,\nabla f(\mathbf{x})\big) \;\le\; f(\mathbf{x}) - c\,\eta\,\|\nabla f(\mathbf{x})\|^2. \tag{35.7}$$

The right-hand side is simply the linear Taylor prediction with its slope scaled down by c. **Backtracking** starts from an optimistic trial step η_0 and repeatedly halves η until Equation 35.7 is satisfied. By the descent lemma, the test is guaranteed to pass as soon as $1 - L\eta/2 \ge c$, or equivalently $\eta \le 2(1-c)/L$. Consequently, the loop always terminates in finitely many halvings and returns a step $\eta \ge \min\big(\eta_0,\, (1-c)/L\big)$—within a factor of two of the theoretical threshold—without ever needing to know L in advance.

Better still, this guarantee only requires L on the region the iterates actually visit. Take the quartic $f(x) = \tfrac{1}{4}x^4$, which has no global L, starting at $x_0 = 3$ with $c = \tfrac{1}{2}$. Because backtracking never increases f, every iterate remains in $[-3, 3]$, where $f''(x) = 3x^2 \le 27$. A trial step with $\eta \le 1/27$ sends x to $x(1 - \eta x^2)$, which lies between $\tfrac{2}{3}x$ and x, keeping the

entire segment inside $[-3, 3]$ so that $L = 27$ suffices locally. Since the quartic's curvature is steep far from the origin and vanishes near zero, no single fixed step size suits the entire trajectory. Let us compare both strategies from $x_0 = 3$: a fixed step $\eta = 0.3$ (which would be completely safe near the origin) and backtracking starting from $\eta_0 = 1$.

```
quartic = lambda v: 0.25 * (v ** 4).sum()
quartic_grad = lambda v: v ** 3

x = np.array([3.0])
for _ in range(6):                          # fixed step, too large at x0
    x = x - 0.3 * quartic_grad(x)
print(f'fixed eta = 0.3 from x0 = 3:  |x_6| = {abs(x[0]):.2e}  (diverged)')

x, etas = np.array([3.0]), []
for _ in range(25):                         # backtracking line search
    g = quartic_grad(x)
    eta = 1.0
    while quartic(x - eta * g) > quartic(x) - 0.5 * eta * (g * g).sum():
        eta *= 0.5                          # Armijo fails: halve the step
    x = x - eta * g
    etas.append(eta)
print('accepted steps:', np.array(etas[:8]), '...')
print(f'backtracking from x0 = 3:  f(x_25) = {quartic(x):.2e}  (monotone descent)')
```

```
fixed eta = 0.3 from x0 = 3:  |x_6| = 6.52e+103  (diverged)
accepted steps: [0.03125 0.0625  0.125   0.25    0.5     1.      1.      1.     ] ...
backtracking from x0 = 3:  f(x_25) = 1.09e-04  (monotone descent)
```

The fixed step explodes immediately: after just six iterations, $|x_6| \approx 6.5 \times 10^{103}$. Because the update $x \mapsto x(1 - \eta x^2)$ shrinks $|x|$ if and only if $\eta x^2 < 2$, a fixed step from $x_0 = 3$ converges for $\eta < 2/9 \approx 0.22$ and diverges above it. Notice that this stability threshold is $2/9$, not $2/f''(x_0) = 2/27$; the $2/f''(x_0)$ rule belongs to quadratics. A step toward the origin experiences the average of f'' between 0 and x (which is x^2) rather than its peak value $3x^2$. The descent lemma must guard against the worst-case curvature along the segment and therefore certifies only a third of the true safe range.

Backtracking, by contrast, accepts 0.031 on the first step. Its previous trial, 0.0625, fails the Armijo test, which on this quartic holds if and only if $\eta x^2 \leq 0.456$ (roughly $\eta \leq 0.05$ at $x_0 = 3$). As the iterate moves toward the origin and the curvature flattens, the accepted steps grow automatically ($0.0625, 0.125, 0.25, 0.5, 1.0$, each close to $0.3/x^2$) because the line search probes the local curvature on the fly. Deep learning training rarely uses backtracking, since a minibatch loss is too noisy to compare two candidate steps reliably and each trial costs an extra forward pass. Instead, training usually specifies the step size in advance via a schedule (Section 9.7).

35.1.1.5 Relaxed Smoothness and Gradient Clipping

A schedule cannot react when the iterate enters a region of high curvature. The safeguard that training uses for this is gradient clipping, and the quartic shows why it works. The curvature $f''(x) = 3x^2$ is unbounded, but it is large only where the gradient $f'(x) = x^3$ is large as well: $3x^2 \leq 4 + |x|^3$ for every x. A twice differentiable function is (L_0, L_1)-**smooth** if its curvature is bounded in this way by its gradient (Zhang, He, et al. 2020):

$$\|\nabla^2 f(\mathbf{x})\| \;\le\; L_0 + L_1 \|\nabla f(\mathbf{x})\| \qquad \text{for all } \mathbf{x}, \tag{35.8}$$

where the norm on the left is the largest absolute eigenvalue of the Hessian. Setting $L_1 = 0$ recovers L-smoothness, and the quartic qualifies with $L_0 = 4$ and $L_1 = 1$. Under this condition, the step that the descent lemma can certify is no longer a constant $1/L$. It is of order $1/(L_0 + L_1\|\mathbf{g}\|)$: a fixed step where the gradient is small, and a fixed *distance* $\eta\,\|\mathbf{g}\|$ of order $1/L_1$ where it is large. Gradient clipping, which replaces $\mathbf{g}$ by $\min(1, c/\|\mathbf{g}\|)\,\mathbf{g}$ for a threshold c, takes steps of this form at no extra cost. On the quartic with $c = 1$, the step $\eta = 0.3$ that diverged above now moves x by 0.3 per iteration until $|x| \le 1$ and converges from there (Exercise 3).

35.1.2 The Quadratic Model and the Condition Number

In the opening, we promised to explain why one bowl takes 69 steps and another takes $6{,}908$. Both objectives are quadratics, and on a quadratic we can solve gradient descent in closed form. Remarkably, the iteration count boils down to a single quantity: the ratio of the largest curvature to the smallest.

35.1.2.1 Ill-Conditioned Valleys

Before writing any algebra, look at Figure 35.2, which contrasts gradient descent on two quadratics. On a round bowl, the iterates march almost straight to the minimum. In an elongated valley, the walls are steep while the floor is flat: any step near the stability ceiling imposed by the walls overshoots across the valley and bounces from wall to wall, while barely inching along the floor. The result is the classic zigzag trajectory. (The valley shown uses $\mathrm{diag}(1, 20)$ with $\eta = 0.097$, just below its stability ceiling 0.1, producing the contraction factors noted in the caption.)

Quadratics deserve a complete analysis because every smooth function looks like one near a strict minimum. Around a minimizer $\mathbf{x}^\star$ with positive-definite Hessian $\mathbf{A}$, the second-order Taylor expansion approximates f by $f(\mathbf{x}^\star) + \tfrac{1}{2}(\mathbf{x}-\mathbf{x}^\star)^\top \mathbf{A}\,(\mathbf{x}-\mathbf{x}^\star)$. Shifting the minimizer to the origin and dropping the additive constant leaves our model problem:

$$f(\mathbf{x}) = \tfrac{1}{2}\,\mathbf{x}^\top \mathbf{A}\,\mathbf{x},$$
$$\mathbf{A} \text{ symmetric positive definite, with eigenvalues } 0 < \lambda_{\min} = \lambda_1 \le \cdots \le \lambda_d = \lambda_{\max}.$$

Its gradient is $\mathbf{A}\mathbf{x}$ and its Hessian is $\mathbf{A}$, so its smoothness constant is simply $L = \lambda_{\max}$. The ratio of the largest curvature to the smallest,

$$\kappa = \frac{\lambda_{\max}}{\lambda_{\min}},$$

is the **condition number** of the problem. It equals 10 for our opening bowl $\mathrm{diag}(1, 10)$ and 10^3 for the chapter's running example. Because $\mathbf{A}$ is symmetric positive definite, κ coincides with the singular-value ratio $\kappa(\mathbf{A})$ introduced in Section 33.5.3.2.

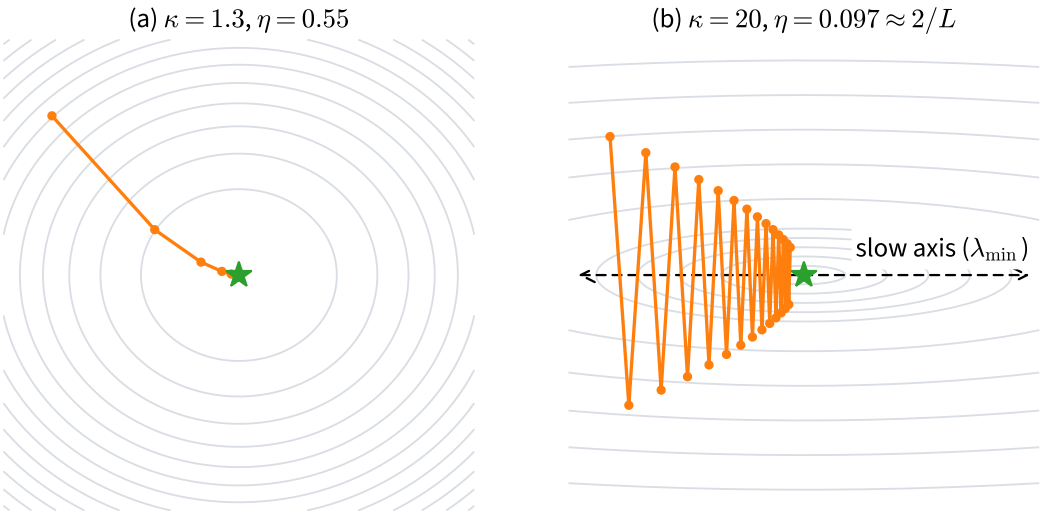

Figure 35.2: Gradient descent on two quadratics $f(\mathbf{x}) = \frac{1}{2}\mathbf{x}^\top \mathbf{A}\mathbf{x}$. Left: on a well-conditioned bowl, the iterates head nearly straight to the minimum. Right: in an ill-conditioned valley, a step near the stability ceiling makes the steep mode overshoot and alternate (factor -0.94) while the slow axis contracts by only 0.90 per step.

35.1.2.2 Per-Mode Contraction and the Stability Ceiling

The zigzagging in Figure 35.2 comes directly from the step-size ceiling enforced by the steepest direction. To pinpoint that ceiling and see how severely it slows down the flat direction, let us solve gradient descent on a quadratic exactly—starting, as always, with a single variable.

Take $f(u) = \frac{\lambda}{2}u^2$ with $\lambda > 0$. One gradient step sends u_k to $u_{k+1} = u_k - \eta\lambda u_k$, so

$$u_{k+1} = (1 - \eta\lambda)\, u_k, \qquad u_k = (1 - \eta\lambda)^k\, u_0.$$

Every iteration simply multiplies the error by the same scalar factor $1 - \eta\lambda$. Convergence occurs if and only if $|1 - \eta\lambda| < 1$, meaning $0 < \eta < 2/\lambda$. At the sweet spot $\eta = 1/\lambda$, the iterate lands on 0 in a single step. For $1/\lambda < \eta < 2/\lambda$, the factor is negative, so u_k flips sign at every step while shrinking toward zero. For $\lambda = 10$, for instance, $\eta = 0.1$ gives factor 0, $\eta = 0.19$ gives -0.9, and $\eta = 0.21$ gives -1.1, which diverges.

The d-dimensional quadratic keeps the exact same structure. Since $\nabla f(\mathbf{x}) = \mathbf{A}\mathbf{x}$, the update Equation 35.2 becomes

$$\mathbf{x}_{k+1} = (\mathbf{I} - \eta\mathbf{A})\, \mathbf{x}_k.$$

Each step applies the same linear operator, so after k steps $\mathbf{x}_k = (\mathbf{I} - \eta\mathbf{A})^k \mathbf{x}_0$. Because $\mathbf{A}$ is symmetric, it admits an orthonormal basis of eigenvectors (Section 33.3). Express $\mathbf{x}_k$ in this eigenbasis with coordinates $u_i^{(k)}$. The matrix $\mathbf{I} - \eta\mathbf{A}$ shares the same eigenvectors with eigenvalues $1 - \eta\lambda_i$, so the coordinates decouple completely and evolve independently:

$$u_i^{(k+1)} = (1 - \eta\lambda_i)\, u_i^{(k)}, \qquad \text{hence} \qquad u_i^{(k)} = (1 - \eta\lambda_i)^k\, u_i^{(0)}. \tag{35.9}$$

Thus, gradient descent on a d-dimensional quadratic is nothing more than d independent copies of the one-variable recursion—one per eigenvalue, or **mode**. Two consequences follow immediately from the factors $1 - \eta\lambda_i$:

- **Convergence** requires $|1 - \eta\lambda_i| < 1$ for every mode, which reduces to $0 < \eta < 2/\lambda_{\max} = 2/L$. This threshold is the **stability ceiling**. On quadratics, the bound $2/L$ that the descent lemma guaranteed as sufficient is also strictly necessary. Push η past it, and the stiffest mode's factor drops below -1: that coordinate oscillates with growing amplitude even while all other modes decay cleanly.
- **Speed** is governed by the slowest mode. The error norm decays as $\rho(\eta)^k$, where $\rho(\eta) = \max_i |1 - \eta\lambda_i|$ is the **spectral radius** of $\mathbf{I} - \eta\mathbf{A}$—the largest eigenvalue magnitude.

On $\mathbf{A} = \mathrm{diag}(1, 10)$, the stability ceiling is $\eta = 0.2$. Before running the sweep below, predict which step size leaves the smallest error after 60 steps from $(1, 1)$: the cautious 0.02, the descent-lemma favorite $0.1 = 1/L$, or something closer to the ceiling?

```
A = np.diag([1.0, 10.0])                    # eigenvalues 1 and 10, so L = 10
x0 = np.array([1.0, 1.0])

def run_gd(A, x0, eta, steps):
    xs = [x0]
    for _ in range(steps):
        xs.append(xs[-1] - eta * (A @ xs[-1]))
    return np.array(xs)

print(' eta    |1-eta*1|  |1-eta*10|  spectral radius   |x_60|')
for eta in [0.02, 0.10, 2 / 11, 0.19, 0.20, 0.21]:
    f1, f10 = abs(1 - eta * 1.0), abs(1 - eta * 10.0)
    print(f'{eta:5.3f}    {f1:6.3f}     {f10:6.3f}        {max(f1, f10):6.3f}     '
          f'{np.linalg.norm(run_gd(A, x0, eta, 60)[-1]):9.1e}')
```

```
 eta    |1-eta*1|  |1-eta*10|  spectral radius   |x_60|
0.020     0.980      0.800         0.980       3.0e-01
0.100     0.900      0.000         0.900       1.8e-03
0.182     0.818      0.818         0.818       8.3e-06
0.190     0.810      0.900         0.900       1.8e-03
0.200     0.800      1.000         1.000       1.0e+00
0.210     0.790      1.100         1.100       3.0e+02
```

The cautious $\eta = 0.02$ is safe but sluggish ($\rho = 0.98$, leaving an error of 0.3 after 60 steps). At $\eta = 0.1$, the stiff mode vanishes in a single step, yet the slow mode still limits the overall rate to $\rho = 0.9$. Interestingly, $\eta = 0.19$ shares that exact same rate $\rho = 0.9$, for the opposite reason: now the stiff mode oscillates with factor -0.9. Between them, $\eta = 2/11 \approx 0.182$ balances both extremes and beats every other choice by two orders of magnitude ($\rho = 0.818$, error 8.3×10^{-6}). Right at the ceiling $\eta = 0.2$, the stiff mode has factor -1, flipping between ± 1 forever so $\|\mathbf{x}_{60}\| = 1.0$. Step just past it to $\eta = 0.21$, and sixty iterations inflate the error to 3×10^2.

35.1.2.3 The Optimal Step

Within the stable range, which fixed step size η converges fastest? The sweep points directly to the answer: balance the two extreme modes. For any fixed η, the map $\lambda \mapsto |1-\eta\lambda|$ traces a V-shape with its vertex at $\lambda = 1/\eta$. On the interval $[\lambda_{\min}, \lambda_{\max}]$, a V-shaped function attains its maximum at one of the endpoints, so $\rho(\eta) = \max(|1-\eta\lambda_{\min}|, |1-\eta\lambda_{\max}|)$. Once η passes $1/\lambda_{\max}$, increasing it further helps the slow mode at $\lambda_{\min}$ while hurting the stiff mode at $\lambda_{\max}$.

Proposition (optimal fixed step on a quadratic). *For $f(\mathbf{x}) = \frac{1}{2}\mathbf{x}^\top \mathbf{A}\mathbf{x}$, the convergence factor $\rho(\eta) = \max_i |1-\eta\lambda_i|$ is minimized by*

$$\eta^\star = \frac{2}{\lambda_{\min}+\lambda_{\max}}, \qquad \rho(\eta^\star) = \frac{\kappa-1}{\kappa+1}, \qquad \kappa = \frac{\lambda_{\max}}{\lambda_{\min}}. \tag{35.10}$$

Proof. For every η, we have $\rho(\eta) \geq \max(1-\eta\lambda_{\min},\ \eta\lambda_{\max}-1)$, and the maximum of two numbers is at least any convex combination of them. Choosing the weights $\lambda_{\max}/(\lambda_{\min}+\lambda_{\max})$ and $\lambda_{\min}/(\lambda_{\min}+\lambda_{\max})$ makes the η-terms cancel cleanly:

$$\rho(\eta) \ \geq\ \frac{\lambda_{\max}(1-\eta\lambda_{\min}) + \lambda_{\min}(\eta\lambda_{\max}-1)}{\lambda_{\min}+\lambda_{\max}} = \frac{\lambda_{\max}-\lambda_{\min}}{\lambda_{\max}+\lambda_{\min}} = \frac{\kappa-1}{\kappa+1}.$$

Equality holds only when the two terms agree, $1-\eta\lambda_{\min} = \eta\lambda_{\max}-1$, which solves to $\eta = \eta^\star$. At $\eta^\star$, both endpoints equal $(\kappa-1)/(\kappa+1)$, and the V-shape keeps every interior eigenvalue below that height, so the bound is attained. ■

Figure 35.3 illustrates this proof on $\mathrm{diag}(1, 10)$: the optimal V is the one whose two endpoints sit at the same height. Here $\eta^\star = 2/11$ and $\rho = 9/11 = 0.818$, so gaining six digits takes $\log 10^6/\log(11/9) \approx 69$ steps. On the chapter's running example ($\kappa = 1000$), $\rho = 999/1001$, and those same six digits demand $6{,}908$ steps.

When $\kappa = 1$ (a perfectly round bowl), $\rho = 0$ and a single step lands on the minimum. For large κ, $(\kappa-1)/(\kappa+1) \approx 1-2/\kappa$, so $\log(1/\rho) \approx 2/\kappa$, and shrinking the error by a factor of ϵ takes roughly $\frac{\kappa}{2}\log\frac{1}{\epsilon}$ iterations: **the iteration count of gradient descent grows linearly with the condition number**. The bottleneck is easy to see in one sentence: stability forces the step to obey the stiffest mode, $\eta \lesssim 2/\lambda_{\max}$, leaving the flattest mode to advance by only $\eta\,\lambda_{\min} \approx 2/\kappa$ per iteration.

At $\eta^\star$, the factor ρ is even stronger than an asymptotic rate. On $\mathrm{diag}(1, 10)$, the two per-mode factors are $+9/11$ and $-9/11$ (the $\eta = 2/11$ row of the sweep): the slow mode contracts monotonically while the stiff mode alternates in sign. Because both coordinates shrink by the same magnitude, $\|\mathbf{x}_k\|$ contracts by $(\kappa-1)/(\kappa+1)$ on every single step, not just on average.

35.1.2.4 The Edge of Stability

The stability ceiling suggests a simple recipe for neural networks: compute the **sharpness**, the largest Hessian eigenvalue $\lambda_{\max}(\nabla^2 f)$, and set $\eta < 2/\lambda_{\max}$. In practice, training a neural network does not cooperate, because the Hessian evolves along the trajectory. Under full-batch gradient descent, the sharpness typically climbs until it hits roughly $2/\eta$ and then hovers right around that threshold; meanwhile, the loss decreases over the long run even

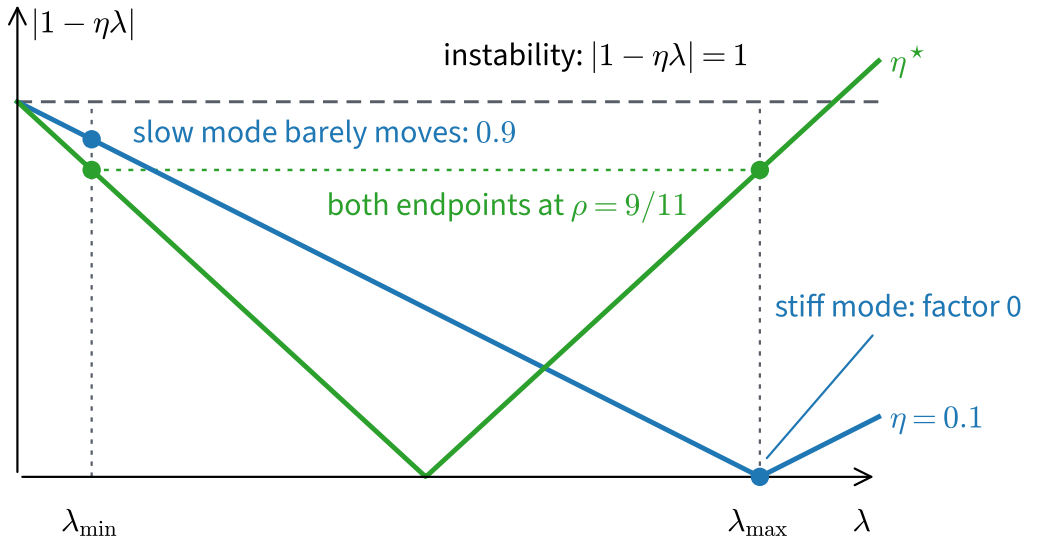

Figure 35.3: The per-mode contraction factors $|1-\eta\lambda|$ form a V with its vertex at $\lambda = 1/\eta$, and the convergence factor $\rho(\eta)$ is the larger of its values at the extreme eigenvalues $\lambda_{\min} = 1$ and $\lambda_{\max} = 10$. Choosing $\eta = 0.1$ eliminates the stiff mode immediately but leaves the slow mode contracting at 0.9; the optimal step $\eta^\star = 2/(\lambda_{\min}+\lambda_{\max})$ equalizes both endpoints at $(\kappa-1)/(\kappa+1) = 9/11$. Lowering either endpoint would raise the other.

though it jumps upward on many individual steps (Cohen et al. 2021). Section 9.1.4 runs this experiment on a small tanh network and examines it in detail. Here we ask a narrower question: how much of this behavior does our quadratic model explain?

Roughly half. In the Hessian's eigenbasis, the top mode's multiplier is $1-\eta\lambda_{\max}$, which drops below -1 precisely when $\lambda_{\max} > 2/\eta$. That coordinate then alternates in sign with growing amplitude, explaining how a loss that trends downward overall can spike on individual steps. On a fixed quadratic, however, that growth would run away to infinity. What pulls the sharpness back down instead lies outside the quadratic approximation: the third-order Taylor term, which the quadratic model ignores, turns the oscillation into a gradual drift toward flatter regions of lower sharpness (Damian et al. 2023). Exercise 8 shows that adding momentum shifts this stability threshold to $(2+2\beta)/\eta$.

35.1.2.5 From Quadratics to Convex Functions

What carries over beyond quadratics is the linear dependence on κ. A differentiable function is convex if it lies on or above each of its tangent planes, and μ-strongly convex if it clears them by a quadratic margin, $f(\mathbf{y}) \geq f(\mathbf{x}) + \nabla f(\mathbf{x})^\top(\mathbf{y}-\mathbf{x}) + \frac{\mu}{2}\|\mathbf{y}-\mathbf{x}\|^2$ for all $\mathbf{x}, \mathbf{y}$; Section 35.3 develops both notions. If f is L-smooth and μ-strongly convex, then at every point it is sandwiched between two quadratics of curvatures μ and L. The ratio $\kappa = L/\mu$ replaces $\lambda_{\max}/\lambda_{\min}$, and gradient descent with $\eta = 1/L$ satisfies

$$f(\mathbf{x}_k) - f^\star \leq \left(1 - \frac{1}{\kappa}\right)^k (f(\mathbf{x}_0) - f^\star), \tag{35.11}$$

which again requires $O(\kappa \log \frac{1}{\epsilon})$ iterations. If f is smooth and convex without being strongly convex, gradient descent still converges to the global optimum, though at the slower sublinear rate $O(1/k)$; drop convexity altogether, and only the stationarity bound Equation 35.6 remains. The proofs rely on convexity and are developed in Section 35.3.3.3, which also compares these general bounds against the sharper rate attained on quadratics.

35.1.3 Momentum and Acceleration

Gradient descent requires $O(\kappa)$ iterations because a single step size must simultaneously accommodate the stiffest and flattest modes. Momentum keeps the same single gradient evaluation per step, yet changes the update rule so that both modes can contract at the same rate.

35.1.3.1 Heavy-Ball Momentum

The geometry of the valley immediately suggests what to change. Along the steep walls, consecutive gradients point in opposite directions (the zigzagging in Figure 35.2), so averaging recent gradients cancels the oscillation. Along the flat floor, consecutive gradients are small but consistently aligned, so accumulating them builds speed. One simple mechanism does both: give the iterate a velocity with memory. **Heavy-ball momentum** (Polyak 1964) replaces the plain gradient step with

$$\mathbf{v}_{k+1} = \beta\, \mathbf{v}_k - \eta\, \nabla f(\mathbf{x}_k), \qquad \mathbf{x}_{k+1} = \mathbf{x}_k + \mathbf{v}_{k+1}, \tag{35.12}$$

where $\beta \in [0, 1)$ is the momentum parameter. The velocity $\mathbf{v}_k$ is an exponentially decaying sum of past gradients. Since $\mathbf{v}_k = \mathbf{x}_k - \mathbf{x}_{k-1}$, eliminating $\mathbf{v}$ gives the equivalent two-step form

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \eta\, \nabla f(\mathbf{x}_k) + \beta\, (\mathbf{x}_k - \mathbf{x}_{k-1}).$$

Each update takes a gradient step and adds β times the previous displacement; setting $\beta = 0$ recovers ordinary gradient descent.

On a quadratic, the modes once again decouple. In a single mode with gradient λu_k, the two-step update reads $u_{k+1} = (1 + \beta - \eta\lambda)\, u_k - \beta\, u_{k-1}$, so each iterate depends on its two predecessors. A second-order recurrence of this form is the discrete counterpart of a damped harmonic oscillator—a heavy ball rolling in a bowl with friction $1 - \beta$—where β controls the damping.

Figure 35.4 displays the three resulting regimes on $\mathrm{diag}(1, 10)$, all using gradient descent's optimal step $\eta = 2/11$. With too little momentum, the path zigzags much like plain gradient descent. With just the right amount, it settles smoothly after a single overshoot. With too much momentum, the ball carries excess inertia and spirals around the minimum. Next, we attach exact convergence rates to all three regimes—and discover that achieving the fastest possible rate also calls for a larger step size.

35.1.3.2 The $\sqrt{\kappa}$ Law

We now show that with the right pair (η, β), every mode contracts at the identical rate $(\sqrt{\kappa} - 1)/(\sqrt{\kappa} + 1)$. For $\kappa = 10$, this optimal pair is $\beta^\star \approx 0.27$ and $\eta_{\mathrm{HB}} \approx 0.23$, dropping

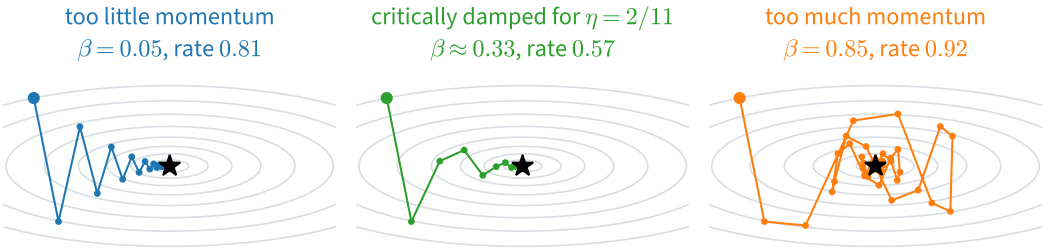

Figure 35.4: Heavy ball on the $\kappa = 10$ valley $\frac{1}{2}(x^2 + 10y^2)$, with all three runs using gradient descent's step $\eta = 2/11$. Too little momentum zigzags like gradient descent (the stiff mode's coefficient $1 + \beta - \eta\lambda_{\text{max}}$ is negative, giving a negative real root); the critically damped β for this step is fastest; too much momentum spirals around the minimum. Reaching the optimal $\sqrt{\kappa}$ rate of 0.52 requires the larger step η_{HB} of Equation 35.14, at which $\beta = 0.05$ would diverge.

the contraction factor from gradient descent's 0.82 to 0.52—reaching six digits in 27 steps instead of 69. Remarkably, the entire result follows from a single algebraic fact about one mode.

Proposition (heavy ball contracts every mode at $\sqrt{\beta}$). *Let $0 < \beta < 1$. On $f(u) = \frac{\lambda}{2}u^2$, the heavy-ball iterates obey $u_{k+1} = (1 + \beta - \eta\lambda)u_k - \beta u_{k-1}$. Whenever $(1 - \sqrt{\beta})^2 \le \eta\lambda \le (1 + \sqrt{\beta})^2$, both roots of the characteristic polynomial have modulus $\sqrt{\beta}$, and $|u_k| \le C\, k\, \beta^{k/2}$ for $k \ge 1$ and a constant C depending on u_0, u_1, and $\eta\lambda$. The linear factor k is needed only at the two endpoints, where the root is repeated.*

Proof. Substitute the trial solution $u_k = z^k$ into the recurrence and divide by z^{k-1} to obtain the characteristic equation

$$z^2 - (1 + \beta - \eta\lambda)\, z + \beta = 0. \tag{35.13}$$

The product of the two roots is β. They form a complex-conjugate pair whenever the discriminant $(1+\beta-\eta\lambda)^2 - 4\beta$ is negative, that is, when $|1+\beta-\eta\lambda| < 2\sqrt{\beta}$, which rearranges to $(1 - \sqrt{\beta})^2 < \eta\lambda < (1 + \sqrt{\beta})^2$. Because complex conjugates $z, \bar{z}$ satisfy $|z|^2 = z\bar{z} = \beta$, both roots have modulus $\sqrt{\beta}$ regardless of λ, and the general solution $u_k = az^k + b\bar{z}^k$ satisfies $|u_k| \le (|a| + |b|)\beta^{k/2}$. At the two endpoints, the discriminant vanishes and we get a double real root $(1 + \beta - \eta\lambda)/2 = \pm\sqrt{\beta}$. A repeated root z yields the general solution $u_k = (a + bk)z^k$, which accounts for the extra factor k. ∎

Corollary (the tuning). Place the two extreme modes right at the endpoints of the complex-root interval: $\eta\lambda_{\text{min}} = (1 - \sqrt{\beta})^2$ and $\eta\lambda_{\text{max}} = (1 + \sqrt{\beta})^2$. Every intermediate eigenvalue then falls inside the interval, so every single mode has root modulus $\sqrt{\beta}$. Taking square roots gives $\sqrt{\eta\lambda_{\text{max}}} - \sqrt{\eta\lambda_{\text{min}}} = 2\sqrt{\beta}$ and $\sqrt{\eta\lambda_{\text{max}}} + \sqrt{\eta\lambda_{\text{min}}} = 2$. Solving the second equation for η and dividing the first by the second gives $\sqrt{\beta} = (\sqrt{\kappa} - 1)/(\sqrt{\kappa} + 1)$. With the tuning

$$\eta_{\text{HB}} = \left(\frac{2}{\sqrt{\lambda_{\max}} + \sqrt{\lambda_{\min}}} \right)^2, \qquad \beta^\star = \left(\frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \right)^2, \tag{35.14}$$

heavy ball contracts every mode at the rate

$$\rho_{\text{HB}} = \sqrt{\beta^\star} = \frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \;\approx\; 1 - \frac{2}{\sqrt{\kappa}}. \tag{35.15}$$

Compare this with Equation 35.10: momentum replaces κ with $\sqrt{\kappa}$, slashing the iteration complexity from $O(\kappa \log \frac{1}{\epsilon})$ to $O(\sqrt{\kappa} \log \frac{1}{\epsilon})$ (Polyak 1964). At finite k, the double roots at the two extreme modes add a modest logarithmic overhead: the error scales as $k\rho^k$, so with $\log(1/\rho) \approx 2/\sqrt{\kappa}$, reaching accuracy ϵ solves $k \approx \frac{\sqrt{\kappa}}{2}(\log \frac{1}{\epsilon} + \log k)$—the asymptotic law plus a correction of order $\sqrt{\kappa} \log \kappa$.

Figure 35.5 makes this proof visual for $\kappa = 10$. On the left, the modulus of the dominant root sits flat at $\sqrt{\beta}$ across the entire complex-root interval. On the right, in the complex plane, every mode's root pair lies squarely on the circle of radius $\sqrt{\beta^\star} = 0.52$, whereas gradient descent's real multipliers stretch out to ± 0.82. By allowing the roots to move off the real axis, momentum lets the stiff and flat modes share a single small modulus instead of forcing the flat mode to crawl at $1 - 2/\kappa$.

The proposition also explains the exact rates of the three trajectories in Figure 35.4, where $\eta = 2/11$ places the two modes at $\eta\lambda = 0.18$ and 1.82. At $\beta = 0.85$, both modes lie strictly inside the interval: the contraction rate is $\sqrt{0.85} = 0.92$, and the complex roots produce the spiraling overshoot. The smallest β whose interval still captures the slow mode, $\beta = (1 - \sqrt{2/11})^2 \approx 0.33$, is the fastest choice for this step size, achieving rate 0.57. At $\beta = 0.05$, the interval $[0.60, 1.50]$ misses both modes: the slow mode gets a real root 0.81, while the stiff mode gets a negative real root that flips sign on every step—an alternation that a continuous-time physical oscillator can never produce.

Be aware that this $\sqrt{\kappa}$ theorem holds strictly for quadratics. Lessard et al. (2016) constructed a one-dimensional, smooth, strongly convex function on which heavy ball with the tuning Equation 35.14 fails to converge from certain initializations, trapping the iterates in a stable limit cycle (exercise 6). Thus, the widespread use of heavy-ball momentum in deep learning (Sutskever et al. 2013) rests on the local quadratic picture and empirical success rather than a global convergence theorem.

35.1.3.3 Nesterov's Look-Ahead

One small modification recovers a global guarantee: evaluate the gradient not at the current position $\mathbf{x}_k$, but at the look-ahead point $\mathbf{x}_k + \beta \mathbf{v}_k$ where momentum is about to carry us. **Nesterov's accelerated gradient** (Nesterov 1983) updates via

$$\mathbf{v}_{k+1} = \beta \mathbf{v}_k - \eta \nabla f(\mathbf{x}_k + \beta \mathbf{v}_k), \qquad \mathbf{x}_{k+1} = \mathbf{x}_k + \mathbf{v}_{k+1}. \tag{35.16}$$

That shift in evaluation point is the only difference from heavy ball. Intuitively, if momentum is about to carry the iterate past the minimum, the gradient at the look-ahead point already points back uphill and applies the brakes before the overshoot occurs.

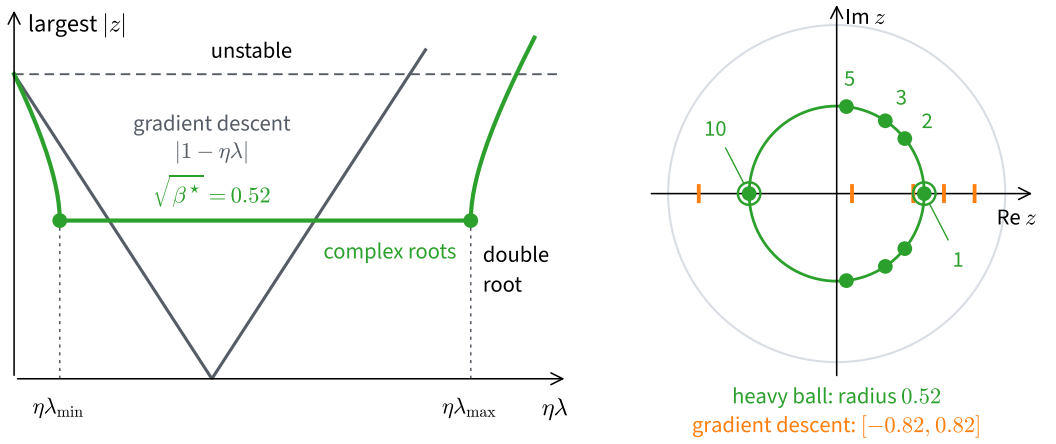

Figure 35.5: Heavy ball at the tuning of Equation 35.14 on the $\kappa = 10$ example. (a) For fixed β, the modulus of the larger root is flat at $\sqrt{\beta}$ wherever the roots are complex; the optimal tuning places the two extreme modes at the ends of that interval. (b) In the complex plane, every mode's root pair (labeled by its eigenvalue λ) lies on the circle of radius $\sqrt{\beta^\star} = 0.52$, while gradient descent's factors span $[-0.82, 0.82]$ on the real axis. The extreme modes are double roots, producing the factor k in the error.

Proposition (Nesterov on quadratics). *Let $\kappa = L/\mu$. With $\eta = 1/L$ and $\beta = (\sqrt{\kappa}-1)/(\sqrt{\kappa}+1)$, every mode of a quadratic with eigenvalues in $[\mu, L]$ has characteristic roots of modulus at most $1 - 1/\sqrt{\kappa}$, with a double root at the slow mode $\lambda = \mu$. Consequently, the error is bounded by $C\,k\,(1-1/\sqrt{\kappa})^k$.*

Proof. In a single mode with eigenvalue λ, write $a = 1 - \eta\lambda \in [0, 1 - 1/\kappa]$. The velocity update becomes $v_{k+1} = a\beta v_k - \eta\lambda u_k$, giving $u_{k+1} = a u_k + a\beta v_k$. Substituting $v_k = u_k - u_{k-1}$ yields the recurrence $u_{k+1} = (1+\beta)a\,u_k - \beta a\,u_{k-1}$, whose characteristic polynomial $z^2 - (1+\beta)a\,z + \beta a$ has discriminant $a\,[(1+\beta)^2 a - 4\beta]$. For our choice of β, $(1+\beta)^2 = 4\kappa/(\sqrt{\kappa}+1)^2$. At the slow mode $a = (\kappa-1)/\kappa$, the bracket evaluates to $4(\kappa-1)/(\sqrt{\kappa}+1)^2 - 4\beta = 4\beta - 4\beta = 0$, giving a double root at $(1+\beta)a/2 = (\sqrt{\kappa}-1)/\sqrt{\kappa} = 1 - 1/\sqrt{\kappa}$. Every stiffer mode has a smaller a, making the bracket strictly negative and producing complex roots (or roots at 0 when $a = 0$) of modulus $\sqrt{\beta a} < \sqrt{\beta(1-1/\kappa)} = 1 - 1/\sqrt{\kappa}$. ■

On quadratics, Nesterov's contraction factor is 0.684 for $\kappa = 10$, 0.900 for $\kappa = 100$, and 0.968 for $\kappa = 1000$—slightly slower than heavy ball's 0.519, 0.818, and 0.939, yet preserving the same $\sqrt{\kappa}$ scaling. Crucially, unlike heavy ball, Nesterov's method keeps its guarantees beyond quadratics, which we state here without proof (Nesterov 2018). On every μ-strongly convex, L-smooth function, Nesterov's update with the same constant β satisfies $f(\mathbf{x}_k) - f^\star \le C\,(1-1/\sqrt{\kappa})^k$. (Mind the units: this bounds the function gap $f - f^\star$, which scales as the squared distance, so its exponent is half the exponent in the quadratic proposition.) On smooth convex functions without strong convexity, a schedule $\beta_k \to 1$ achieves $f(\mathbf{x}_k) - f^\star = O(1/k^2)$, improving on gradient descent's $O(1/k)$. Moreover, this speed cannot be beaten in general: no method that builds its iterates solely from past gradients can surpass $O(1/k^2)$ or the $\sqrt{\kappa}$ dependence in the worst case, provided the dimension is large relative to the number of iterations (Nemirovski and Yudin 1983). Exercise 7 constructs the

worst-case function that proves this limit.

Let us now verify the iteration counts we quoted at the start of the section. On $\mathrm{diag}(1, \kappa)$ starting from $(1, 1)$, gaining six digits should cost gradient descent roughly $\frac{\kappa}{2} \log 10^6 \approx 6.9\,\kappa$ steps and heavy ball somewhat more than $6.9\sqrt{\kappa}$.

```
def iterations(lam, eta, beta=0.0, lookahead=False, tol=1e-6):
    """Steps until |x_k| <= tol |x_0| on f(x) = sum_i lam_i x_i^2 / 2."""
    x, v = np.array([1.0, 1.0]), np.zeros(2)
    n0 = np.linalg.norm(x)
    for k in range(1, 10**6):
        g = lam * (x + beta * v) if lookahead else lam * x
        v = beta * v - eta * g
        x = x + v
        if np.linalg.norm(x) <= tol * n0:
            return k

print('kappa      GD   heavy ball   Nesterov     GD/kappa   HB/sqrt(kappa)')
for kappa in [10.0, 100.0, 1000.0]:
    lam, sk = np.array([1.0, kappa]), np.sqrt(kappa)
    gd = iterations(lam, 2 / (1 + kappa))
    hb = iterations(lam, (2 / (1 + sk))**2, ((sk - 1) / (sk + 1))**2)
    na = iterations(lam, 1 / kappa, (sk - 1) / (sk + 1), lookahead=True)
    print(f'{kappa:5.0f} {gd:7d} {hb:9d} {na:10d}      '
          f'{gd / kappa:7.1f}     {hb / sk:7.1f}')
```

```
kappa      GD   heavy ball   Nesterov     GD/kappa   HB/sqrt(kappa)
   10      69         27         43          6.9          8.5
  100     691         93        155          6.9          9.3
 1000    6908        315        508          6.9         10.0
```

The table confirms every prediction. Gradient descent's step count divided by κ stays pinned at 6.9, reaching $6{,}908$ iterations at $\kappa = 1000$, while heavy ball finishes in just 315. Notice that heavy ball's ratio $k/\sqrt{\kappa}$ drifts gently upward (8.5, 9.3, 10.0) because each extreme mode has a double root: its 2×2 iteration matrix forms a Jordan block, a repeated eigenvalue with only a single eigenvector (Section 33.3.1.5), whose k-th power brings in the factor k. The refined prediction $k \approx \frac{\sqrt{\kappa}}{2}(\log 10^6 + \log k)$ matches closely (8.6, 9.2, 9.8), and at $\kappa = 10^4$, heavy ball takes $1{,}056$ steps, a ratio of 10.6 (exercise 5). Nesterov's 508 iterations at $\kappa = 1000$ sit cleanly between the two, just as its contraction factor 0.968 versus heavy ball's 0.939 predicts. Because all three methods evaluate only one gradient per step, momentum's speedup costs no extra gradient work. Yet $\sqrt{\kappa}$ is also the limit of what gradients alone can achieve: by the first-order lower bound, no method built solely from past gradients can beat it in high dimensions. Removing the dependence on κ altogether requires a step that actually models the curvature (Section 35.2).

35.1.4 Summary

Smoothness caps how far a gradient step can be trusted: on an L-smooth objective, descent is guaranteed up to $\eta = 2/L$. On a quadratic, the best fixed step contracts the error by $(\kappa - 1)/(\kappa + 1)$ per iteration, forcing the step count to grow linearly with the condition number κ because stability is governed by the stiffest mode while progress is governed by the flattest. Momentum equalizes every mode at the shared contraction rate $\sqrt{\beta}$, and its tuned factor

$(\sqrt{\kappa}-1)/(\sqrt{\kappa}+1)$ cuts the iteration count from $O(\kappa)$ to $O(\sqrt{\kappa})$ at no extra gradient cost. On neural networks, sharpness rises to the stability ceiling $2/\eta$ of the chosen step size, a phenomenon that the quadratic model explains only in part. Three questions remain open: what an optimizer can achieve when it models curvature directly (Section 35.2), when a stationary point is guaranteed to be a global minimum (Section 35.3), and what changes when gradients are noisy (Section 35.4).

35.1.5 Exercises

1. **Preconditioned descent directions.** The proposition of Section 35.1.1.1 measures the length of a direction with the Euclidean norm. Choosing a different norm yields a different steepest-descent direction.
   1. Show that $\mathbf{d} = -\mathbf{P}^{-1}\nabla f(\mathbf{x})$ is a descent direction for every positive definite matrix $\mathbf{P}$.
   2. Measure length by $\|\mathbf{d}\|_{\mathbf{P}} = \sqrt{\mathbf{d}^\top \mathbf{P}\,\mathbf{d}}$. Show that the minimizer of $\nabla f(\mathbf{x})^\top \mathbf{d}$ over $\|\mathbf{d}\|_{\mathbf{P}} = 1$ is proportional to $-\mathbf{P}^{-1}\nabla f(\mathbf{x})$, and identify the $\mathbf{P}$ that recovers Newton's direction $-\big(\nabla^2 f(\mathbf{x})\big)^{-1}\nabla f(\mathbf{x})$, the subject of Section 35.2. The change of variables $\mathbf{u} = \mathbf{P}^{1/2}\mathbf{d}$ reduces the problem to the Euclidean case.
2. code **Smoothness constants.** The smoothness constant L of Equation 35.3 bounds the curvature of f, and for a logistic loss it can be computed directly from the data.
   1. Let f be twice continuously differentiable and L-smooth. Show that $\|\nabla^2 f(\mathbf{x})\,\mathbf{v}\| \le L\,\|\mathbf{v}\|$ for all $\mathbf{x}$ and $\mathbf{v}$, and conclude that every Hessian eigenvalue lies in $[-L, L]$. This establishes the converse direction of the equivalence stated after Equation 35.3.
   2. Consider

$$f(\mathbf{w}) = \frac{1}{n}\sum_{i=1}^{n} \log\left(1 + \exp(-y_i\,\mathbf{x}_i^\top \mathbf{w})\right) + \frac{\nu}{2}\|\mathbf{w}\|^2$$

   with labels $y_i = \pm 1$ and $\nu = 0.1$—the `loss` function that we will use in the data cell of Section 35.2.1, where $\mathbf{x}_i^\top$ is the i-th row of $\mathbf{X} \in \mathbb{R}^{n\times d}$ ($n = 200$, $d = 5$, with independent standard Gaussian entries). Show that $L = \lambda_{\max}(\mathbf{X}^\top\mathbf{X})/(4n) + \nu$ is a valid smoothness constant and that the Hessian attains this bound at $\mathbf{w} = \mathbf{0}$.
   3. Compute this L for a 200×5 matrix $\mathbf{X}$ of standard Gaussian entries and labels $y_i \in \{\pm 1\}$ drawn with $P(y_i = 1) = 1/(1 + \exp(-\mathbf{x}_i^\top \mathbf{w}_{\text{true}}))$ for $\mathbf{w}_{\text{true}} = (1, -2, 1.5, 0, 2)$. It comes out near 0.4 for every draw; explain why using $\lambda_{\max}(\mathbf{X}^\top\mathbf{X})/n \approx (1 + \sqrt{d/n})^2$ for standard Gaussian entries. Count how many steps $\eta = 0.5$ (the reference step) and $\eta = 1/L$ each need from $\mathbf{w} = \mathbf{0}$ to reach $\|\nabla f(\mathbf{w})\| \le 10^{-10}$. Which is faster, and does $\eta = 0.5$ stay below $2/L$?
3. code **Clipping on the quartic.** Take $f(x) = \frac{1}{4}x^4$ and the clipped update $x \leftarrow x - \eta\,\min(1, c/|g|)\,g$ with $g = x^3$.
   1. Show that $3x^2 \le 4 + |x|^3$ for all x, with equality at $|x| = 2$, so that f satisfies Equation 35.8 with $L_0 = 4$ and $L_1 = 1$. Show also that no L_0 works with $L_1 = 0$.

2. Run the clipped update from $x_0 = 3$ with $\eta = 0.3$ and $c = 1$, the step at which the unclipped iteration reached 6.5×10^{103} in six steps. How many steps are clipped, and how far does each of them move x?
3. Show that the clipped update decreases $|x|$ at every step, from every starting point $x_0 \neq 0$, whenever $\eta\, c^{2/3} < 2$. Treat the clipped case $|x| > c^{1/3}$ and the unclipped case separately. Why can no fixed step without clipping have this property?

4. **Steepest descent in other norms.** ● Problem 1b measures length by a norm $\|\cdot\|_{\mathbf{A}}$ induced by an inner product. Norms that do not come from an inner product produce steepest directions of a very different form.

   1. Find the minimizers of $\nabla f(\mathbf{x})^{\top}\mathbf{d}$ over $\|\mathbf{d}\|_{\infty} = 1$ and over $\|\mathbf{d}\|_{1} = 1$, together with their minimal slopes, and state when each minimizer is unique.
   2. Let the parameter be a matrix whose gradient $\mathbf{G}$ has reduced SVD $\mathbf{G} = \mathbf{U}\,\mathrm{diag}(\sigma_i)\,\mathbf{V}^{\top}$, let the directional slope of $\mathbf{D}$ be $\mathrm{tr}(\mathbf{G}^{\top}\mathbf{D})$, and measure length by the spectral norm $\|\mathbf{D}\|_2$. Show that the minimal slope over $\|\mathbf{D}\|_2 \le 1$ is $-\sum_i \sigma_i$, attained at $\mathbf{D} = -\mathbf{U}\mathbf{V}^{\top}$—the polar factor that Muon applies to its momentum matrix (Section 9.6). Writing $\mathrm{tr}(\mathbf{G}^{\top}\mathbf{D}) = \sum_i \sigma_i\, \mathbf{u}_i^{\top}\mathbf{D}\,\mathbf{v}_i$ is a helpful first step. This is the steepest-descent perspective of Bernstein and Newhouse (2024) .

5. code **Heavy ball: the double root and the factor k.** ● Apply heavy ball Equation 35.12 to $f(u) = \frac{\lambda}{2}u^2$.

   1. Write one iteration as a linear map on the state (u_k, u_{k-1}) and show that the characteristic polynomial of its 2×2 matrix is Equation 35.13.
   2. At the tuning Equation 35.14, the two extreme modes have double eigenvalues $\sqrt{\beta^\star}$ and $-\sqrt{\beta^\star}$. Show that the matrix then has only a single eigenvector, and that the k-th power of the Jordan block $\left(\begin{smallmatrix}\rho & 1\\ 0 & \rho\end{smallmatrix}\right)$ has entry $k\rho^{k-1}$ above the diagonal.
   3. With $\|\mathbf{e}_k\| \approx k\rho^k$ and $\log(1/\rho) \approx 2/\sqrt{\kappa}$, solve $k = \frac{\sqrt{\kappa}}{2}\big(\log\frac{1}{\epsilon} + \log k\big)$ numerically for $\epsilon = 10^{-6}$ and $\kappa \in \{10, 100, 1000\}$, and compare $k/\sqrt{\kappa}$ with the momentum cell's column 8.5, 9.3, 10.0.
   4. Run the momentum cell's heavy ball at $\kappa = 10^4$ and compare its step count with your prediction. Explain why the ratio $k/\sqrt{\kappa}$ never settles to a constant as κ grows.

6. code **Heavy ball beyond quadratics.** ● Lessard et al. (2016) define a one-dimensional function through its gradient:

$$\nabla f(x) = \begin{cases} 25x, & x < 1, \\ x + 24, & 1 \le x < 2, \\ 25x - 24, & x \ge 2. \end{cases}$$

   1. Show that f is μ-strongly convex with $\mu = 1$ and L-smooth with $L = 25$.
   2. Run heavy ball with the tuning Equation 35.14 for 300 steps from $x_0 = 3.3$ with zero initial velocity, and run Nesterov's method Equation 35.16 with $\eta = 1/L$ and $\beta = (\sqrt{\kappa} - 1)/(\sqrt{\kappa} + 1)$ from the same start, where $\kappa = L/\mu$. Plot x_k against k for both methods.
   3. The heavy-ball iterates approach a period-three cycle that visits the piece $x < 1$ twice and the piece $x \ge 2$ once. Express the heavy-ball update across these

pieces as a linear system for the three cycle points, solve it, and compare your solution with the simulation.

4. Repeat the heavy-ball run from a grid of starting points on $[-6, 6]$ and report the fraction that land on the cycle. Every piece of f is a quadratic with curvature in $[\mu, L]$; why does the per-mode analysis behind Equation 35.15 fail to apply to f?

7. code **A lower bound for first-order methods.** ● This problem derives the $O(1/k^2)$ part of the bound of Nemirovski and Yudin (1983) quoted in Section 35.1.3 (the smooth convex case), following the construction of Nesterov (2018) . Here, a first-order method is any algorithm whose iterates satisfy $\mathbf{x}_k \in \mathbf{x}_0 + \operatorname{span}\{\nabla f(\mathbf{x}_0), \dots, \nabla f(\mathbf{x}_{k-1})\}$; take $\mathbf{x}_0 = \mathbf{0}$. For $p \le d$, let $\mathbf{A}_p \in \mathbb{R}^{d\times d}$ be zero except for its leading $p \times p$ block, which is tridiagonal with 2 on the diagonal and -1 on both off-diagonals, and define

$$f_p(\mathbf{x}) = \frac{L}{4}\left(\tfrac{1}{2}\,\mathbf{x}^\top \mathbf{A}_p\,\mathbf{x} - x_1\right).$$

1. Show that f_p is convex and L-smooth.
2. Show that if $\mathbf{x}$ is supported on the first j coordinates, then $\nabla f_p(\mathbf{x})$ is supported on the first $j+1$. Conclude that the k-th iterate of every first-order method is supported on the first k coordinates.
3. Show that the minimizer of f_p has entries $x_i^\star = 1 - i/(p+1)$ for $i \le p$ and zero beyond, that the minimum value is $-\frac{L}{8}(1 - \frac{1}{p+1})$, and that $\|\mathbf{x}^\star\|^2 \le (p+1)/3$.
4. Let $2k+1 \le d$. The functions f_{2k+1} and f_k agree on all vectors supported on the first k coordinates. Use this fact to show that every first-order method applied to f_{2k+1} satisfies, with $\mathbf{x}^\star$ the minimizer of f_{2k+1},

$$f_{2k+1}(\mathbf{x}_k) - \min f_{2k+1} \;\ge\; \frac{3L\,\|\mathbf{x}_0 - \mathbf{x}^\star\|^2}{32\,(k+1)^2}.$$

   Because the construction requires $d \ge 2k+1$, the bound governs roughly the first $d/2$ iterations. In fixed dimension, long runs can eventually do better asymptotically, but for neural networks with d in the millions this restriction never bites.

5. For $k \in \{5, 10, 25, 50, 100, 200, 400\}$, run k steps of gradient descent with $\eta = 1/L$ and of Nesterov's update Equation 35.16 with $\eta = 1/L$ and $\beta_j = (j-1)/(j+2)$ at step $j = 1, 2, \dots$ on f_{2k+1} with $d = 2k+1$, and divide each suboptimality gap by the lower bound. Which ratio stays bounded as k grows?

8. code **Edge of stability with momentum.** ●● Cohen et al. (2021) report that when momentum is added, the sharpness settles at a threshold different from $2/\eta$.

1. Use the iteration matrix from problem 5a to show that heavy ball Equation 35.12 on $f(x) = \frac{\lambda}{2}x^2$ with $0 \le \beta < 1$ converges if and only if $0 < \eta\lambda < 2 + 2\beta$. Derive the corresponding stability interval for Nesterov's update Equation 35.16.
2. Modify the edge-of-stability experiment of Section 9.1.4 to train with heavy ball and with Nesterov's update for $\beta \in \{0.25, 0.5\}$, choosing for each run a step size whose predicted threshold lies between 5 and 12. Track the sharpness against both $2/\eta$ and your threshold from (a).

3. At which threshold does the sharpness settle? What does this imply for choosing η from a sharpness measured at initialization when training with momentum?

35.2 Curvature Methods: Newton, Quasi-Newton, and Trust Regions

Gradient descent never measures the curvature of the function it minimizes; it only endures it. The steepest direction caps the step size, the flattest direction then crawls, and the number of iterations grows with the condition number κ, or with $\sqrt{\kappa}$ once momentum is added (Section 35.1.3). On our running example $\frac{1}{2}(x_1^2 + 1000\,x_2^2)$, that came to $6{,}908$ steps of gradient descent, or 315 with momentum. Yet anyone can solve this problem by inspection: divide each coordinate of the gradient by its curvature (1 or 1000) and a single step lands directly on the minimum. What can an optimizer achieve when it accounts for curvature instead of merely surviving it?

The classical answer is Newton's method, which predates gradient descent by a century and a half. At each iterate, it fits a quadratic approximation to the objective and jumps straight to the minimizer of that quadratic. In this section we examine how fast that step converges, what it costs, where it breaks down, and how much of its curvature information can be recovered from gradients alone when second derivatives are unavailable. Near a minimum, Newton's method is remarkably fast; for a neural network, however, forming the Hessian is far too expensive, and on nonconvex functions the method is drawn to saddle points just as readily as to minima. We then turn to two remedies: quasi-Newton methods, which rebuild curvature from successive gradient differences, and trust-region methods, which restrict each step to a neighborhood where the quadratic model actually agrees with the function.

For training deep networks, these classical methods are used much less often than first-order optimizers, and it is worth being candid about why. A full Hessian is too large to form, and minibatch noise spoils curvature estimates built from differences of gradients. Even so, the underlying ideas reappear throughout deep learning: the per-coordinate scaling of Adam acts as a diagonal stand-in for Newton's inverse Hessian (Section 35.5), and the damping added to curvature matrices plays the same stabilizing role as a trust region. The central result to keep in mind is the quadratic convergence of Newton's method Equation 35.19; the subsection on quasi-Newton methods may be skipped on a first reading. From Section 35.1, we carry over two ingredients: the Armijo condition for backtracking line search and the test function $\frac{1}{2}x^2 + \cos y$, whose saddle point stalled gradient descent.

35.2.1 Newton's Method

Gradient descent builds a linear approximation to f at the current point. Because a linear function has no minimum, the algorithm cannot choose its own step length and must rely on an external learning rate. A quadratic approximation, by contrast, has a unique minimum whenever it curves upward, giving us a step whose length is set automatically by the local geometry.

35.2.1.1 The Newton Step

Newton's method lets the local curvature determine both the direction and the length of the step (Section 9.1.5.1). Writing $\mathbf{g}_k = \nabla f(\mathbf{x}_k)$, we approximate f near $\mathbf{x}_k$ by its second-order Taylor expansion in the displacement $\mathbf{p}$:

$$m_k(\mathbf{p}) = f(\mathbf{x}_k) + \mathbf{g}_k^\top \mathbf{p} + \tfrac{1}{2}\,\mathbf{p}^\top \nabla^2 f(\mathbf{x}_k)\,\mathbf{p}. \tag{35.17}$$

When the Hessian $\nabla^2 f(\mathbf{x}_k)$ is positive definite, the model m_k is a strictly convex bowl with a unique minimizer, found by setting $\nabla m_k(\mathbf{p}) = \mathbf{g}_k + \nabla^2 f(\mathbf{x}_k)\,\mathbf{p} = \mathbf{0}$. Solving for $\mathbf{p}$ and moving there gives **Newton's method**:

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \left(\nabla^2 f(\mathbf{x}_k)\right)^{-1} \nabla f(\mathbf{x}_k). \tag{35.18}$$

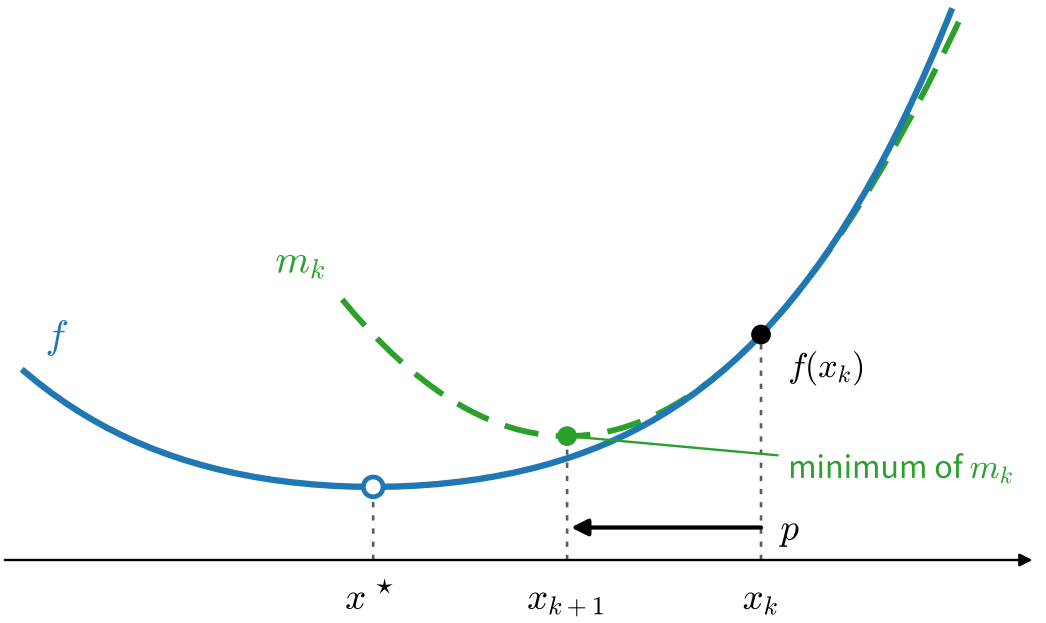

Figure 35.6: One Newton step on $f(x) = \frac{1}{4}x^4 + \frac{1}{2}x^2$ from $x_k = 1$. The model m_k (dashed) shares the value, slope and curvature of f at x_k, and the step p moves to the minimizer of the model, $x_{k+1} = \frac{1}{2}$. The minimizer of f is $x^\star = 0$.

Figure 35.6 shows one such step in one dimension. Notice that no step size appears in Equation 35.18: the inverse Hessian rescales each direction according to its curvature. More broadly, Newton's direction belongs to the family of preconditioned steps $\mathbf{d} = -\mathbf{P}^{-1}\nabla f$ with a positive definite matrix $\mathbf{P}$ (here $\mathbf{P} = \nabla^2 f$). Every such direction is a descent direction, since $\nabla f^\top \mathbf{d} = -\nabla f^\top \mathbf{P}^{-1} \nabla f < 0$. In fact, Newton's direction is simply the direction of steepest descent when step lengths are measured in the norm induced by the Hessian rather than the Euclidean norm (exercise 1).

On a positive definite quadratic $\frac{1}{2}\mathbf{x}^\top \mathbf{A}\mathbf{x}$, the Taylor model is exact, so a single Newton step lands immediately on the minimizer: $\mathbf{x}_1 = \mathbf{x}_0 - \mathbf{A}^{-1}\mathbf{A}\mathbf{x}_0 = \mathbf{0}$, regardless of the condition number κ. The reason goes deeper than matrix cancellation. Newton's method is **affine-invariant**, meaning that its trajectory does not depend on the choice of coordinates. Under any invertible linear change of variables $\mathbf{x} = \mathbf{T}\mathbf{y}$, running Newton's method on $f(\mathbf{T}\mathbf{y})$ produces the exact images of Newton's iterates for f. Gradient descent, by contrast, changes its

path under every non-orthogonal $\mathbf{T}$, while a scalar multiple of an orthogonal matrix merely rescales the effective step size (exercise 1). Because some linear transformation turns any positive definite quadratic into a perfect sphere, the condition number cannot affect Newton's method. A long valley is, to Newton's method, a round bowl drawn on stretched paper.

35.2.1.2 Quadratic Convergence

For a general non-quadratic objective, the Taylor model is only a local approximation, so one step is no longer enough. What survives is remarkable speed. Once the iterate enters a neighborhood of a minimizer, Newton's method converges much faster than geometrically, and the proof requires little more than the fundamental theorem of calculus. Let $\mathbf{e}_k = \mathbf{x}_k - \mathbf{x}^\star$ denote the error at iteration k.

Proposition (quadratic convergence). *Let $\nabla f(\mathbf{x}^\star) = \mathbf{0}$, and suppose that on a ball around $\mathbf{x}^\star$ the Hessian satisfies $\nabla^2 f(\mathbf{x}) \succeq \mu \mathbf{I}$ and $\|\nabla^2 f(\mathbf{x}) - \nabla^2 f(\mathbf{y})\| \le L_2 \|\mathbf{x} - \mathbf{y}\|$. If $\mathbf{x}_k$ lies in the ball, then*

$$\|\mathbf{e}_{k+1}\| \;\le\; \frac{L_2}{2\mu}\,\|\mathbf{e}_k\|^2. \tag{35.19}$$

Proof. Abbreviate $\nabla^2 f_k = \nabla^2 f(\mathbf{x}_k)$. Because $\nabla f(\mathbf{x}^\star) = \mathbf{0}$, subtracting $\mathbf{x}^\star$ from the Newton update yields $\mathbf{e}_{k+1} = \mathbf{e}_k - (\nabla^2 f_k)^{-1}\mathbf{g}_k = (\nabla^2 f_k)^{-1}\big[\nabla^2 f_k\,\mathbf{e}_k - (\nabla f(\mathbf{x}_k) - \nabla f(\mathbf{x}^\star))\big]$. Applying the fundamental theorem of calculus along the line segment from $\mathbf{x}^\star$ to $\mathbf{x}_k$ expresses the gradient difference as $\int_0^1 \nabla^2 f(\mathbf{x}^\star + t\mathbf{e}_k)\,\mathbf{e}_k\,dt$, so the bracketed term becomes $\int_0^1 \big[\nabla^2 f_k - \nabla^2 f(\mathbf{x}^\star + t\mathbf{e}_k)\big]\mathbf{e}_k\,dt$. Since $\mathbf{x}_k$ and $\mathbf{x}^\star + t\mathbf{e}_k$ are separated by $(1-t)\mathbf{e}_k$, the Lipschitz bound on the Hessian gives this integral norm at most $\int_0^1 L_2(1-t)\|\mathbf{e}_k\|^2\,dt = \tfrac{L_2}{2}\|\mathbf{e}_k\|^2$. Combining this with $\|(\nabla^2 f_k)^{-1}\| \le 1/\mu$ completes the proof. $\blacksquare$

To read what Equation 35.19 implies, multiply both sides by $L_2/(2\mu)$: $\tfrac{L_2}{2\mu}\|\mathbf{e}_{k+1}\| \le \big(\tfrac{L_2}{2\mu}\|\mathbf{e}_k\|\big)^2$. The scaled error squares at every step. If it starts below 1, it shrinks monotonically and every subsequent iterate remains in the ball. Once it drops below 0.1, it plunges to 10^{-2}, 10^{-4}, 10^{-8}, roughly doubling the number of accurate digits at each iteration. Compare that with gradient descent on our running example, which needs about $1{,}150$ steps to gain a single digit. The catch is written directly into the hypotheses: this quadratic rate is strictly local and guarantees nothing until the iterate is already close to $\mathbf{x}^\star$.

Far from $\mathbf{x}^\star$, the pure Newton step can overshoot even when the Hessian is positive definite. The standard safeguard is **damping**: update via $\mathbf{x}_k + \alpha_k \mathbf{p}_k$ along the Newton direction $\mathbf{p}_k = -(\nabla^2 f(\mathbf{x}_k))^{-1}\mathbf{g}_k$, choosing $\alpha_k \le 1$ by backtracking until the Armijo condition $f(\mathbf{x}_k + \alpha \mathbf{p}_k) \le f(\mathbf{x}_k) + c\,\alpha\,\mathbf{g}_k^\top \mathbf{p}_k$ holds (the general-direction form of the Armijo rule in Section 35.1). Near a minimizer with a positive definite Hessian, the full step $\alpha = 1$ automatically passes this test whenever $c < \tfrac{1}{2}$, so damping adds no overhead once quadratic convergence kicks in.

To test these predictions in code, we use ℓ_2-regularized logistic regression on $n = 200$ synthetic examples in $d = 5$ dimensions,

$$f(\mathbf{w}) = \frac{1}{n}\sum_{i=1}^{n} \log\left(1 + \exp(-y_i\, \mathbf{x}_i^{\top}\mathbf{w})\right) + \frac{\nu}{2}\|\mathbf{w}\|^2, \qquad \nu = 0.1,$$

with binary labels $y_i = \pm 1$ sampled from a logistic model (we write ν for the weight-decay coefficient to reserve λ for eigenvalues). The setup cell below also computes a reference optimum $\mathbf{w}^\star$ using $4{,}000$ gradient steps of size $\eta = 0.5$, which is safely below $2/L$ because $L = \lambda_{\max}(\mathbf{X}^{\top}\mathbf{X})/(4n) + \nu$ is roughly 0.4 here (exercise 2).

```
rng = np.random.default_rng()
n, d, nu = 200, 5, 0.1
w_true = np.array([1.0, -2.0, 1.5, 0.0, 2.0])
X = rng.normal(size=(n, d))
y = np.where(rng.random(n) < 1 / (1 + np.exp(-X @ w_true)), 1.0, -1.0)

def loss(w, X, y, nu):
    return np.logaddexp(0, -y * (X @ w)).mean() + nu / 2 * (w @ w)

def grad_rows(w, X, y, nu):                    # row i: gradient of example i
    s = 1 / (1 + np.exp(y * (X @ w)))          # sigmoid(-y_i x_i^T w)
    return -(y * s)[:, None] * X + nu * w

w_star = np.zeros(d)
for _ in range(4000):                          # full-batch reference optimum
    w_star = w_star - 0.5 * grad_rows(w_star, X, y, nu).mean(axis=0)
```

We can now test both predictions directly. On our running quadratic $\mathrm{diag}(1, 1000)$, a single Newton step should replace the $\log 10^6 / \log(1001/999) \approx 6{,}908$ steps required by gradient descent at its optimal fixed step size (Section 35.1.3). On the non-quadratic logistic loss, the exponent of the gradient norm should roughly double at every iteration once the local phase begins.

```
A2 = np.diag([1.0, 1000.0])                    # the running example, kappa = 1000
x = np.array([1.0, 1.0])
x_new = x - np.linalg.solve(A2, A2 @ x)        # one Newton step
rate = (1000 - 1) / (1000 + 1)
print(f'Newton on the quadratic: |x_1| = {np.linalg.norm(x_new):.1e} after one step')
print(f'GD at the optimal step contracts by {rate:.4f}; it needs '
      f'{int(np.ceil(np.log(1e-6) / np.log(rate)))} steps for |x_k| <= 1e-6 |x_0|')
w = np.zeros(d)                                # Newton on the logistic loss
for it in range(6):
    s = 1 / (1 + np.exp(y * (X @ w)))
    g = grad_rows(w, X, y, nu).mean(axis=0)
    hess = (X * (s * (1 - s))[:, None]).T @ X / n + nu * np.eye(d)
    w = w - np.linalg.solve(hess, g)
    print(f'Newton iteration {it + 1}:  |grad| = {np.linalg.norm(g):.1e}')
print(f'max |w - w_star| = {np.abs(w - w_star).max():.1e}')
```

```
Newton on the quadratic: |x_1| = 0.0e+00 after one step
GD at the optimal step contracts by 0.9980; it needs 6908 steps for |x_k| <= 1e-6 |x_0|
Newton iteration 1:  |grad| = 3.5e-01
Newton iteration 2:  |grad| = 4.1e-02
```

```
Newton iteration 3:  |grad| = 1.6e-03
Newton iteration 4:  |grad| = 3.0e-06
Newton iteration 5:  |grad| = 9.8e-12
Newton iteration 6:  |grad| = 2.5e-17
max |w - w_star| = 4.4e-16
```

Both predictions hold. On the quadratic, a single Newton step drives the error to zero, whereas optimal fixed-step gradient descent contracts by only 0.998 per step and requires $6{,}908$ iterations. On the logistic loss, the gradient norm starts at a few tenths and drops below 10^{-8} by the fifth iteration, its exponent roughly doubling once it becomes small. After just six iterations, Newton's iterate agrees with the reference optimum to roughly 10^{-15}, matching the precision of the reference itself. Six linear solves have accomplished what took $4{,}000$ gradient steps.

35.2.1.3 The Cost of a Step

Unfortunately, comparing iteration counts alone flatters Newton's method. The Hessian contains d^2 entries, and solving the linear system in Equation 35.18 generally requires $O(d^3)$ operations per step. For $d = 5$ this cost is negligible, but for a neural network with even a modest 10^8 parameters, the Hessian has 10^{16} entries, ruling out exact Newton's method before the first step is ever taken (Section 9.1.5.1). Practical alternatives either approximate the Hessian from gradients, as in the quasi-Newton methods below, or use cheap diagonal and structured preconditioners (Section 35.5).

35.2.1.4 Saddle Points

Computational cost is not the only drawback of Newton's method, nor is it the most instructive one. Because the Newton step solves $\nabla m_k = \mathbf{0}$, it jumps to the stationary point of the quadratic model whether that point is a minimum, a maximum, or a saddle. Return to the function $f(x, y) = \frac{1}{2}x^2 + \cos y$ from Section 35.1, which has a saddle at the origin and a minimum of -1 at $(0, \pi)$, and start at $(0.5, 0.3)$. Here the gradient is $(0.5, -\sin 0.3) = (0.5, -0.296)$, and the Hessian $\mathrm{diag}(1, -\cos 0.3) = \mathrm{diag}(1, -0.955)$ is indefinite: the surface curves upward along x and downward along y. Which way does a Newton step move y from this point, compared with a plain gradient step of size $\eta = 1$?

```
def f_s(v):
    return 0.5 * v[0]**2 + np.cos(v[1])

def grad_s(v):
    return np.array([v[0], -np.sin(v[1])])

def hess_s(v):
    return np.diag([1.0, -np.cos(v[1])])

x_n = x_g = np.array([0.5, 0.3])
ys_n, ys_g = [], []
for _ in range(6):
    x_n = x_n - np.linalg.solve(hess_s(x_n), grad_s(x_n))    # Newton
    x_g = x_g - 1.0 * grad_s(x_g)                            # GD, eta = 1
    ys_n.append(x_n[1])
    ys_g.append(x_g[1])
```

```
print('Newton y:', np.array(ys_n[:3]), f'  f = {f_s(x_n):.4f}')
print('GD     y:', np.array(ys_g).round(4), f'  f = {f_s(x_g):.4f}')
```

```
Newton y: [-9.33624961e-03  2.71275924e-07 -6.61744490e-21]   f = 1.0000
GD     y: [0.5955 1.1565 2.0718 2.9489 3.1404 3.1416]   f = -1.0000
```

Newton's first step sends x to 0 and y to $0.3 - \tan 0.3 = -0.0093$; the second sends y to 2.7×10^{-7}. We are seeing Newton's rapid local convergence (here even cubic, since $y - \tan y \approx -y^3/3$), driving the iterate straight into the saddle $(0, 0)$ with $f = 1$. Gradient descent moves y in the opposite direction, through 0.60, 1.16, 2.07, 2.95, 3.140, and 3.1416, reaching the minimum $(0, \pi)$ with $f = -1$. The richer model has led to the worse point. Because the curvature along y is negative, the stationary point of the quadratic model is a saddle, and Newton's method is blind to the difference between a saddle and a minimum. A trust region (Section 35.2.3) fixes this flaw.

35.2.2 Quasi-Newton Methods

Newton's method requires explicit second derivatives. Can we instead infer curvature from the gradients we are already computing? When the gradient changes rapidly along a step, the objective must have large curvature in that direction. An optimizer that records these changes can gradually assemble a model of the Hessian without ever evaluating a second derivative.

35.2.2.1 The Secant Method

In one dimension the idea is immediate: the slope of the chord connecting the last two gradients estimates f'',

$$h_k = \frac{f'(x_k) - f'(x_{k-1})}{x_k - x_{k-1}}, \qquad x_{k+1} = x_k - \frac{f'(x_k)}{h_k}.$$

This is the **secant method**, which is simply Newton's step with $f''(x_k)$ replaced by a finite difference of gradients. Consider $f(x) = e^x - 2x$, whose minimizer is $\log 2 \approx 0.6931$, starting from $x_0 = 0$ and $x_1 = 1$. The first secant slope is $h_1 = (e-2) - (1-2) = e - 1 \approx 1.718$, giving $x_2 = 1 - (e-2)/1.718 \approx 0.582$. From there the errors shrink as 1.1×10^{-1}, 1.6×10^{-2}, 9.3×10^{-4}, 7.7×10^{-6}, and 3.6×10^{-9}. Each error is roughly half the product of the previous two (the factor of one-half comes from $f'''/(2f'')$ at the minimizer), so the number of correct digits grows by a factor approaching 1.6 per step. That is slightly slower than Newton's factor of 2, yet each iteration requires only a single gradient evaluation and no second derivative. On a one-dimensional quadratic $\frac{\lambda}{2}x^2$, the secant slope equals λ exactly, and the step from x_1 lands directly on the minimizer.

In d dimensions, the analogous secant condition is a single vector equation, which is far from enough to pin down a $d \times d$ matrix: one step reveals curvature along one direction only. We need a principled rule to fill in the remaining directions.

35.2.2.2 BFGS

A **quasi-Newton** method maintains an approximation $\mathbf{M}_k$ to the inverse Hessian and updates it after each step using the observed change in the gradient. After moving from $\mathbf{x}_k$ to

$\mathbf{x}_{k+1}$, we record the secant pair

$$\mathbf{s}_k = \mathbf{x}_{k+1} - \mathbf{x}_k, \qquad \mathbf{y}_k = \nabla f(\mathbf{x}_{k+1}) - \nabla f(\mathbf{x}_k).$$

On a quadratic $\frac{1}{2}\mathbf{x}^\top \mathbf{A}\mathbf{x}$, the gradient difference satisfies $\mathbf{y}_k = \mathbf{A}\mathbf{s}_k$, so the true inverse Hessian maps $\mathbf{y}_k$ back to $\mathbf{s}_k$. We require the updated approximation $\mathbf{M}_{k+1}$ to obey the same **secant equation**:

$$\mathbf{M}_{k+1}\,\mathbf{y}_k = \mathbf{s}_k. \tag{35.20}$$

Among all symmetric matrices satisfying Equation 35.20, **BFGS** (named after Broyden, Fletcher, Goldfarb, and Shanno) chooses the one closest to the previous estimate $\mathbf{M}_k$ in a suitably weighted Frobenius norm:

$$\mathbf{M}_{k+1} = (\mathbf{I} - \gamma_k \mathbf{s}_k \mathbf{y}_k^\top)\,\mathbf{M}_k\,(\mathbf{I} - \gamma_k \mathbf{y}_k \mathbf{s}_k^\top) + \gamma_k \mathbf{s}_k \mathbf{s}_k^\top, \qquad \gamma_k = \frac{1}{\mathbf{y}_k^\top \mathbf{s}_k}. \tag{35.21}$$

Even without deriving Equation 35.21, we can read off how it works (dropping the index k on the pair for clarity). The right factor $\mathbf{I} - \gamma \mathbf{y}\mathbf{s}^\top$ sends $\mathbf{y}$ to zero, because $\gamma\,\mathbf{s}^\top\mathbf{y} = 1$, while leaving every vector orthogonal to $\mathbf{s}$ untouched. Thus the first term erases what $\mathbf{M}_k$ previously predicted along $\mathbf{y}$, and the second term writes in the new observation: $\mathbf{M}_{k+1}\mathbf{y} = \gamma\,\mathbf{s}\,(\mathbf{s}^\top\mathbf{y}) = \mathbf{s}$, satisfying the secant equation.

Just as importantly, the update preserves positive definiteness, ensuring that the next search direction $-\mathbf{M}_{k+1}\nabla f(\mathbf{x}_{k+1})$ remains a descent direction. For any nonzero vector $\mathbf{z}$, set $\mathbf{w} = (\mathbf{I} - \gamma \mathbf{y}\mathbf{s}^\top)\mathbf{z}$, so that $\mathbf{z}^\top \mathbf{M}_{k+1}\mathbf{z} = \mathbf{w}^\top \mathbf{M}_k \mathbf{w} + \gamma(\mathbf{s}^\top\mathbf{z})^2$. When $\mathbf{M}_k \succ 0$ and $\gamma > 0$, both terms are nonnegative and cannot vanish simultaneously: $\mathbf{w} = \mathbf{0}$ forces $\mathbf{z} = \gamma(\mathbf{s}^\top\mathbf{z})\,\mathbf{y}$, which requires $\mathbf{s}^\top\mathbf{z} \neq 0$. The requirement $\gamma > 0$ is the **curvature condition** $\mathbf{y}_k^\top \mathbf{s}_k > 0$, meaning that the directional slope increased along the step. It holds automatically on any strictly convex objective; on general objectives, the line search enforces it via a second check known as the Wolfe condition (Nocedal and Wright 2006).

How quickly do secant pairs reconstruct the true curvature? Let us run BFGS from $(1, 1)$ on the two-dimensional quadratic $\mathrm{diag}(1, 10)$, starting with $\mathbf{M}_0 = \mathbf{I}$ and using the exact line search $\alpha = -\mathbf{g}^\top\mathbf{p}/(\mathbf{p}^\top\mathbf{A}\mathbf{p})$, and inspect both $\mathbf{x}$ and $\mathbf{M}$ after each step.

```
def bfgs_update(M, s, y):
    gamma = 1.0 / (y @ s)
    V = np.eye(len(s)) - gamma * np.outer(s, y)
    return V @ M @ V.T + gamma * np.outer(s, s)

A = np.diag([1.0, 10.0])
x, M = np.array([1.0, 1.0]), np.eye(2)
for k in range(2):
    g = A @ x
    p = -M @ g
    alpha = -(g @ p) / (p @ A @ p)           # exact line search
    s = alpha * p
    M = bfgs_update(M, s, A @ s)             # y = A s on a quadratic
    x = x + s
```

```
        print(f'step {k + 1}: x = {x.round(4)},  M = {M.round(4).tolist()}')
    print(f'A^-1 = {np.linalg.inv(A).tolist()},  '
          f'max |M_2 - A^-1| = {np.abs(M - np.linalg.inv(A)).max():.0e}')
```

```
step 1: x = [ 0.8991 -0.009 ],  M = [[1.009, -0.0001], [-0.0001, 0.1]]
step 2: x = [0. 0.],  M = [[1.0, -0.0], [-0.0, 0.1]]
A^-1 = [[1.0, 0.0], [0.0, 0.1]],  max |M_2 - A^-1| = 1e-16
```

After a single step, $\mathbf{M}_1 \approx \operatorname{diag}(1.009, 0.100)$ is already close to $\mathbf{A}^{-1}$ along the steep direction it has just probed. After the second step, $\mathbf{M}_2 = \mathbf{A}^{-1}$ up to floating-point rounding and $\mathbf{x}_2 = \mathbf{0}$. This two-dimensional behavior generalizes cleanly: on any d-dimensional positive definite quadratic with exact line searches, each secant equation remains satisfied after subsequent updates, and the steps are mutually $\mathbf{A}$-conjugate ($\mathbf{s}_i^\top \mathbf{A}\mathbf{s}_j = 0$ for $i \neq j$). After d steps, $\mathbf{M}_d\mathbf{A} = \mathbf{I}$ and BFGS reaches the exact minimizer (exercise 2).

Finite termination, however, holds specifically for quadratics with exact line searches and should not be taken as a general guarantee. On non-quadratic objectives, line searches are inexact, the true Hessian varies from step to step, and stochastic gradients corrupt $\mathbf{y}_k$: the difference between two minibatch gradients is often dominated by sampling noise rather than curvature. In addition, full BFGS stores a dense $d \times d$ matrix. **L-BFGS** avoids that memory cost by retaining only the m most recent secant pairs and applying the resulting inverse-Hessian approximation (a scaled identity plus a correction of rank at most $2m$) in $O(md)$ time and memory (Liu and Nocedal 1989). It works very well on deterministic, medium-scale problems, though it remains awkward when fresh minibatch noise makes gradient differences unreliable.

35.2.3 Trust Regions

Newton's method went astray at $(0.5, 0.3)$ because it trusted its local quadratic model across the entire space. That model was built from derivatives at a single point and accurately reflects f only nearby. A trust-region method takes this limitation literally: it keeps the full curvature information, including directions of negative curvature, and instead bounds the step to a region where the model can be trusted.

35.2.3.1 The Subproblem

At $(0.5, 0.3)$, the quadratic model of $\frac{1}{2}x^2 + \cos y$ has curvature -0.955 along y. Because it curves downward without bound, asking for its unconstrained minimum makes no sense. A **trust-region method** instead minimizes the quadratic model inside a ball of radius Δ_k, which represents how far we believe the approximation holds:

$$\min_{\|\mathbf{p}\| \le \Delta_k} m_k(\mathbf{p}) = f(\mathbf{x}_k) + \nabla f(\mathbf{x}_k)^\top \mathbf{p} + \tfrac{1}{2}\mathbf{p}^\top \mathbf{B}_k \mathbf{p}. \tag{35.22}$$

Here $\mathbf{B}_k$ is either the exact Hessian or a symmetric approximation to it. Restricting $\mathbf{p}$ to a closed ball guarantees that a minimizer exists even when $\mathbf{B}_k$ has negative eigenvalues, because any continuous function achieves a minimum on a compact set. Better still, the exact solutions of this constrained problem have a clean characterization.

Proposition (solution of the subproblem). *A step $\mathbf{p}$ with $\|\mathbf{p}\| \le \Delta$ solves Equation 35.22 if and only if there is a $\tau \ge 0$ with*

$$(\mathbf{B} + \tau \mathbf{I})\,\mathbf{p} = -\mathbf{g}, \qquad \mathbf{B} + \tau \mathbf{I} \succeq \mathbf{0}, \qquad \tau\,(\Delta - \|\mathbf{p}\|) = 0.$$

This result is Theorem 4.1 of Nocedal and Wright (2006); exercise 3 proves the sufficiency of these conditions. Geometrically, the trust region adds a uniform shift τ to every eigenvalue of $\mathbf{B}$, just enough to make the shifted quadratic convex. Two cases arise. When $\mathbf{B}$ is positive definite and the unconstrained Newton step already lies inside the ball, we have $\tau = 0$ and simply take the Newton step. Otherwise the solution lies on the boundary $\|\mathbf{p}\| = \Delta$, and τ is the root of the scalar equation $\|(\mathbf{B} + \tau \mathbf{I})^{-1}\mathbf{g}\| = \Delta$ over $\tau > -\lambda_{\min}(\mathbf{B})$, where the left-hand side decreases strictly as τ grows.

This scalar equation fails to have a root only in the degenerate *hard case*, when $\mathbf{g}$ is orthogonal to the eigenvectors associated with the smallest eigenvalue of $\mathbf{B}$ (explored in part d of exercise 3). As we will see in Section 35.6, the shift τ is simply the Lagrange multiplier enforcing the constraint $\tfrac{1}{2}\|\mathbf{p}\|^2 \le \tfrac{1}{2}\Delta^2$.

Between iterations, the radius Δ_k adapts according to how accurately the model predicted the actual drop in f. After solving Equation 35.22, we form the ratio of actual decrease to predicted decrease:

$$r_k = \frac{f(\mathbf{x}_k) - f(\mathbf{x}_k + \mathbf{p}_k)}{m_k(\mathbf{0}) - m_k(\mathbf{p}_k)}. \tag{35.23}$$

A ratio near 1 indicates that the quadratic model matched the objective well. In the implementation below, we accept the step whenever $r_k > 0.1$. Independently, we shrink the radius to $\Delta \leftarrow \Delta/4$ whenever $r_k < \tfrac{1}{4}$, and we double it when $r_k > \tfrac{3}{4}$ and the step hit the boundary $\|\mathbf{p}_k\| = \Delta_k$.

35.2.3.2 The Trust-Region Step at a Saddle

Let us work out one trust-region step at $(0.5, 0.3)$ by hand with $\Delta = 0.5$. At this point $\mathbf{g} = (0.5, -0.296)$ and $\mathbf{B} = \mathrm{diag}(1, -0.955)$. Making $\mathbf{B} + \tau\mathbf{I}$ positive semidefinite requires $\tau \ge 0.955$, so $\tau = 0$ is impossible and the step must lie on the boundary of the ball. The optimality system gives $(1+\tau)p_1 = -0.5$ and $(\tau - 0.955)p_2 = 0.296$ subject to $p_1^2 + p_2^2 = 0.25$, whose solution is $\tau \approx 1.60$ and $\mathbf{p} \approx (-0.19, 0.46)$. Moving to $(0.31, 0.76)$ lowers f from 1.080 to 0.771. Because the model predicted a decrease of 0.316 and the actual decrease is 0.309, the ratio is $r = 0.98$, so the step is accepted and the radius doubles. Crucially, the trust-region step moves *away* from the saddle along the negative-curvature direction where the model drops, whereas the unconstrained Newton step $(-0.5, -0.31)$ marched straight toward it.

To see where this subproblem solution leads over several iterations, we first implement `tr_step(g, B, Delta)`, which returns the unconstrained Newton step when $\mathbf{B} \succ \mathbf{0}$ and $\|\mathbf{B}^{-1}\mathbf{g}\| \le \Delta$, and otherwise bisects on τ until $\|(\mathbf{B} + \tau\mathbf{I})^{-1}\mathbf{g}\| = \Delta$:

```
def tr_step(g, B, Delta):
    """Minimize g p + p B p / 2 over |p| <= Delta; return (p, tau)."""
    eig_min = np.linalg.eigvalsh(B).min()
    if eig_min > 0 and np.linalg.norm(np.linalg.solve(B, -g)) <= Delta:
        return np.linalg.solve(B, -g), 0.0     # Newton step fits: tau = 0
    lo = hi = max(0.0, -eig_min)
```

```
        hi += 1e3
        for _ in range(100):                        # bisection for |p(tau)| = Delta
            tau = (lo + hi) / 2
            p = np.linalg.solve(B + tau * np.eye(len(g)), -g)
            lo, hi = (tau, hi) if np.linalg.norm(p) > Delta else (lo, tau)
        return p, tau
```

Starting from $\mathbf{x} = (0.5, 0.3)$ with $\Delta = 0.5$, we now run six trust-region iterations on f_s, printing the iterate, objective value, step norm $\|\mathbf{p}\|$, shift τ, agreement ratio r, and radius Δ at each step:

```
x, Delta = np.array([0.5, 0.3]), 0.5
print(' k        x            f      |p|    tau      r  Delta')
for k in range(6):
    g, B = grad_s(x), hess_s(x)
    p, tau = tr_step(g, B, Delta)
    r = (f_s(x) - f_s(x + p)) / -(g @ p + 0.5 * p @ B @ p)
    print(f'{k:2d} ({x[0]:6.3f},{x[1]:6.3f}) {f_s(x):7.4f} '
          f'{np.linalg.norm(p):6.3f} {tau:6.3f} {r:6.2f} {Delta:5.2f}')
    if r > 0.1:                                     # accept the step
        x = x + p
    if r < 0.25:
        Delta /= 4                                  # poor prediction: shrink
    elif r > 0.75 and np.linalg.norm(p) > 0.99 * Delta:
        Delta *= 2                                  # good, and on the boundary
print(f'final x = ({x[0]:.4f}, {x[1]:.4f}),  f = {f_s(x):.4f}')
```

```
 k        x            f      |p|    tau      r  Delta
 0 ( 0.500, 0.300)  1.0803  0.500  1.596   0.98  0.50
 1 ( 0.307, 0.761)  0.7711  1.000  1.419   0.87  1.00
 2 ( 0.180, 1.753) -0.1652  2.000  0.311   0.41  2.00
 3 ( 0.043, 3.749) -0.8205  0.696  0.000   0.88  2.00
 4 ( 0.000, 3.054) -0.9962  0.088  0.000   1.00  2.00
 5 ( 0.000, 3.142) -1.0000  0.000  0.000   1.00  2.00
final x = (0.0000, 3.1416),  f = -1.0000
```

The first row matches our hand calculation. The radius doubles from 0.5 to 1 and then to 2, while the third step (with ratio 0.41) is accepted without changing the radius. By the fourth iterate, $(0.04, 3.75)$, the algorithm has entered the basin where the Hessian is positive definite. From that point on, the unconstrained Newton step fits inside the trust-region ball with $\tau = 0$, so the method seamlessly turns into Newton's method and converges quadratically to the minimum $(0, \pi)$ with $f = -1$. Six iterations are enough; Figure 35.7 contrasts both trajectories.

Solving the trust-region subproblem exactly requires factoring $\mathbf{B}_k + \tau \mathbf{I}$ for each trial value of τ. Large-scale implementations instead solve it approximately using Hessian–vector products, each costing roughly the same as a single gradient evaluation (Section 34.5). Even with that speedup, neither BFGS nor trust-region methods replace stochastic gradient descent on large, noisy deep learning objectives.

The saddle of $\frac{1}{2}x^2 + \cos y$ has now tripped up two optimizers: gradient descent stalled at it from a start on the line $y = 0$, and Newton's method ran straight into it from a generic one. A trust region escapes, but only by checking each local model against the true objective. Yet

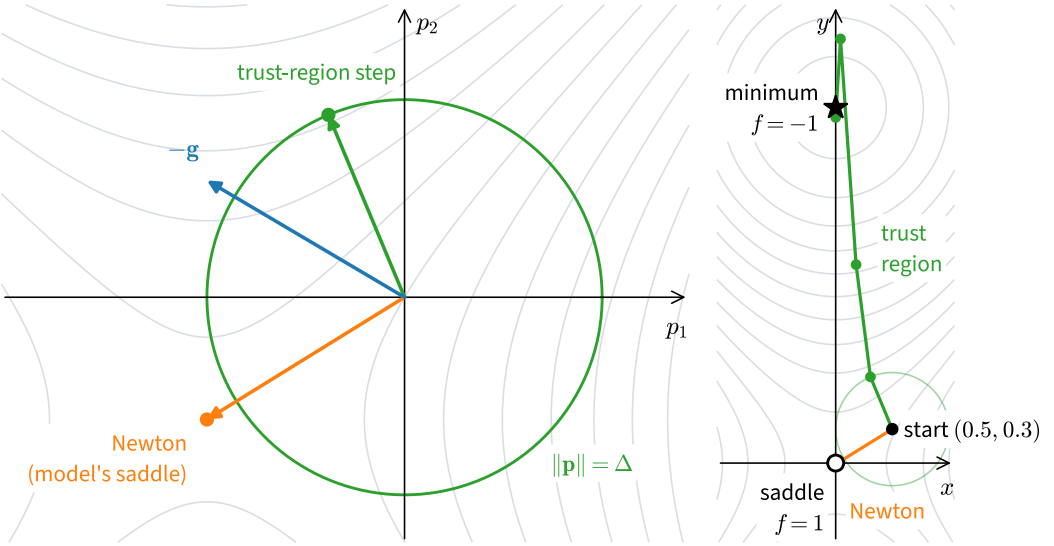

Figure 35.7: Newton's method and a trust-region method from $(0.5, 0.3)$ on $\frac{1}{2}x^2 + \cos y$, where the Hessian is $\mathrm{diag}(1, -0.96)$. (a) The local quadratic model forms a saddle surface: Newton's step moves to its stationary point, whereas minimizing the model over the ball of radius $\Delta = 0.5$ follows the negative-curvature direction away from the saddle. (b) Newton's method converges quadratically to the saddle $(0, 0)$ with $f = 1$, while the trust-region method (shown with its initial radius) reaches the minimum $(0, \pi)$ with $f = -1$ in six steps as its radius expands through $0.5, 1, 2$.

there is a large class of functions where none of these precautions are needed: functions with no saddles, no spurious basins, and where every stationary point is a global minimum. Identifying those functions is the subject of Section 35.3.

35.2.4 Summary

Newton's method minimizes a local quadratic model of f at each iterate. It solves any positive definite quadratic in a single step regardless of the condition number, and near a minimizer with a positive definite, Lipschitz-continuous Hessian it squares the error at every iteration. That speed comes with two obstacles: each step requires $O(d^2)$ memory and $O(d^3)$ operations, far beyond what a neural network can afford, and the unconstrained step is attracted to saddle points just as strongly as to minima. BFGS avoids explicit second derivatives by reconstructing the inverse Hessian from past step and gradient differences, recovering it completely in d steps on a d-dimensional quadratic. Trust-region methods make any quadratic model safe to use by confining each step to a ball, comparing the predicted and actual decreases in f, and expanding or shrinking the ball accordingly.

35.2.5 Exercises

1. **Reparametrization and preconditioning.** Let $\mathbf{T}$ be an invertible matrix and $h(\mathbf{y}) = f(\mathbf{T}\mathbf{y})$, so that $\mathbf{x} = \mathbf{T}\mathbf{y}$ is a change of coordinates.
   1. Express ∇h and $\nabla^2 h$ through the derivatives of f. Show that Newton's iterates Equation 35.18 for h, started at $\mathbf{y}_0 = \mathbf{T}^{-1}\mathbf{x}_0$, satisfy $\mathbf{y}_k = \mathbf{T}^{-1}\mathbf{x}_k$, where $\mathbf{x}_k$ are Newton's iterates for f.
   2. Run gradient descent with step η on h and map every iterate back by $\mathbf{x}_k = \mathbf{T}\mathbf{y}_k$. Show that the mapped iterates follow $\mathbf{x}_{k+1} = \mathbf{x}_k - \eta\,\mathbf{P}^{-1}\nabla f(\mathbf{x}_k)$ for a positive definite matrix $\mathbf{P}$, and find $\mathbf{P}$. By problem 1b this direction is the steepest one in the norm $\|\cdot\|_{\mathbf{P}}$. What is $\|\mathbf{x}\|_{\mathbf{P}}$ in the coordinates $\mathbf{y}$?
   3. For $f(\mathbf{x}) = \frac{1}{2}\mathbf{x}^\top \mathbf{A}\,\mathbf{x}$ with $\mathbf{A} = \operatorname{diag}(1, 1000)$, the $\kappa = 1000$ quadratic of the Newton subsection, find a diagonal $\mathbf{T}$ for which gradient descent on h with $\eta = 1$ reaches the minimizer in one step. What does constructing such a $\mathbf{T}$ require for a general positive definite $\mathbf{A}$?
2. code **BFGS on a quadratic.** ● Let $f(\mathbf{x}) = \frac{1}{2}\mathbf{x}^\top \mathbf{A}\mathbf{x} - \mathbf{b}^\top \mathbf{x}$ with $\mathbf{A}$ positive definite, and run BFGS Equation 35.21 with exact line searches from $\mathbf{M}_0 = \mathbf{I}$.
   1. Show that an exact line search along $\mathbf{p}_k$ gives $\nabla f(\mathbf{x}_{k+1})^\top \mathbf{p}_k = 0$, and that $\mathbf{y}_k = \mathbf{A}\mathbf{s}_k$.
   2. Show the hereditary property: if $\mathbf{M}_k \mathbf{y}_j = \mathbf{s}_j$ for all $j < k$ and the steps $\mathbf{s}_0, \dots, \mathbf{s}_{k-1}$, $\mathbf{s}_k$ are $\mathbf{A}$-conjugate, then $\mathbf{M}_{k+1}\mathbf{y}_j = \mathbf{s}_j$ for all $j \le k$. (Hint: $\mathbf{s}_j^\top \mathbf{y}_k = \mathbf{s}_j^\top \mathbf{A}\mathbf{s}_k = 0$ for $j < k$.) Conclude that after d linearly independent steps $\mathbf{M}_d\mathbf{A} = \mathbf{I}$.
   3. Run the BFGS loop of the text in $d = 6$ dimensions, on a randomly rotated quadratic with eigenvalues from 1 to 1000. Print $\max_{j \le k} \|\mathbf{M}_{k+1}\mathbf{y}_j - \mathbf{s}_j\|$ after each step, and confirm that it stays at rounding level and that $\mathbf{M}_6 = \mathbf{A}^{-1}$. How far from the minimizer is gradient descent at its best fixed step after the same six gradients?
   4. The symmetric rank-one update $\mathbf{M}_{k+1} = \mathbf{M}_k + \frac{(\mathbf{s} - \mathbf{M}_k\mathbf{y})(\mathbf{s} - \mathbf{M}_k\mathbf{y})^\top}{(\mathbf{s} - \mathbf{M}_k\mathbf{y})^\top \mathbf{y}}$ also satisfies the secant equation. Show by a 2×2 example that it need not stay positive definite even when $\mathbf{y}^\top \mathbf{s} > 0$, and say which of the two checks in the text fails for it.
3. code **Trust region at a saddle.** ● Consider the model $m(\mathbf{p}) = \mathbf{g}^\top \mathbf{p} + \frac{1}{2}\mathbf{p}^\top \mathbf{B}\mathbf{p}$ with

$\mathbf{B} = \operatorname{diag}(1, -1)$ and $\mathbf{g} = (\frac{1}{2}, -\frac{3}{10})$.

1. Show that m is unbounded below on $\mathbb{R}^2$ and that the Newton point $-\mathbf{B}^{-1}\mathbf{g} = (-\frac{1}{2}, -\frac{3}{10})$ is a saddle of m, not a minimum.
2. Prove that the conditions of the subproblem proposition are sufficient: if $(\mathbf{B} + \tau\mathbf{I})\mathbf{p} = -\mathbf{g}$ with $\tau \geq 0$, $\mathbf{B} + \tau\mathbf{I} \succeq \mathbf{0}$, and $\tau(\Delta - \|\mathbf{p}\|) = 0$, then every $\|\mathbf{q}\| \leq \Delta$ satisfies $m(\mathbf{q}) \geq m(\mathbf{p}) + \frac{\tau}{2}(\|\mathbf{p}\|^2 - \|\mathbf{q}\|^2) \geq m(\mathbf{p})$. (Hint: expand $m(\mathbf{q}) - m(\mathbf{p})$ around $\mathbf{p}$ and use $\mathbf{g} = -(\mathbf{B} + \tau\mathbf{I})\mathbf{p}$.)
3. For $\Delta = \frac{1}{2}$ find $\tau \geq 1$ by bisection on $\|(\mathbf{B} + \tau\mathbf{I})^{-1}\mathbf{g}\| = \Delta$ (the answer is $\tau \approx 1.65$, $\mathbf{p} \approx (-0.19, 0.46)$), and check that the step increases the coordinate with negative curvature while the Newton step decreases it.
4. Replace $\mathbf{g}$ by $(\frac{1}{2}, 0)$. Show that $\|(\mathbf{B}+\tau\mathbf{I})^{-1}\mathbf{g}\| = \frac{1}{2}/(1+\tau) \leq \frac{1}{4}$ for all $\tau > 1$, so the boundary equation has no solution with $\tau > 1$. Find the minimizers on the ball directly (they have $\tau = 1$ and $p_2 = \pm\sqrt{\Delta^2 - p_1^2}$), and explain in one sentence what the ball does with a direction of negative curvature that the gradient does not see.

35.3 Convexity

When a training run finishes, we usually know only one thing about the point where it stopped: the loss no longer decreases there. Gradient descent with a safe step size reliably reaches such a point, where the gradient is nearly zero (Section 35.1), and Newton's method gets there faster, even when the stationary point turns out to be a saddle (Section 35.2). Neither guarantee tells us whether a much better point is hiding somewhere else. In this section we ask when a stationary point is actually the best point available, and how quickly gradient descent converges to it.

A simple one-dimensional experiment shows that this is not an idle question. Suppose we run the exact same gradient-descent loop from 500 random starting points, first on the bowl $f(x) = (x - \frac{1}{2})^2$ and then on the tilted double well $\phi(x) = (x^2 - 1)^2 + x/2$. On the bowl, every single run lands at the same minimizer. On the double well, nearly half of the runs get trapped in a shallower valley whose loss sits almost a full unit above the global minimum. Those stranded runs still have zero gradient—which is all that a stationarity guarantee promises—and looking at the gradient alone gives no hint that a deeper valley exists nearby.

The difference between the two functions comes down to a single geometric property. Every chord drawn between two points on the bowl lies above its graph, whereas the double well has chords that cut below the curve. Functions whose chords always lie on or above their graph are called *convex*, and for them our opening question has the cleanest possible answer: every local minimum is a global minimum. The proof takes just three lines (Section 35.3.2.2). Underneath it lies an even more useful fact: any tangent line to a convex function stays below the graph across the entire domain, so local information at a single point constrains the function everywhere. Summing this tangent bound along the iterates of gradient descent yields convergence rates that hold from any starting point. Averaging it over a random variable yields Jensen's inequality, a workhorse of the probability and information-theory chapters.

We cover a fair amount of ground here, and not every result carries the same weight. Three ideas are worth keeping at your fingertips: the tangent lower bound, the fact that local minima are global, and the linear convergence rate of gradient descent—whose proof relies on

a single inequality that survives even when convexity fails. We begin with convex sets and three equivalent tests for convex functions, derive their main consequences, and assemble a short calculus for recognizing convex losses. Since deep-network losses are not convex, we close by asking which parts of the theory carry over to them. If you are in a hurry, you can read the chord and tangent conditions in Section 35.3.2 and jump straight to Section 35.3.3. Two examples will accompany us throughout: the chapter's running quadratic $\frac{1}{2}(x_1^2 + 1000\, x_2^2)$ for measuring convergence rates, and the double well ϕ, which fails every test of convexity we throw at it.

35.3.1 Convex Sets

Because convex functions are defined along line segments between points of their domain, we start with the sets those points live in. The domain of a loss, the feasible region of a constrained problem, and the set of all minimizers are all sets. Fortunately, we need only a short toolkit: one definition, three standard families of examples, and one rule for building new convex sets from old ones.

35.3.1.1 Definition and Examples

Geometrically, a set is convex if the straight line segment connecting any two of its points stays entirely inside the set. Formally, a set $C \subseteq \mathbb{R}^d$ of d-dimensional points is **convex** if

$$\theta \mathbf{x} + (1-\theta)\,\mathbf{y} \in C \qquad \text{for all } \mathbf{x}, \mathbf{y} \in C \text{ and all } \theta \in [0,1]. \tag{35.24}$$

As θ moves from 1 to 0, the combination $\theta\mathbf{x}+(1-\theta)\mathbf{y}$ sweeps out the line segment from $\mathbf{x}$ to $\mathbf{y}$. Figure 35.8 contrasts a convex set with a nonconvex crescent and illustrates the two convex sets that appear most often in deep learning: the probability simplex and a half-space.

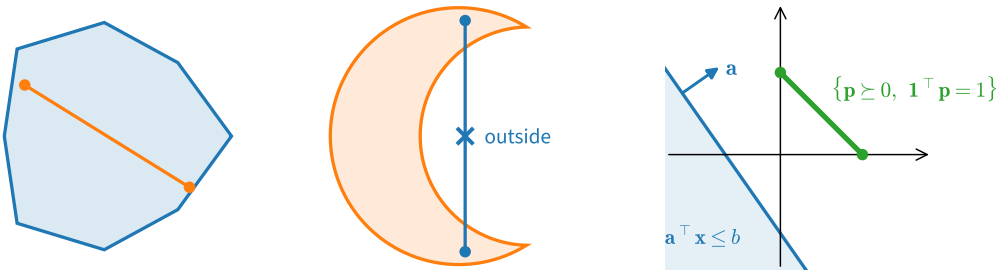

Figure 35.8: Convex versus nonconvex sets. Left: a convex set, where the segment between any two points stays inside. Middle: a nonconvex crescent, where a chord between two of its points passes outside the set. Right: the probability simplex $\{\mathbf{p} \succeq 0,\ \mathbf{1}^\top \mathbf{p} = 1\}$ and a half-space $\{\mathbf{x} : \mathbf{a}^\top \mathbf{x} \le b\}$, both convex.

To see what the definition rules out, consider the annulus $\{\mathbf{x} : 1 \le \|\mathbf{x}\| \le 2\}$. It contains both $(\frac{3}{2}, 0)$ and $(-\frac{3}{2}, 0)$, yet their midpoint is the origin, which lies in the hole. A single missing midpoint is enough to violate Equation 35.24.

Three families of convex sets cover almost everything we meet in this chapter. First, any hyperplane $\{\mathbf{x} : \mathbf{a}^\top \mathbf{x} = b\}$ and any half-space $\{\mathbf{x} : \mathbf{a}^\top \mathbf{x} \le b\}$ are convex because $\mathbf{a}^\top \mathbf{x}$

is linear: a weighted average of two numbers equal to b (or at most b) is again equal to b (or at most b). Second, any norm ball $\{\mathbf{x} : \|\mathbf{x}\| \le r\}$ is convex by the triangle inequality and homogeneity, $\|\theta\mathbf{x} + (1-\theta)\mathbf{y}\| \le \theta\|\mathbf{x}\| + (1-\theta)\|\mathbf{y}\| \le r$. This single check covers both the ℓ_2 balls of weight decay and gradient clipping and the ℓ_1 balls of sparsity-inducing regularization. Third is the probability simplex $\Delta = \{\mathbf{p} \in \mathbb{R}^d : \mathbf{p} \succeq 0,\ \mathbf{1}^\top \mathbf{p} = 1\}$, where $\mathbf{p} \succeq 0$ means every entry is nonnegative. Attention weights, class probabilities, and mixture weights all live on Δ, and its convexity follows immediately from our next rule.

35.3.1.2 New Convex Sets from Old

The intersection of any collection of convex sets, finite or infinite, is always convex. If two points lie in the intersection, then they lie in every set of the collection, so the segment between them stays inside every set and therefore inside the intersection. Intuitively, a convex set has no dents, and carving a dent-free set with another dent-free set cannot create one. Unions, by contrast, have no such guarantee: $[0,1] \cup [2,3]$ is a union of two convex intervals, yet the segment from 1 to 2 leaves the set.

This single intersection rule certifies two central sets at once. The probability simplex is the intersection of one hyperplane ($\mathbf{1}^\top \mathbf{p} = 1$) with d half-spaces ($-p_i \le 0$), so it is convex. Likewise, the set of symmetric positive semidefinite (PSD) matrices is convex because it is an intersection of infinitely many half-spaces: for each fixed vector $\mathbf{z}$, the constraint $\mathbf{z}^\top \mathbf{A}\mathbf{z} \ge 0$ is a single linear inequality in the entries of $\mathbf{A}$.

We can also build a convex set from the inside out. The **convex hull** of a set S is the collection of all weighted averages $\sum_i \theta_i \mathbf{x}_i$ of points $\mathbf{x}_i \in S$ with $\theta_i \ge 0$ and $\sum_i \theta_i = 1$. It is convex, and in fact it is the smallest convex set containing S (Exercise 2). Seen this way, the probability simplex is simply the convex hull of the standard basis vectors $\mathbf{e}_1, \dots, \mathbf{e}_d$: every probability distribution is a weighted average of certainties.

35.3.2 Convex Functions

Just as a convex set has no dents, a convex function is one whose graph curves upward without ever dipping into a second valley. We now develop three equivalent tests for convexity—requiring zero, one, and two derivatives respectively—followed by two refinements: strong convexity, which governs how fast gradient descent converges, and subgradients, which handle losses with corners. If you remember only one of the three tests, make it the second: the tangent lower bound is the engine behind almost every proof in this section.

35.3.2.1 The Chord Condition

The first test needs no derivatives at all, which means it applies just as easily to the absolute value and the hinge loss as to smooth objectives. A function $f : C \to \mathbb{R}$ on a convex domain C is **convex** if its graph lies on or below every chord joining two of its points:

$$f\left(\theta\mathbf{x} + (1-\theta)\,\mathbf{y}\right) \;\le\; \theta f(\mathbf{x}) + (1-\theta) f(\mathbf{y}) \qquad \text{for all } \mathbf{x}, \mathbf{y} \in C,\ \theta \in [0,1]. \tag{35.25}$$

Here the left side evaluates f at a point on the segment between $\mathbf{x}$ and $\mathbf{y}$, while the right side gives the height of the straight chord joining $(\mathbf{x}, f(\mathbf{x}))$ to $(\mathbf{y}, f(\mathbf{y}))$ directly above that point. Let us check a concrete case: for $f(x) = x^2$ with $x = 0$, $y = 2$, and $\theta = \tfrac{1}{2}$, the graph sits at $f(1) = 1$ while the chord sits at $\tfrac{1}{2}\cdot 0 + \tfrac{1}{2}\cdot 4 = 2$, and indeed $1 \le 2$. For arbitrary x, y, and θ, expanding the squares shows that the height gap between chord and graph is

$$\theta x^2 + (1-\theta)y^2 - \big(\theta x + (1-\theta)y\big)^2 = \theta(1-\theta)(x-y)^2 \;\geq\; 0.$$

Thus x^2 is convex, with a gap that grows quadratically with the separation between the two points. We will meet this exact expression again shortly as the variance in Jensen's inequality.

Two nearby notions are worth naming right away. If the inequality Equation 35.25 is strict whenever $\mathbf{x} \neq \mathbf{y}$ and $\theta \in (0,1)$, we call f **strictly convex**; if $-f$ is convex, we call f **concave**. Notice that a linear function $f(x) = x$ is convex (and concave) but not strictly convex, because every chord lies directly on its graph. Notice also why the domain C must be convex: without that requirement, the intermediate point $\theta\mathbf{x} + (1-\theta)\mathbf{y}$ might not even belong to the domain where f is defined.

Convex functions and convex sets are two sides of the same geometric coin. The **epigraph** of f is the region on and above its graph, $\{(\mathbf{x}, t) : t \geq f(\mathbf{x})\}$. A function f is convex if and only if its epigraph is a convex set, because a chord between two points of the epigraph stays above the graph precisely when Equation 35.25 holds. Convexity also passes from functions to sets via their **sublevel sets** $\{\mathbf{x} \in C : f(\mathbf{x}) \leq c\}$: if $f(\mathbf{x}) \leq c$ and $f(\mathbf{y}) \leq c$, the chord inequality immediately gives $f(\theta\mathbf{x} + (1-\theta)\mathbf{y}) \leq \theta c + (1-\theta)c = c$. This is why any inequality constraint $g(\mathbf{x}) \leq 0$ with a convex g automatically carves out a convex feasible region. Figure 35.9(a) shows both sets for a parabola.

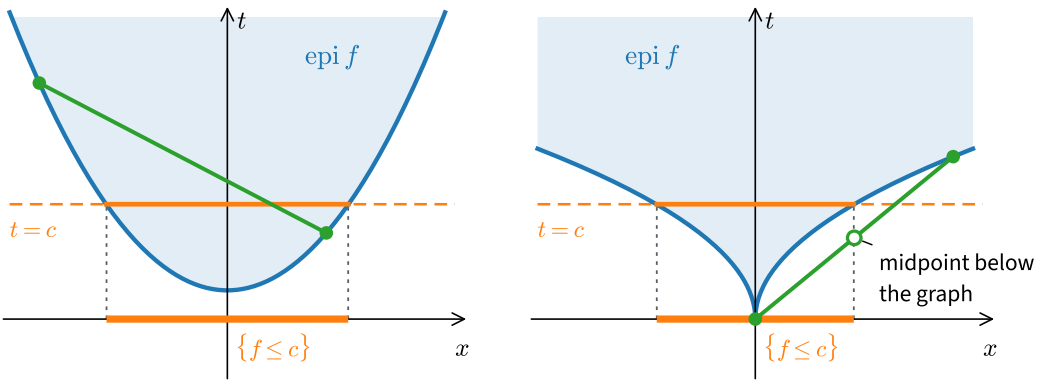

Figure 35.9: Epigraphs and sublevel sets. (a) The epigraph of the convex function $f(x) = \frac{1}{2}x^2 + \frac{1}{4}$ (shaded, continuing upward without bound) is a convex set, so the chord between any two of its points stays inside it. Cutting the epigraph at height c and projecting onto the x-axis gives the sublevel set $\{f \leq c\}$. (b) Every sublevel set of $f(x) = \sqrt{|x|}$ is an interval, yet the epigraph is not convex: the midpoint of the chord lies below the graph.

Be careful, though: the converse does not hold. Every sublevel set of $f(x) = \sqrt{|x|}$ is a convex interval $\{|x| \leq c^2\}$, yet f itself is not convex. At $x = 0$, $y = 1$, and $\theta = \frac{1}{2}$, the graph sits at $\sqrt{1/2} \approx 0.71$ while the chord sits below it at 0.5 (Figure 35.9(b)).

35.3.2.2 Local Minima Are Global

Remarkably, the chord condition alone is already enough to answer the question we posed at the opening. Figure 35.10 contrasts the two landscapes: a single basin on a convex objective

versus two competing basins on the double well.

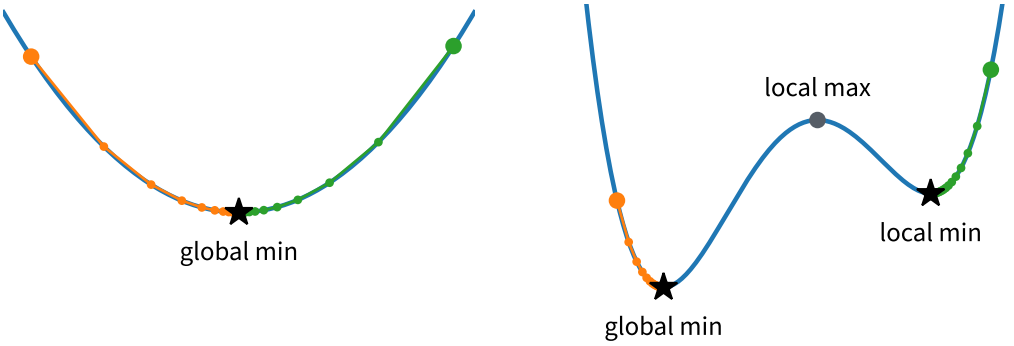

Figure 35.10: (a) On a convex objective, gradient descent with a small fixed step reaches the global minimizer from either start. (b) On a double well, the same update from different starts reaches different minima; the basins meet at the local maximum.

Proposition (local minima are global). *If f is convex on a convex set C, every local minimizer of f on C is a global minimizer.*

Proof. Let $\mathbf{x}^\star$ be a local minimizer and let $\mathbf{y} \in C$ be any other point. For sufficiently small $\theta > 0$, the point $\mathbf{z}_\theta = (1-\theta)\mathbf{x}^\star + \theta\mathbf{y}$ along the segment toward $\mathbf{y}$ falls inside the neighborhood where $\mathbf{x}^\star$ is minimal. Combining local minimality with the chord inequality gives

$$f(\mathbf{x}^\star) \;\le\; f(\mathbf{z}_\theta) \;\le\; (1-\theta) f(\mathbf{x}^\star) + \theta f(\mathbf{y}).$$

Subtract $(1-\theta) f(\mathbf{x}^\star)$ from both sides and divide by $\theta > 0$ to obtain $f(\mathbf{x}^\star) \le f(\mathbf{y})$. $\blacksquare$

The geometric picture is just as crisp: if any strictly better point $\mathbf{y}$ existed anywhere in C, the chord from $\mathbf{x}^\star$ toward $\mathbf{y}$ would slope downward immediately, forcing the graph below $f(\mathbf{x}^\star)$ arbitrarily close to $\mathbf{x}^\star$ and contradicting local minimality.

Let us now run the experiment from the opening and see how the proposition plays out numerically. We apply the same gradient-descent loop (step size 0.05, 600 steps) to both the bowl $(x - \tfrac{1}{2})^2$ and the double well ϕ, starting from the same 500 points drawn uniformly on $[-1.5, 1.5]$. Because the step is small, each iterate rolls downhill without hopping over the central hump, so a run on ϕ should land in whichever well lies on its own side of the local maximum. We compute that local maximum as a root of $\phi'(x) = 4x^3 - 4x + \tfrac{1}{2}$ and check whether the fraction of starts to its right matches the fraction of runs that end in the shallower right well.

```
def gd(grad_fn, x, eta=0.05, steps=600):
    for _ in range(steps):
        x = x - eta * grad_fn(x)
    return x

phi = lambda x: (x**2 - 1)**2 + 0.5 * x        # tilted double well
dphi = lambda x: 4 * x * (x**2 - 1) + 0.5      # its derivative
rng = np.random.default_rng()
inits = rng.uniform(-1.5, 1.5, size=500)       # 500 random starting points
```

```
bowl = gd(lambda x: 2 * (x - 0.5), inits)      # convex: (x - 1/2)^2
well = gd(dphi, inits)
left, right = well[well < 0], well[well > 0]
print(f'bowl: all {bowl.size} runs end at x = {bowl.mean():.6f}'
      f' (spread {np.ptp(bowl):.0e})')
for name, w in (('left ', left), ('right', right)):
    print(f'well, {name}: {w.size} runs, x = {w.mean():.4f}, phi = {phi(w.mean()):.4f}')
x_max = np.sort(np.roots([4, 0, -4, 0.5]).real)[1]   # local max of phi
print(f'local max at {x_max:.4f}: predicted share right {(1.5 - x_max) / 3:.3f},'
      f' observed {right.size / inits.size:.3f}')
```

```
bowl: all 500 runs end at x = 0.500000 (spread 7e-16)
well, left : 281 runs, x = -1.0575, phi = -0.5148
well, right: 219 runs, x = 0.9304, phi = 0.4833
local max at 0.1271: predicted share right 0.458, observed 0.438
```

On the bowl, all 500 runs converge to $x = 0.5$ to within numerical rounding. On the double well, the runs split cleanly into two camps: one at $x \approx -1.0575$ with $\phi \approx -0.515$, and another at $x \approx 0.9304$ with $\phi \approx 0.483$—nearly a full unit worse. The local maximum separating the two basins sits at $x \approx 0.127$, so a fraction $(1.5 - 0.127)/3 \approx 0.458$ of uniform starts fall to its right. Across random draws, the observed share hovers within a few percentage points of 46%, matching the prediction up to the sampling noise of 500 starts.

Both experiments ran the exact same optimizer; only the objective changed. Convexity eliminates the second basin, though it does not by itself guarantee that gradient descent will reach the minimizer—that still requires smoothness and a safe step size, as in Section 35.1.1.

35.3.2.3 The First-Order Condition

The chord condition has the virtue of needing no derivatives, but optimization proofs are built out of gradients. When f is differentiable, convexity takes an equivalent first-order form: the tangent hyperplane at any point is a *global under-estimator* of the function,

$$f(\mathbf{y}) \;\geq\; f(\mathbf{x}) + \nabla f(\mathbf{x})^{\top}(\mathbf{y} - \mathbf{x}) \qquad \text{for all } \mathbf{x}, \mathbf{y} \in C. \tag{35.26}$$

Check this on $f(x) = x^2$ at $x = 1$: the tangent line is $1 + 2(y - 1) = 2y - 1$, and the vertical gap between graph and tangent is $y^2 - (2y - 1) = (y - 1)^2 \geq 0$ for every y. Pause to appreciate how strong a statement Equation 35.26 is: a single gradient, computed at a single point $\mathbf{x}$, bounds f from below at every other point in the domain. Almost every proof in the rest of this section rests on this one inequality. Figure 35.11 places the first two tests side by side: chords lie above the graph, while tangents lie below it.

35.3.2.4 The Second-Order Condition

For smooth objectives, the quickest way to verify convexity is usually a matrix test. When f is twice differentiable on an **open** convex domain C, f is convex if and only if its Hessian is positive semidefinite everywhere:

$$\nabla^2 f(\mathbf{x}) \succeq 0 \qquad \text{for all } \mathbf{x} \in C.$$

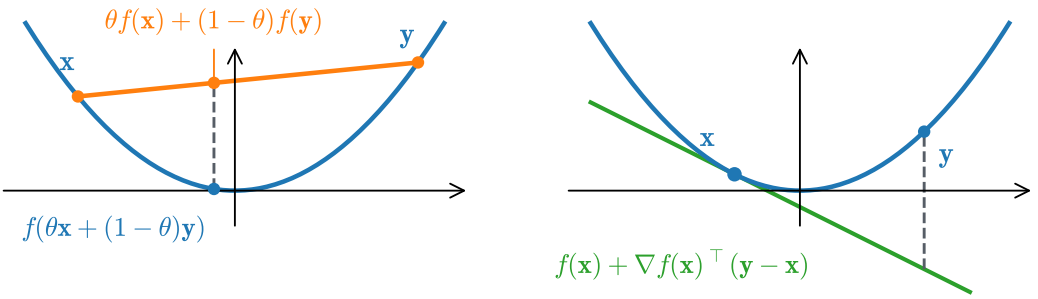

Figure 35.11: Two equivalent conditions. (a) The chord joining two points of the graph lies above the graph: $f(\theta\mathbf{x}+(1-\theta)\mathbf{y}) \le \theta f(\mathbf{x}) + (1-\theta) f(\mathbf{y})$. (b) The tangent at any point lies below the graph: $f(\mathbf{y}) \ge f(\mathbf{x}) + \nabla f(\mathbf{x})^\top (\mathbf{y} - \mathbf{x})$.

In one dimension this reduces to the familiar calculus rule $f''(x) \ge 0$: the curve bends upward. In d dimensions it says that every one-dimensional slice through $\mathbf{x}$ bends upward, since $\mathbf{v}^\top \nabla^2 f(\mathbf{x})\, \mathbf{v}$ is the second derivative of f along the line in direction $\mathbf{v}$ (Section 34.2).

This matrix test settles three workhorse examples immediately. First, a quadratic $\frac{1}{2}\mathbf{x}^\top \mathbf{A}\mathbf{x} + \mathbf{b}^\top \mathbf{x}$ with symmetric $\mathbf{A}$ has constant Hessian $\mathbf{A}$, so it is convex if and only if $\mathbf{A} \succeq 0$. Second, the least-squares loss $\frac{1}{2}\|\mathbf{X}\mathbf{w} - \mathbf{y}\|^2$ for a design matrix $\mathbf{X} \in \mathbb{R}^{n \times d}$ (n examples, d weights) has Hessian $\mathbf{X}^\top \mathbf{X}$; because $\mathbf{v}^\top \mathbf{X}^\top \mathbf{X} \mathbf{v} = \|\mathbf{X}\mathbf{v}\|^2 \ge 0$ for every $\mathbf{v}$, least squares is always convex (Section 33.3.2.2). Third, the scalar functions e^x, $-\log x$, and $x \log x$ are all convex on their domains, since their second derivatives e^x, $1/x^2$, and $1/x$ are positive everywhere.

Why did we insist that the domain C be open? On a lower-dimensional domain, only directions that stay inside C matter: for instance, $x^2 - y^2$ is convex when restricted to the line $y = 0$, even though its full two-dimensional Hessian is indefinite.

We now verify that all three tests single out the exact same class of functions. The proof has four short parts, and the second is the one worth remembering: applying the tangent bound at the *intermediate* point of a chord makes the gradient terms cancel—the same trick we will use to prove Jensen's inequality.

Proposition (the three characterizations agree). *Let f be differentiable on an open convex domain C. Then the chord condition Equation 35.25 and the first-order condition Equation 35.26 are equivalent. If f is twice differentiable, both are equivalent to $\nabla^2 f(\mathbf{x}) \succeq 0$ on C.*

Proof. *(Chord $\Rightarrow$ first-order.)* Fix $\mathbf{x}, \mathbf{y} \in C$ and $\theta \in (0, 1]$. Apply the chord inequality at the intermediate point $\mathbf{x} + \theta(\mathbf{y} - \mathbf{x})$, subtract $f(\mathbf{x})$ from both sides, and divide by θ:

$$\frac{f(\mathbf{x} + \theta(\mathbf{y} - \mathbf{x})) - f(\mathbf{x})}{\theta} \;\le\; f(\mathbf{y}) - f(\mathbf{x}).$$

Letting $\theta \downarrow 0$, the left side approaches the directional derivative $\nabla f(\mathbf{x})^\top (\mathbf{y} - \mathbf{x})$, yielding Equation 35.26.

(First-order $\Rightarrow$ chord.) Set $\mathbf{z} = \theta\mathbf{x} + (1-\theta)\mathbf{y}$ and apply the tangent lower bound at $\mathbf{z}$ twice, once toward each endpoint:

$$f(\mathbf{x}) \geq f(\mathbf{z}) + \nabla f(\mathbf{z})^\top (\mathbf{x} - \mathbf{z}), \qquad f(\mathbf{y}) \geq f(\mathbf{z}) + \nabla f(\mathbf{z})^\top (\mathbf{y} - \mathbf{z}).$$

Multiply the first inequality by θ, the second by $1 - \theta$, and add. The linear terms combine to $\nabla f(\mathbf{z})^\top (\theta \mathbf{x} + (1-\theta)\mathbf{y} - \mathbf{z}) = 0$, leaving Equation 35.25.

(Second-order $\Rightarrow$ first-order.) Restrict f to the line segment between $\mathbf{x}$ and $\mathbf{y}$ by defining $g(t) = f(\mathbf{x} + t(\mathbf{y} - \mathbf{x}))$. Its second derivative is $g''(t) = (\mathbf{y}-\mathbf{x})^\top \nabla^2 f(\mathbf{x} + t(\mathbf{y}-\mathbf{x}))\,(\mathbf{y}-\mathbf{x}) \geq 0$. By Taylor's theorem with the Lagrange remainder (Section 34.1), $g(1) = g(0) + g'(0) + \frac{1}{2} g''(\tau)$ for some $\tau \in (0, 1)$. Dropping the nonnegative remainder yields Equation 35.26.

(First-order $\Rightarrow$ second-order.) Suppose for contradiction that $\mathbf{v}^\top \nabla^2 f(\mathbf{x})\, \mathbf{v} < 0$ for some $\mathbf{x} \in C$ and direction $\mathbf{v}$. Expanding f along $\mathbf{v}$ gives

$$f(\mathbf{x} + t\mathbf{v}) = f(\mathbf{x}) + t\, \nabla f(\mathbf{x})^\top \mathbf{v} + \frac{t^2}{2}\, \mathbf{v}^\top \nabla^2 f(\mathbf{x})\, \mathbf{v} + o(t^2).$$

For sufficiently small $t > 0$, the negative quadratic term dominates the $o(t^2)$ remainder, so $f(\mathbf{x} + t\mathbf{v})$ drops strictly below the tangent value $f(\mathbf{x}) + t \nabla f(\mathbf{x})^\top \mathbf{v}$, contradicting Equation 35.26. ■

35.3.2.5 A Numerical Check of the Three Tests

Let us put all three tests to work numerically on two losses: the least-squares objective $f(\mathbf{w}) = \frac{1}{2}\|\mathbf{X}\mathbf{w} - \mathbf{y}\|^2$ with $n = 20$ random examples and $d = 2$ weights, and the double well ϕ from our opening experiment. For least squares we already know the exact formulas for the violations: expanding the squares as we did for x^2 gives the chord gap (graph minus chord) as $-\frac{1}{2}\theta(1-\theta)\|\mathbf{X}(\mathbf{u} - \mathbf{v})\|^2$ and the tangent gap (tangent minus graph) as $-\frac{1}{2}\|\mathbf{X}(\mathbf{v} - \mathbf{u})\|^2$, both nonpositive. For each loss, the code below samples $1{,}000$ random chords and tangents in $[-1.5, 1.5]^d$, reports the largest violation of each kind, and checks the smallest Hessian eigenvalue across the sampled points.

```
X, y = rng.normal(size=(20, 2)), rng.normal(size=20)  # least squares, d = 2
losses = {'least squares': (2, lambda w: 0.5 * ((X @ w - y) ** 2).sum(),
                            lambda w: X.T @ (X @ w - y), lambda w: X.T @ X),
          'double well': (1, lambda w: phi(w[0]), dphi,  # phi'' = 12 x^2 - 4
                          lambda w: np.diag(12 * w**2 - 4))}
print('               worst chord gap  worst tangent gap  smallest Hessian eig')
for name, (d, f, grad, hess) in losses.items():
    U, V = rng.uniform(-1.5, 1.5, size=(2, 1000, d))  # 1000 random pairs
    T = rng.uniform(size=1000)
    chord = [f(t * u + (1 - t) * v) - (t * f(u) + (1 - t) * f(v))
             for u, v, t in zip(U, V, T)]             # graph minus chord
    tangent = [f(u) + grad(u) @ (v - u) - f(v)        # tangent minus graph
               for u, v in zip(U, V)]
    eig = min(np.linalg.eigvalsh(hess(u))[0] for u in U)
    print(f'{name:15s}{max(chord):15.3f}{max(tangent):19.3f}{eig:22.3f}')
i = int(np.argmax(chord))                             # the double well's worst
print(f'worst chord of the double well: from {U[i, 0]:.2f} to {V[i, 0]:.2f}')
```

```
                worst chord gap  worst tangent gap  smallest Hessian eig
least squares           -0.000             -0.009                 7.630
double well              0.957              2.998                -4.000
worst chord of the double well: from -1.01 to 0.89
```

For least squares, not a single sampled chord dips below the graph, no tangent rises above it, and the Hessian eigenvalues stay positive, just as the algebra predicted. The double well fails all three checks: its worst chord cuts nearly one unit below the graph between points in the two valleys, its tangents slice through the curve, and its second derivative drops near -4 at the central hump, where $\phi''(0) = -4$. Notice, however, an asymmetry between the tests. Random sampling can *refute* convexity—a single bad chord is a complete counterexample for ϕ—but it can never *prove* convexity; for least squares it only failed to find a violation. What proves convexity for least squares is the Hessian test, because $\mathbf{X}^\top\mathbf{X}$ is the same PSD matrix at every $\mathbf{w}$.

35.3.2.6 Strict and Strong Convexity

Plain convexity still permits arbitrarily flat stretches, and on a flat stretch gradient descent can crawl arbitrarily slowly. To guarantee fast convergence, we need curvature that stays bounded away from zero everywhere. Three simple functions illustrate the hierarchy, shown in Figure 35.12(a). The line $f(x) = x$ is convex but not strictly convex, because its chords sit right on its graph. The quartic x^4 is strictly convex—its second derivative $12x^2$ vanishes only at 0, so its slope increases strictly everywhere—yet $f''(0) = 0$ leaves it completely flat at the minimizer. The quadratic x^2, by contrast, has constant curvature $f''(x) = 2$ at every point.

Strong convexity turns this observation into a quantitative bound. For $\mu > 0$, a function f is μ-**strongly convex** if subtracting a quadratic of curvature μ leaves a convex function—that is, if $h(\mathbf{x}) = f(\mathbf{x}) - \frac{\mu}{2}\|\mathbf{x}\|^2$ is convex. When f is differentiable, applying the first-order condition to h (whose gradient is $\nabla f(\mathbf{x}) - \mu\mathbf{x}$) and using the identity $\|\mathbf{y}\|^2 - \|\mathbf{x}\|^2 - 2\mathbf{x}^\top(\mathbf{y} - \mathbf{x}) = \|\mathbf{y} - \mathbf{x}\|^2$ yields the equivalent inequality

$$f(\mathbf{y}) \;\geq\; f(\mathbf{x}) + \nabla f(\mathbf{x})^\top(\mathbf{y} - \mathbf{x}) + \frac{\mu}{2}\,\|\mathbf{y} - \mathbf{x}\|^2 \qquad \text{for all } \mathbf{x}, \mathbf{y}. \tag{35.27}$$

Geometrically, the graph of f must sit not merely above its tangent line at $\mathbf{x}$, but above a parabola of curvature μ tangent to it there. Applying the second-order condition to h gives the matrix test: a twice-differentiable f is μ-strongly convex if and only if $\nabla^2 f(\mathbf{x}) \succeq \mu\mathbf{I}$ everywhere, where $\mathbf{I}$ is the identity matrix. Thus x^2 is 2-strongly convex, whereas x^4 fails to be strongly convex on any neighborhood of 0 because $f''(0) = 0 < \mu$ for every $\mu > 0$. Notice also a practical bonus: adding the ridge penalty $\frac{\lambda}{2}\|\mathbf{w}\|^2$ to any convex loss immediately makes the sum λ-strongly convex, because subtracting $\frac{\lambda}{2}\|\mathbf{w}\|^2$ recovers the original convex loss. Weight decay does not just shrink parameters; it guarantees strong convexity.

Strong convexity is the natural counterpart to smoothness. Recall from Section 35.1.1 that f is L-**smooth** when its gradient is L-Lipschitz, $\|\nabla f(\mathbf{x}) - \nabla f(\mathbf{y})\| \leq L\|\mathbf{x} - \mathbf{y}\|$; for a convex twice-differentiable function, this means $\nabla^2 f \preceq L\mathbf{I}$. Smoothness places a quadratic ceiling above the graph, $f(\mathbf{y}) \leq f(\mathbf{x}) + \nabla f(\mathbf{x})^\top(\mathbf{y} - \mathbf{x}) + \frac{L}{2}\|\mathbf{y} - \mathbf{x}\|^2$, while strong convexity places a quadratic floor Equation 35.27 beneath it. Together they sandwich f between two tangent parabolas of curvatures μ and L, as illustrated in Figure 35.12(b) for $f(x) = \frac{1}{2}x^2 +$

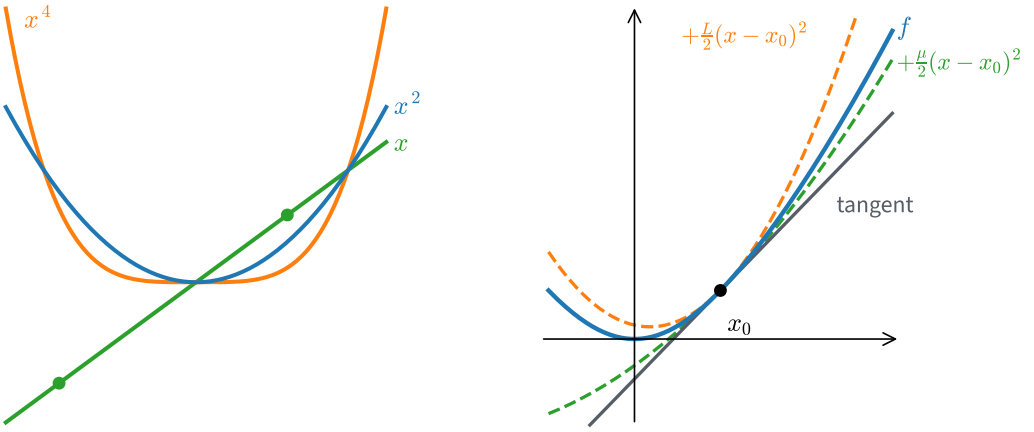

Figure 35.12: (a) Convex, strictly convex, strongly convex: x has chords on its graph, x^4 is flat at the origin, x^2 curves everywhere. (b) A μ-strongly convex, L-smooth function, here $f(x) = \frac{1}{2}x^2 + 3\log\cosh x$, lies between two parabolas tangent at $x_0 = 1$, with curvatures $\mu = 1$ and $L = 4$; their ratio is κ.

$3\log\cosh x$, whose second derivative $f''(x) = 1 + 3/\cosh^2 x$ ranges between $\mu = 1$ and $L = 4$.

The ratio $\kappa = L/\mu$ is the **condition number**, generalizing the eigenvalue ratio we encountered for quadratics in Section 35.1.2. On our running quadratic $\frac{1}{2}(x_1^2 + 1000\,x_2^2)$, the extreme curvatures are $\mu = 1$ and $L = 1000$, giving $\kappa = 10^3$.

35.3.2.7 Subgradients

Important losses such as the ℓ_1 norm $\|\mathbf{x}\|_1$ and the hinge loss $\max(0, 1 - z)$ have sharp corners, where no gradient exists and Equation 35.26 cannot be written as stated. Rather than give up on the tangent bound, we keep the *job* the gradient was doing—producing a global linear under-estimator—and turn that job into a definition. A vector $\mathbf{g}$ is a **subgradient** of f at $\mathbf{x}$ if

$$f(\mathbf{y}) \;\geq\; f(\mathbf{x}) + \mathbf{g}^\top(\mathbf{y} - \mathbf{x}) \qquad \text{for all } \mathbf{y}. \tag{35.28}$$

The set of all subgradients at $\mathbf{x}$ is called the **subdifferential**, written $\partial f(\mathbf{x})$. Wherever a convex function f is differentiable, the subdifferential collapses to a single vector, $\{\nabla f(\mathbf{x})\}$. At a corner, however, it fans out into a whole set of supporting slopes (Figure 35.13). For $f(x) = |x|$ at $x = 0$, every slope $g \in [-1, 1]$ satisfies $|y| \geq gy$ for all y, so $\partial f(0) = [-1, 1]$; similarly, for the hinge loss $\max(0, 1 - z)$ at the kink $z = 1$, we get $\partial f(1) = [-1, 0]$.

This immediately gives a derivative-free optimality test: $\mathbf{x}^\star$ minimizes f if and only if $\mathbf{0} \in \partial f(\mathbf{x}^\star)$. The proof is a one-line tautology: setting $\mathbf{g} = \mathbf{0}$ in Equation 35.28 reads $f(\mathbf{y}) \geq f(\mathbf{x}^\star)$ for all $\mathbf{y}$, which is literally the definition of a global minimizer.

Does a convex function always possess a subgradient? At every interior point of its domain, yes—a fact we will rely on to prove Jensen's inequality. In one dimension the reason is elementary. For any three points $a < b < c$ in an open interval where f is convex, rearranging

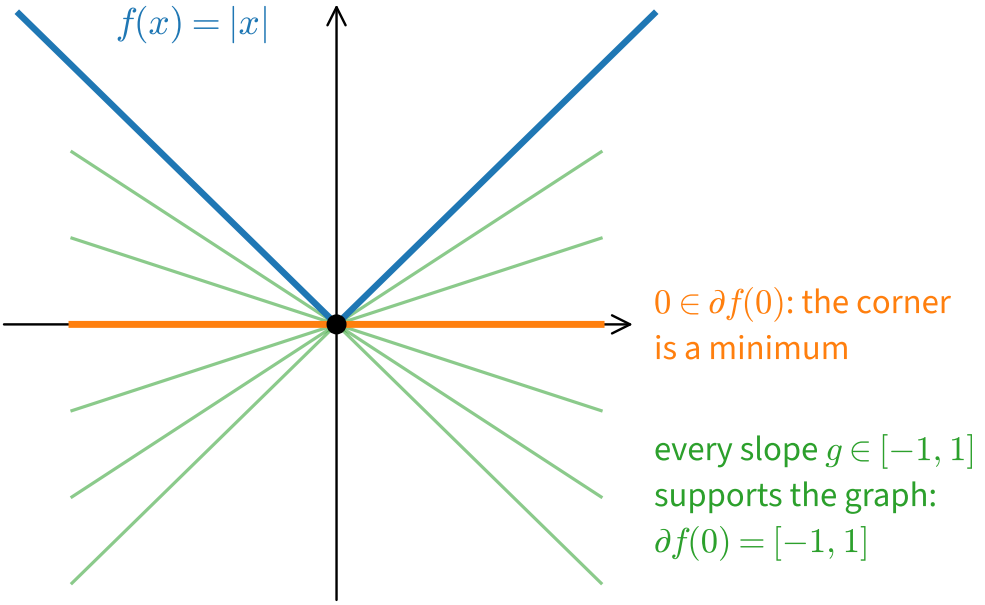

Figure 35.13: At the kink of $f(x) = |x|$ the gradient does not exist, but the subdifferential is a set: every slope $g \in (-1, 1)$ defines a supporting line below the V, and the two extreme slopes ± 1 lie along the branches themselves, so $\partial f(0)$ is the whole interval from -1 to 1. The zero-slope member (orange) is the optimality certificate $0 \in \partial f(0)$: the corner is a minimum certified without differentiability.

the chord inequality at b gives

$$\frac{f(b)-f(a)}{b-a} \;\le\; \frac{f(c)-f(a)}{c-a} \;\le\; \frac{f(c)-f(b)}{c-b},$$

meaning that chord slopes are nondecreasing from left to right. Consequently, the difference quotient $q(x) = (f(x) - f(x_0))/(x - x_0)$ at any interior point x_0 is nondecreasing in x, so its one-sided limits—the left and right derivatives $f'_-(x_0) \le f'_+(x_0)$—both exist and are finite. Every slope $g \in [f'_-(x_0), f'_+(x_0)]$ is a subgradient: for $y > x_0$ we have $q(y) \ge f'_+(x_0) \ge g$, which rearranges to $f(y) \ge f(x_0) + g(y - x_0)$, and the case $y < x_0$ is symmetric.

The same guarantee extends to d dimensions: at every interior point of its domain, a convex function has at least one subgradient, so a supporting hyperplane always fits beneath its graph (Rockafellar (1970); Boyd and Vandenberghe (2004), section 2.5). We will use this result without proof. Keep in mind, though, that as a search direction a subgradient is much weaker than a true gradient: stepping along $-\mathbf{g}$ need not decrease f at all (at the minimum $x = 0$ of $|x|$, the valid subgradient $g = \frac{1}{2}$ steps to $-\eta/2$, raising the loss). For that reason, the subgradient method requires diminishing step sizes and converges slowly, with error falling only as $1/\sqrt{k}$.

35.3.3 Consequences of Convexity

The rest of this book draws on three major consequences of convexity, and all three spring from the same geometric source: a supporting line or hyperplane that bounds the function from below everywhere. Averaged over a random variable, that bound yields Jensen's inequality. Evaluated at a stationary point, it certifies global optimality—sharpening what Section 35.3.2.2 deduced from the chord condition alone. Summed along the steps of gradient descent, it turns local progress into global convergence rates. Jensen's inequality stands on its own, so if you are reading purely for optimization you can skip directly to the next subsection.

35.3.3.1 Jensen's Inequality

Expected losses, average log-likelihoods, and KL divergences all confront the same basic question: how does a function of an average compare with the average of the function? The simplest two-point example shows which way the inequality points. Let Z take the values 0 and 2 with probability $\frac{1}{2}$ each, and let $f(x) = x^2$. Evaluating f at the mean gives $f(\mathbb{E}[Z]) = f(1) = 1$, whereas averaging f over the outcomes gives $\mathbb{E}[f(Z)] = \frac{1}{2}\cdot 0 + \frac{1}{2}\cdot 4 = 2$. The gap of 1 is simply the variance of Z; in fact, for $f(x) = x^2$ the difference $\mathbb{E}[Z^2] - (\mathbb{E}[Z])^2$ is always the variance. Look back at Figure 35.11(a): the chord inequality is making this exact comparison for a two-point distribution with weights θ and $1-\theta$, and the gap $\theta(1-\theta)(x-y)^2$ we computed earlier for x^2 is that distribution's variance.

Nothing about this argument is restricted to two points. Applying Equation 35.25 inductively (Exercise 2) gives the finite form

$$f\left(\sum_i \theta_i \mathbf{x}_i\right) \;\le\; \sum_i \theta_i\, f(\mathbf{x}_i), \qquad \theta_i \ge 0,\ \sum_i \theta_i = 1. \tag{35.29}$$

Because nonnegative weights summing to one define a discrete probability distribution on the points $\mathbf{x}_i$, the natural generalization replaces the finite average with an arbitrary expectation.

Proposition (Jensen's inequality). *Let f be convex on a convex set $C \subseteq \mathbb{R}^d$, and let $\mathbf{Z}$ be a random vector taking values in C, with $\mathbb{E}\|\mathbf{Z}\| < \infty$ and mean $\mathbf{m} = \mathbb{E}[\mathbf{Z}]$ in the interior of C. Then*

$$f(\mathbf{m}) \;\le\; \mathbb{E}\left[f(\mathbf{Z})\right]. \tag{35.30}$$

If f is strictly convex, equality holds if and only if $\mathbf{Z} = \mathbf{m}$ with probability one.

Proof. Because $\mathbf{m}$ lies in the interior of C, f has at least one subgradient $\mathbf{g} \in \partial f(\mathbf{m})$. The supporting hyperplane at $\mathbf{m}$ bounds f for every outcome at once: by Equation 35.28,

$$f(\mathbf{Z}) \;\ge\; f(\mathbf{m}) + \mathbf{g}^{\top}(\mathbf{Z} - \mathbf{m}).$$

Now take expectations of both sides. Because $\mathbb{E}[\mathbf{Z} - \mathbf{m}] = \mathbf{0}$, the linear term vanishes, leaving $\mathbb{E}[f(\mathbf{Z})] \ge f(\mathbf{m})$. When f is strictly convex, this supporting hyperplane touches the graph *only* at $\mathbf{m}$: if it also touched at some $\mathbf{x} \neq \mathbf{m}$, strict convexity would force $f(\frac{\mathbf{x}+\mathbf{m}}{2}) < \frac{1}{2}f(\mathbf{x}) + \frac{1}{2}f(\mathbf{m})$, placing the graph strictly below the supporting hyperplane at the midpoint, a contradiction. Hence the pointwise inequality is strict whenever $\mathbf{Z} \neq \mathbf{m}$, so equality in expectation forces $\mathbf{Z} = \mathbf{m}$ with probability one. ■

As a bonus, the same pointwise bound shows that $f(\mathbf{Z})$ is bounded below by an integrable random variable, so $\mathbb{E}[f(\mathbf{Z})]$ is always well-defined (possibly $+\infty$, in which case the inequality holds trivially). In plain terms, spreading a random variable out while keeping its mean fixed can only increase the expected value of a convex function. For a concave function f, the inequality reverses: $\mathbb{E}[f(\mathbf{Z})] \le f(\mathbb{E}[\mathbf{Z}])$.

In machine learning, the most frequent application of Jensen's inequality is proving that KL divergence is never negative; Section 37.1 meets this same result as Gibbs' inequality.

Corollary (nonnegativity of KL divergence). *For probability distributions p and q on a common finite alphabet, with $q(x) > 0$ wherever $p(x) > 0$,*

$$D_{\mathrm{KL}}(p \,\|\, q) \;=\; \sum_{x} p(x) \log \frac{p(x)}{q(x)} \;\ge\; 0,$$

with equality if and only if $p = q$.

Proof. Draw $Z \sim p$ and apply Jensen's inequality to the strictly convex function $-\log$ and the positive random variable $R = q(Z)/p(Z)$:

$$D_{\mathrm{KL}}(p \,\|\, q) = \mathbb{E}_p\left[-\log R\right] \;\ge\; -\log \mathbb{E}_p[R] = -\log \sum_{x : p(x) > 0} p(x)\, \frac{q(x)}{p(x)} \;\ge\; -\log 1 = 0,$$

where the last step uses $\sum_{x:p(x)>0} q(x) \le 1$. By the equality condition of Jensen's inequality, equality holds if and only if R is constant with probability one and q places no mass outside the support of p—that is, $q = c\,p$ with $c = 1$. ■

Applying the same idea to the concave function log yields the classical **arithmetic–geometric mean inequality**: for any positive numbers $x_1, \dots, x_N$, concavity gives $\log(\frac{1}{N}\sum_i x_i) \geq \frac{1}{N}\sum_i \log x_i$, and exponentiating both sides produces

$$\frac{1}{N}\sum_{i=1}^{N} x_i \;\geq\; \left(\prod_{i=1}^{N} x_i\right)^{1/N},$$

with equality if and only if all x_i are equal, since log is strictly concave. Likewise, the evidence lower bound (ELBO) of Section 36.7, which bounds the logarithm of an expectation from below, is another direct application of Jensen's inequality to log.

Let us test both Jensen's gap and the KL equality case numerically. First, for $Z \sim \mathcal{N}(0,1)$ and $f(x) = e^x$, we can compute both sides in closed form—$\mathbb{E}[e^Z] = \sqrt{e} \approx 1.649$ versus $e^{\mathbb{E}[Z]} = 1$—and see how closely Monte Carlo matches them. Second, as we blend q into p via $(1-\varepsilon)p + \varepsilon q$, how quickly does the KL divergence vanish: linearly in ε, or faster?

```
rng = np.random.default_rng()
z = rng.normal(size=1_000_000)                # Z ~ N(0, 1)
print(f'E[exp(Z)] = {np.exp(z).mean():.2f} vs exp(E[Z]) = {np.exp(z.mean()):.2f}'
      f'  (population: {np.exp(0.5):.4f} vs 1)')
kl = lambda p, q: (p * np.log(p / q)).sum(axis=1)
p = rng.dirichlet(np.ones(10), size=1000)     # 1000 random pairs, 10 symbols
q = rng.dirichlet(np.ones(10), size=1000)
print('median KL(p || (1-eps) p + eps q), eps = 1e-2, 1e-3, 1e-4:',
      *[f'{np.median(kl(p, (1 - e) * p + e * q)):.1e}' for e in (1e-2, 1e-3, 1e-4)])
```

```
E[exp(Z)] = 1.65 vs exp(E[Z]) = 1.00  (population: 1.6487 vs 1)
median KL(p || (1-eps) p + eps q), eps = 1e-2, 1e-3, 1e-4: 1.7e-04 1.8e-06 1.8e-08
```

The Monte Carlo averages land right around 1.65 versus 1.00; drawing more samples shrinks the estimation noise, but the structural Jensen gap remains fixed. In the KL experiment, the divergence vanishes much faster than ε: every tenfold reduction in ε cuts the median divergence roughly a hundredfold. Expanding the logarithm explains why: $D_{\mathrm{KL}}(p \,\|\, (1-\varepsilon)p + \varepsilon q) \approx \frac{\varepsilon^2}{2}\sum_x (q(x)-p(x))^2/p(x)$ once $\varepsilon\, q(x)/p(x)$ is small for every x. (Pairs where p assigns tiny probability to some symbol enter this quadratic regime last, which is why we report the median rather than the maximum.) Equality is approached quadratically, and attained only in the limit $q \to p$.

35.3.3.2 Local and Global Minima

We already proved that every local minimum of a convex function is global (Section 35.3.2.2). Three companion facts follow just as effortlessly, each in a single line. First, the set of all global minimizers is convex: if both $\mathbf{x}$ and $\mathbf{y}$ attain the minimum value $f^\star$, the chord inequality forces every point between them to lie at or below $f^\star$. Second, for a differentiable convex f on an open set, $\nabla f(\mathbf{x}) = \mathbf{0}$ immediately implies $f(\mathbf{x}) = f^\star$, because the first-order condition with a zero gradient reads $f(\mathbf{y}) \geq f(\mathbf{x})$ for all $\mathbf{y}$. Third, a small gradient guarantees a small suboptimality gap: pointing the first-order condition at a minimizer $\mathbf{x}^\star$ gives $f(\mathbf{x}) - f^\star \leq \nabla f(\mathbf{x})^\top(\mathbf{x} - \mathbf{x}^\star) \leq \|\nabla f(\mathbf{x})\|\,\|\mathbf{x} - \mathbf{x}^\star\|$. Thus the stationarity result of Section 35.1.1—that gradient descent with $\eta = 1/L$ drives the smallest gradient norm to zero—upgrades for convex objectives into a guarantee on the *loss value* itself, provided the

iterates stay within a bounded distance of $\mathbf{x}^\star$. In Section 35.3.3.3 we will prove that they do, and pin down the exact rate.

Be aware of two things that plain convexity does *not* guarantee: a minimizer need not be unique (a convex function can be flat along an entire segment), and it need not even exist (e^x approaches 0 as $x \to -\infty$ without ever attaining it). Strict convexity rules out multiple minimizers, and strong convexity guarantees both existence and uniqueness.

Proposition (uniqueness). *A strictly convex f has at most one minimizer. A continuous μ-strongly convex f on a nonempty closed convex set C with nonempty interior has exactly one.*

Proof. Suppose $\mathbf{x} \neq \mathbf{y}$ were both global minimizers with value $f^\star$. By the strict chord inequality at $\theta = \frac{1}{2}$, their midpoint would satisfy $f(\frac{\mathbf{x}+\mathbf{y}}{2}) < f^\star$, a contradiction. Because strong convexity implies strict convexity, it remains only to prove existence. We prove it for a differentiable f on $C = \mathbb{R}^d$, which covers the unconstrained losses in this book; the general case follows the same steps using a subgradient of $f - \frac{\mu}{2}\|\cdot\|^2$ at an interior point of C. Fix any starting point $\mathbf{x}_0$. In Equation 35.27, the linear term is at least $-\|\nabla f(\mathbf{x}_0)\|\,\|\mathbf{y} - \mathbf{x}_0\|$, so $f(\mathbf{y}) > f(\mathbf{x}_0)$ whenever $\|\mathbf{y} - \mathbf{x}_0\| > 2\|\nabla f(\mathbf{x}_0)\|/\mu$. Hence the sublevel set $\{\mathbf{y} : f(\mathbf{y}) \leq f(\mathbf{x}_0)\}$ is bounded, and continuity of f ensures that it is closed. Every continuous function on a nonempty closed and bounded set attains its minimum, and the minimum over this sublevel set is automatically the global minimum over $\mathbb{R}^d$. ■

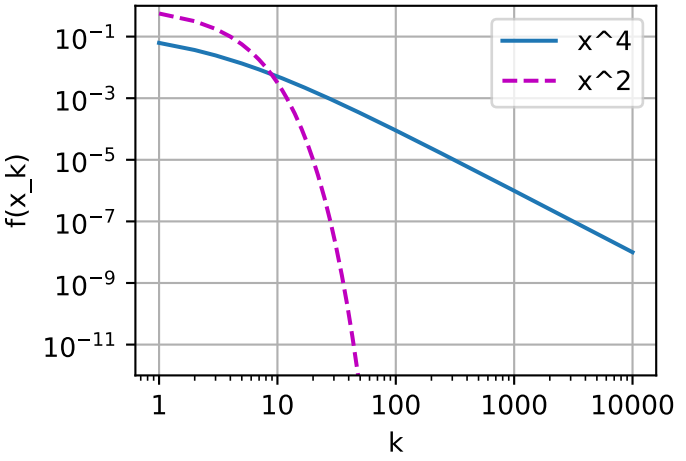
The technical hypotheses on C and continuity merely exclude pathological functions that jump upward at the boundary of their domain, which never occur for the losses in this book. By contrast, the missing minimizer of e^x shows up in real machine learning: Exercise 3 traces it directly to logistic regression on linearly separable data.

35.3.3.3 Convergence Rates

Convexity tells us *where* gradient descent stops, but not *how fast* it gets there—and on speed, plain convexity promises surprisingly little. Compare $f(x) = x^2$ and $f(x) = x^4$: both are strictly convex with unique minimizer 0, yet only x^2 is strongly convex. Let us run the exact same gradient-descent loop ($\eta = \frac{1}{8}$, starting from $x_0 = 1$) on both functions for 10^4 steps and watch how differently they behave.

```
eta, steps = 1 / 8, 10_000
x2, x4 = np.ones(steps + 1), np.ones(steps + 1)  # iterates from x_0 = 1
for j in range(steps):                           # same start, same step
    x2[j + 1] = x2[j] - eta * 2 * x2[j]          # f(x) = x^2
    x4[j + 1] = x4[j] - eta * 4 * x4[j]**3       # f(x) = x^4
k = np.arange(1, steps + 1)
print('x^2: first k with x_k < 1e-6:', k[x2[1:] < 1e-6][0])
print('x^4: x_k * sqrt(k) at k = 1e2, 1e3, 1e4:',
      (x4[1:] * np.sqrt(k))[[99, 999, 9999]].round(3))
d2l.plot(k, [x4[1:]**4, x2[1:]**2], 'k', 'f(x_k)', xscale='log',
         yscale='log', ylim=(1e-12, 1), legend=['x^4', 'x^2'])
```

```
x^2: first k with x_k < 1e-6: 49
x^4: x_k * sqrt(k) at k = 1e2, 1e3, 1e4: [0.973 0.996 1.   ]
```



The contrast is dramatic. On x^2, every step multiplies the iterate by a constant factor $1 - 2\eta = 0.75$, driving it below 10^{-6} in just 49 steps; the loss drops off the bottom of the plot almost immediately. On x^4, by contrast, each step multiplies x_k by $1 - 4\eta x_k^2$, a contraction factor that creeps closer and closer to 1 as the iterate approaches the flat valley at 0. The printed products $x_k\sqrt{k}$ settle near 1, showing that x_k decays only like $1/\sqrt{k}$ and still sits at 0.01 after $10{,}000$ steps. On a log–log plot, the loss gap x_k^4 therefore traces a straight line of slope -2. Strict convexity rules out multiple minimizers, but it cannot guarantee fast convergence; a geometric rate requires $\mu > 0$.

The next two propositions make this contrast completely general: every smooth strongly convex function converges geometrically like x^2, whereas without $\mu > 0$ we can guarantee only an $O(1/k)$ decay. Both proofs begin with the **descent lemma** from Section 35.1.1: for an L-smooth function f and the gradient step $\mathbf{x}_{k+1} = \mathbf{x}_k - \frac{1}{L}\nabla f(\mathbf{x}_k)$,

$$f(\mathbf{x}_{k+1}) \;\le\; f(\mathbf{x}_k) - \frac{1}{2L}\,\|\nabla f(\mathbf{x}_k)\|^2.$$

Each step reduces the objective by at least $\|\nabla f(\mathbf{x}_k)\|^2/(2L)$. On a general nonconvex function, that only proves the gradient shrinks to zero. Convexity supplies the missing link between the gradient and the suboptimality gap: whenever $f(\mathbf{x}_k) - f^\star$ is still large, the gradient must be large enough to keep making progress, so the iterates cannot stall far from the optimum.

Proposition (gradient descent on smooth convex functions). *Let f be convex and L-smooth with a minimizer $\mathbf{x}^\star$. Gradient descent with $\eta = 1/L$ satisfies, for every $k \ge 1$,*

$$f(\mathbf{x}_k) - f(\mathbf{x}^\star) \;\le\; \frac{L\,\|\mathbf{x}_0 - \mathbf{x}^\star\|^2}{2k}. \tag{35.31}$$

Thus the loss gap decays at least as fast as $1/k$, scaled by the smoothness constant and the squared initial distance to the minimizer. To put numbers on it, if $L = 1$ and $\|\mathbf{x}_0 - \mathbf{x}^\star\| = 10$, the bound is $50/k$, guaranteeing a gap below 10^{-2} within $5{,}000$ steps.

Proof. Combine the descent lemma with the first-order condition Equation 35.26 evaluated at $\mathbf{x}_k$ toward the optimum, $f(\mathbf{x}_k) - f(\mathbf{x}^\star) \le \nabla f(\mathbf{x}_k)^\top(\mathbf{x}_k - \mathbf{x}^\star)$:

$$f(\mathbf{x}_{k+1}) - f(\mathbf{x}^\star) \;\le\; \nabla f(\mathbf{x}_k)^\top(\mathbf{x}_k - \mathbf{x}^\star) - \frac{1}{2L}\|\nabla f(\mathbf{x}_k)\|^2.$$

Now comes the clever step: complete the square so that the right side turns into a difference of two squared distances to $\mathbf{x}^\star$,

$$\begin{aligned}\nabla f(\mathbf{x}_k)^\top(\mathbf{x}_k - \mathbf{x}^\star) - \frac{1}{2L}\|\nabla f(\mathbf{x}_k)\|^2 \\ = \frac{L}{2}\left(\|\mathbf{x}_k - \mathbf{x}^\star\|^2 - \left\|\mathbf{x}_k - \mathbf{x}^\star - \tfrac{1}{L}\nabla f(\mathbf{x}_k)\right\|^2\right).\end{aligned}$$

Notice that the second norm is simply $\|\mathbf{x}_{k+1} - \mathbf{x}^\star\|^2$. Summing over $j = 0, \dots, k-1$, the right side telescopes cleanly:

$$\begin{aligned}\sum_{j=0}^{k-1}\left(f(\mathbf{x}_{j+1}) - f(\mathbf{x}^\star)\right) &\le \frac{L}{2}\left(\|\mathbf{x}_0 - \mathbf{x}^\star\|^2 - \|\mathbf{x}_k - \mathbf{x}^\star\|^2\right) \\ &\le \frac{L}{2}\|\mathbf{x}_0 - \mathbf{x}^\star\|^2.\end{aligned}$$

Because the descent lemma ensures that $f(\mathbf{x}_j)$ never increases, the final term $f(\mathbf{x}_k) - f(\mathbf{x}^\star)$ is the smallest term in the sum, so $k\,(f(\mathbf{x}_k) - f(\mathbf{x}^\star))$ is bounded by the total sum. Dividing by k gives Equation 35.31. ■

Two features of this proof are worth noting. First, the dimension d never appears: a model with a billion weights and the same L and initial distance enjoys the exact same worst-case guarantee. Second, before summing, the per-step inequality has a nonnegative left side $f(\mathbf{x}_{k+1}) - f^\star \ge 0$, which forces $\|\mathbf{x}_{k+1} - \mathbf{x}^\star\| \le \|\mathbf{x}_k - \mathbf{x}^\star\|$: every single step moves monotonically closer to every minimizer.

Adding strong convexity transforms this $1/k$ decay into a geometric rate.

Proposition (linear rate under strong convexity). *Let f be μ-strongly convex and L-smooth, with minimizer $\mathbf{x}^\star$. Gradient descent with $\eta = 1/L$ satisfies*

$$f(\mathbf{x}_k) - f(\mathbf{x}^\star) \;\le\; \left(1 - \frac{\mu}{L}\right)^k \left(f(\mathbf{x}_0) - f(\mathbf{x}^\star)\right). \tag{35.32}$$

In words, every iteration shaves off at least a fraction $\mu/L = 1/\kappa$ of the remaining loss gap.

Proof. The proof splits into two short steps. First, strong convexity bounds the squared gradient norm from below in terms of the suboptimality gap. Minimize both sides of Equation 35.27 over $\mathbf{y}$: the left side attains its minimum $f(\mathbf{x}^\star)$, while the right side is a simple quadratic in $\mathbf{y}$ minimized at $\mathbf{y} = \mathbf{x} - \frac{1}{\mu}\nabla f(\mathbf{x})$, where its value is $f(\mathbf{x}) - \frac{1}{2\mu}\|\nabla f(\mathbf{x})\|^2$. Rearranging gives

$$\frac{1}{2}\|\nabla f(\mathbf{x})\|^2 \;\ge\; \mu\left(f(\mathbf{x}) - f(\mathbf{x}^\star)\right) \qquad \text{for all } \mathbf{x}. \tag{35.33}$$

Second, substitute Equation 35.33 directly into the descent lemma:

$$f(\mathbf{x}_{k+1}) - f(\mathbf{x}^\star) \le f(\mathbf{x}_k) - f(\mathbf{x}^\star) - \frac{1}{2L}\|\nabla f(\mathbf{x}_k)\|^2$$
$$\le \left(1 - \frac{\mu}{L}\right)\left(f(\mathbf{x}_k) - f(\mathbf{x}^\star)\right).$$

Applying this contraction k times completes the proof. ■

Look closely at the second half of that proof: it never invoked convexity at all, only the inequality Equation 35.33. We will return to that surprising fact in Section 35.3.5. Notice also the enormous speedup over the non-strongly-convex case: reaching relative accuracy ϵ now takes roughly $\kappa \log(1/\epsilon)$ steps instead of $O(1/\epsilon)$. On our running quadratic with $\kappa = 10^3$, gaining six digits of accuracy, $(1 - 10^{-3})^k \le 10^{-6}$, takes about $13{,}800$ steps by this bound.

How tight is Equation 35.32 in practice? Let us measure it on a least-squares problem whose Hessian $\mathbf{X}^\top\mathbf{X}$ has eigenvalues 1 and 10 by construction ($\mu = 1$, $L = 10$, $\kappa = 10$). We run gradient descent with $\eta = 1/L$ and track the actual per-step ratio of successive loss gaps, $(f(\mathbf{w}_{k+1}) - f^\star)/(f(\mathbf{w}_k) - f^\star)$.

```
rng = np.random.default_rng()
Q, _ = np.linalg.qr(rng.normal(size=(20, 2)))  # orthonormal columns
R, _ = np.linalg.qr(rng.normal(size=(2, 2)))   # random rotation
X = Q @ np.diag([1.0, np.sqrt(10.0)]) @ R      # X^T X has eigenvalues 1, 10
y = rng.normal(size=20)
f = lambda w: 0.5 * ((X @ w - y) ** 2).sum()
mu, L = np.linalg.eigvalsh(X.T @ X)[[0, -1]]
w_star = np.linalg.lstsq(X, y, rcond=None)[0]
w, gaps = np.zeros(2), [f(np.zeros(2)) - f(w_star)]
for _ in range(60):                            # gradient descent, eta = 1/L
    w = w - X.T @ (X @ w - y) / L
    gaps.append(f(w) - f(w_star))
r = np.array(gaps[1:]) / np.array(gaps[:-1])   # per-step contraction of f - f*
print(f'mu = {mu:.4f}, L = {L:.4f}: bound 1 - mu/L = {1 - mu / L:.4f},'
      f' its square {(1 - mu / L)**2:.4f}')
print('first three ratios:', r[:3].round(4), ' largest ratio:', r.max().round(4))
```

```
mu = 1.0000, L = 10.0000: bound 1 - mu/L = 0.9000, its square 0.8100
first three ratios: [0.5899 0.81   0.81  ]  largest ratio: 0.81
```

Our bound promises a contraction factor of 0.9 per step, yet from the second step onward the measured ratio is 0.81—which is $(1 - \mu/L)^2$. (The very first ratio depends on the random starting direction and varies from run to run.) Viewing the update in the eigenvector coordinates of $\mathbf{X}^\top\mathbf{X}$ explains what happened. With $\eta = 1/L$, the first step multiplies the stiff eigen-component of $\mathbf{w} - \mathbf{w}^\star$ by $1 - L/L = 0$, wiping it out completely. In two dimensions, only the slow component remains; its distance to $\mathbf{w}^\star$ shrinks by $1 - \mu/L$ per step, so the loss gap—which is quadratic in that distance—shrinks by $(1 - \mu/L)^2$. In higher dimensions, the ratio climbs toward $(1 - \mu/L)^2$ as the faster eigen-components decay.

Our short proof gave away a square in the contraction factor. A sharper analysis shows that gradient descent with $\eta = 1/L$ in fact contracts $f - f^\star$ by $(1 - \mu/L)^2$ per step on *every* L-smooth μ-strongly convex function (Taylor et al. 2018), with quadratics achieving equality; Exercise 5 proves the closely related bound $\kappa(1-\mu/L)^{2k}$. Returning to our $\kappa = 10^3$ running

quadratic, six digits of accuracy in the loss gap (three digits in the distance to the minimizer) cost roughly $13{,}800$ steps by our simple bound, about $6{,}900$ steps at the true $(1-\mu/L)^2$ rate, and half as many, $3{,}454$ steps, at the optimal fixed step $\eta = 2/(\mu+L)$. This is half of the $6{,}908$ steps that Section 35.1 counted at the same step for six digits in the distance. One factor of two came from the looseness of our proof, and the second from doubling the step size.

35.3.4 Recognizing Convexity

Global optimality and clean convergence rates are useful only if we can tell whether a given loss function is convex in the first place. Computing Hessians by hand quickly becomes tedious (and fails altogether at kinks), so in practice we rarely check convexity from scratch. Instead, we recognize convex objectives by assembling them from simple convex building blocks.

35.3.4.1 A Calculus of Convex Functions

Four elementary operations preserve convexity, and almost every convex loss in machine learning is built from basic convex atoms using just these four rules.

1. **Nonnegative weighted sums.** If $f_1, \dots, f_m$ are convex and $w_i \geq 0$, then $\sum_i w_i f_i$ is convex: simply multiply the chord inequality for each f_i by w_i and add. In particular, averaging a convex per-example loss over a training set always yields a convex objective.

2. **Affine pre-composition.** If f is convex, then so is $\mathbf{x} \mapsto f(\mathbf{A}\mathbf{x} + \mathbf{b})$: an affine map carries the line segment between $\mathbf{x}$ and $\mathbf{y}$ onto the segment between their images with the exact same weight θ, so the chord inequality transfers directly. As a result, any loss that is convex in a model's *predictions* is automatically convex in the *weights of a linear model* producing those predictions.

3. **Pointwise maximum and supremum.** If every f_i is convex, then so is $\max_i f_i$. The quickest proof uses epigraphs: the epigraph of a pointwise maximum is the intersection of the individual epigraphs, and intersections of convex sets are convex. Consequently, the upper envelope of any collection of affine functions is convex, no matter how large the collection.

4. **Monotone composition.** If g is convex and h is both convex *and nondecreasing*, then the composition $h \circ g$ is convex. Two lines prove it:

$$h(g(\theta\mathbf{x} + (1-\theta)\mathbf{y})) \;\leq\; h(\theta g(\mathbf{x}) + (1-\theta) g(\mathbf{y})) \;\leq\; \theta\, h(g(\mathbf{x})) + (1-\theta)\, h(g(\mathbf{y})),$$

   where the first inequality uses convexity of g together with monotonicity of h, and the second uses convexity of h. Do not forget the monotonicity requirement on h: $h(t) = t^2$ is convex but not nondecreasing, and composing it with the convex function $g(x) = x^2 - 1$ produces the nonconvex double well $(x^2-1)^2$ (which becomes ϕ after adding $x/2$).

These four rules certify nearly all the standard convex losses in one sweep. The hinge loss $\max(0, 1 - y\,\mathbf{w}^\top \mathbf{x})$ is the maximum of two affine functions of $\mathbf{w}$ (rules 3 and 2). The ℓ_1 norm $\|\mathbf{w}\|_1 = \sum_i \max(w_i, -w_i)$ is a sum of maxima of affine functions (rules 1, 3, and 2).

The logistic loss $\log(1 + e^{-y\,\mathbf{w}^\top \mathbf{x}})$ starts from the scalar function $t \mapsto \log(1 + e^t)$—convex because its second derivative $e^t/(1 + e^t)^2$ is strictly positive—pre-composed with an affine map (rule 2) and summed over training examples (rule 1). Adding the ridge penalty $\frac{\lambda}{2}\|\mathbf{w}\|^2$ to any of these produces a strongly convex objective. Notice, however, that convexity does not automatically upgrade to strong convexity under rule 3: $\max(x^2, 1 - x)$ is convex, yet it equals the flat affine line $1 - x$ across the entire interval $(-1.618, 0.618)$ between the two roots of $x^2 = 1 - x$, so it is not strongly convex.

Notice what is conspicuously absent from our list: composition with an inner map that is neither affine nor convex. A two-layer neural network $\mathbf{W}_2\,\mathrm{relu}(\mathbf{W}_1\mathbf{x})$ is precisely such a composition in its weights, which is the exact point where convexity breaks down (Section 35.3.5).

35.3.4.2 Log-Sum-Exp and the Softmax Covariance

One fundamental loss sits just outside the four rules above: the log-sum-exp function $\mathrm{lse}(\mathbf{x}) = \log \sum_{i=1}^{d} e^{x_i}$ at the heart of every softmax cross-entropy loss. Geometrically, $\mathrm{lse}(\mathbf{x})$ is a smooth upper approximation to $\max_i x_i$ that never overshoots it by more than $\log d$. Rather than force it into the composition rules, we can certify its convexity directly through its Hessian—which turns out to have a remarkably clean probabilistic interpretation.

Proposition (log-sum-exp is convex). *The Hessian of* lse *at* $\mathbf{x}$ *is*

$$\nabla^2 \mathrm{lse}(\mathbf{x}) = \mathrm{diag}(\mathbf{s}) - \mathbf{s}\mathbf{s}^\top, \qquad \mathbf{s} = \mathrm{softmax}(\mathbf{x}), \tag{35.34}$$

which is the covariance matrix of the one-hot encoding of a class drawn from $\mathbf{s}$*. Since every covariance matrix is PSD,* lse *is convex.*

Proof. Differentiating once gives $\partial\,\mathrm{lse}/\partial x_i = e^{x_i}/\sum_k e^{x_k} = s_i$, so the gradient of lse is simply the softmax vector $\mathbf{s}$. Differentiating $s_i = e^{x_i}/\sum_k e^{x_k}$ a second time by the quotient rule yields

$$\frac{\partial s_i}{\partial x_j} = \frac{\delta_{ij}\, e^{x_i}}{\sum_k e^{x_k}} - \frac{e^{x_i}\, e^{x_j}}{\left(\sum_k e^{x_k}\right)^2} = s_i\,(\delta_{ij} - s_j),$$

which is the (i, j) entry of $\mathrm{diag}(\mathbf{s}) - \mathbf{s}\mathbf{s}^\top$ (the same softmax Jacobian derived in Section 34.4). Now let Y be a random class index drawn with probabilities $P(Y = i) = s_i$, and let $\mathbf{e}_Y$ be its one-hot vector. Then $\mathbb{E}[\mathbf{e}_Y] = \mathbf{s}$ and $\mathbb{E}[\mathbf{e}_Y \mathbf{e}_Y^\top] = \mathrm{diag}(\mathbf{s})$, so the Hessian is literally $\mathrm{Cov}(\mathbf{e}_Y) = \mathrm{diag}(\mathbf{s}) - \mathbf{s}\mathbf{s}^\top$. Every covariance matrix is PSD; explicitly, for any direction $\mathbf{v}$,

$$\mathbf{v}^\top \nabla^2 \mathrm{lse}(\mathbf{x})\,\mathbf{v} = \sum_i s_i v_i^2 - \left(\sum_i s_i v_i\right)^2 = \mathbb{E}\left[v_Y^2\right] - \left(\mathbb{E}[v_Y]\right)^2 = \mathrm{Var}(v_Y) \;\geq\; 0. \;\blacksquare$$

In other words, the curvature of log-sum-exp along a direction $\mathbf{v}$ is nothing more than the variance of the coordinate v_Y under the softmax distribution.

Three practical consequences follow immediately from this formula. First, the cross-entropy loss as a function of the logits, $\ell(\mathbf{z}) = \operatorname{lse}(\mathbf{z}) - z_y$ for true class y, is log-sum-exp minus a linear term, hence convex. Second, softmax regression (Section 3.1) feeds affine logits $\mathbf{z} = \mathbf{W}\mathbf{x} + \mathbf{b}$ into $\ell(\mathbf{z})$, so by rule 2 the loss is convex in the weights: training a linear classifier on fixed features is always a convex problem. Third, the variance formula immediately predicts a *zero* eigenvalue along the all-ones vector $\mathbf{1}$, because $\operatorname{Var}(v_Y) = 0$ whenever all entries v_i are equal. That flat direction reflects the shift invariance $\operatorname{lse}(\mathbf{x} + c\mathbf{1}) = \operatorname{lse}(\mathbf{x}) + c$ that makes the numerically stable softmax possible. The very same Jacobian $\operatorname{diag}(\mathbf{s}) - \mathbf{s}\mathbf{s}^\top$ also governs the backward pass of every attention head, whose attention weights are a softmax of query–key scores (Section 10.2).

How large can the curvature of log-sum-exp get? As Exercise 6 proves, no eigenvalue of its Hessian ever exceeds $\frac{1}{2}$, regardless of the logits, so $\frac{1}{2}$ is a global smoothness constant. Where is that ceiling approached, and how curved is the loss at typical logits? Below, we draw $10{,}000$ random six-class logit vectors, rescale them by a temperature multiplier c, and report both the largest Hessian eigenvalue across all draws and the median.

```
z = rng.normal(size=(10_000, 6))              # 10,000 draws of six logits
print('  c   largest eigenvalue   median')
for c in (0.1, 1.0, 3.0, 10.0, 30.0):
    s = np.exp(c * z - (c * z).max(axis=1, keepdims=True))
    s /= s.sum(axis=1, keepdims=True)         # softmax of each row
    hess = s[:, :, None] * np.eye(6) - s[:, :, None] * s[:, None, :]
    top = np.linalg.eigvalsh(hess)[:, -1]     # largest eigenvalue per draw
    print(f'{c:5.1f}  {top.max():14.4f}  {np.median(top):12.4f}')
```

```
  c   largest eigenvalue   median
  0.1          0.2212        0.1845
  1.0          0.4539        0.3077
  3.0          0.4988        0.2944
 10.0          0.5000        0.0143
 30.0          0.5000        0.0000
```

As predicted, the largest eigenvalue never exceeds $\frac{1}{2}$, confirming that softmax cross-entropy is $\frac{1}{2}$-smooth in the logits at every temperature. When the logits are small ($c = 0.1$), the softmax is nearly uniform across the six classes and the curvature hovers just above $\frac{1}{6}$. At moderate scales, the typical curvature peaks with a median near 0.3. Push c larger, however, and a split emerges: a typical draw becomes sharply confident (nearly one-hot), so its median curvature collapses toward zero—the loss is almost completely flat around a confident prediction. Meanwhile, the *maximum* over the $10{,}000$ draws climbs toward $\frac{1}{2}$, coming from the rare draws where the top two logits nearly tie and the softmax splits its probability evenly between two classes.

35.3.5 Beyond Convexity

Deep neural networks do not have convex loss landscapes. In this final subsection we show why with just two scalar weights, identify the weaker condition that preserves gradient descent's linear convergence rate without convexity, and ask how an optimizer chooses a single solution when infinitely many global minimizers exist.

35.3.5.1 Nonconvex Networks

Consider $f(a,b) = (ab-1)^2$: a linear model with two scalar weights stacked in sequence under a squared loss—the simplest possible "deep" network. As Figure 35.14 shows, its global minimizers form the hyperbola $\{ab = 1\}$. We proved in Section 35.3.3 that the minimizer set of any convex function must be convex, yet a hyperbola is manifestly not convex: the midpoint of the two minimizers $(1,1)$ and $(-1,-1)$ is the origin $(0,0)$, where $f(0,0) = 1$ sits well above the minimum value 0. The origin is a stationary point, not a minimum—its Hessian $\nabla^2 f(0,0)$ has eigenvalues ± 2, making it a saddle point.

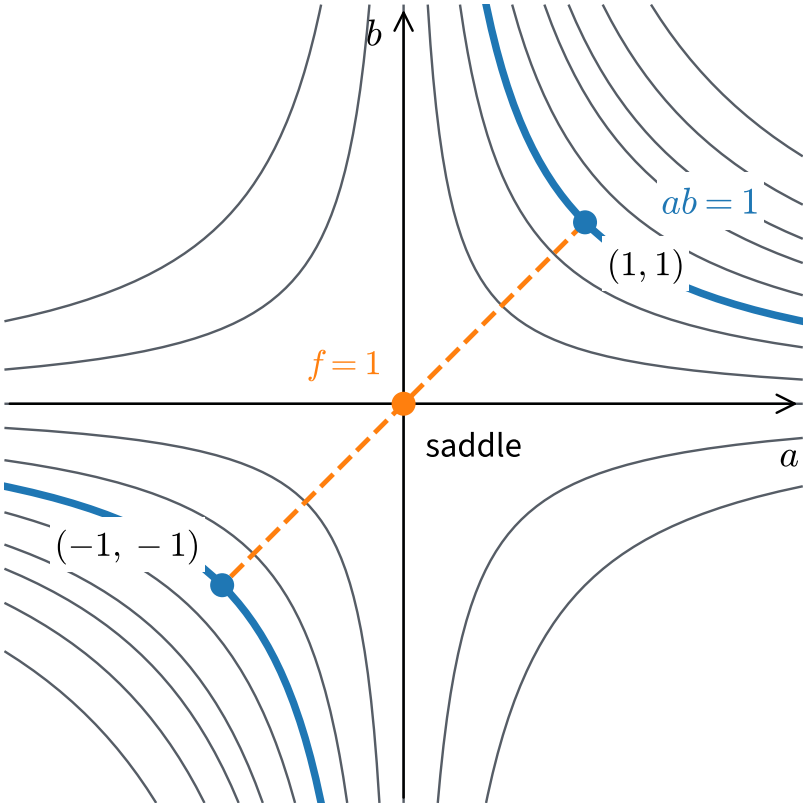


Figure 35.14: The two-weight model $(ab-1)^2$. Its minimizers form the hyperbola $ab = 1$, which is not convex: the midpoint of $(1,1)$ and $(-1,-1)$ is the origin, where $f = 1$ and the Hessian has eigenvalues ± 2.

Real neural networks lose convexity for a closely related structural reason. Permuting the hidden units of any layer—together with their incoming and outgoing weights—leaves the network's input–output function unchanged, so every minimizer automatically comes with a huge number of symmetric copies scattered across parameter space. Generically these copies are distinct, and averaging two of them alters the function and raises the loss, just as averaging $(1,1)$ and $(-1,-1)$ landed on the saddle at the origin. A minimizer set that contains distinct points without containing their midpoints cannot belong to a convex objective.

Even a tiny network with two ReLU units already exhibits this failure. The parameter vector

$(w_1, v_1, w_2, v_2) = (1, 1, -1, 1)$ in $v_1 \operatorname{relu}(w_1 x) + v_2 \operatorname{relu}(w_2 x)$ computes $|x|$, and swapping the two units computes $|x|$ identically. Yet averaging the two parameter vectors cancels the input weights to zero and collapses the network to the zero function.

35.3.5.2 The Polyak–Łojasiewicz Condition

Remember how our proof of the linear convergence rate under strong convexity worked? It used convexity *only* in the first step, to derive Equation 35.33; the second step never touched convexity at all. That intermediate inequality has a name of its own. A function f with infimum $f^\star$ satisfies the **Polyak–Łojasiewicz (PL) inequality** with constant $\mu > 0$ if $\frac{1}{2}\|\nabla f(\mathbf{x})\|^2 \geq \mu\,(f(\mathbf{x}) - f^\star)$ for all $\mathbf{x}$, a condition introduced independently by Polyak and Łojasiewicz in 1963 (Polyak 1963; Łojasiewicz 1963). Intuitively, it says that the gradient is allowed to be small only where the loss is already close to optimal.

Proposition (linear rate under PL). *Let f be L-smooth, bounded below with $f^\star = \inf f$, and satisfy the PL inequality with constant μ. Then gradient descent with $\eta = 1/L$ satisfies $f(\mathbf{x}_k) - f^\star \leq (1 - \mu/L)^k\,(f(\mathbf{x}_0) - f^\star)$.*

Proof. Repeat the second half of the strong-convexity proof verbatim: combining the descent lemma with the PL inequality yields $f(\mathbf{x}_{k+1}) - f^\star \leq (1 - \mu/L)(f(\mathbf{x}_k) - f^\star)$ (Karimi et al. 2016), and iterating k times finishes the proof. ■

What makes the PL condition so appealing is how much nonconvexity it tolerates. A PL function can have multiple minimizers, flat manifolds of minimizers, and regions of negative curvature. Two things, however, are non-negotiable: every stationary point must be a global minimizer (since $\nabla f(\mathbf{x}) = \mathbf{0}$ forces $f(\mathbf{x}) = f^\star$), *and* $f - f^\star$ must grow at least quadratically away from the minimizer set. The quartic x^4 shows why the second requirement matters: it has only one stationary point, its global minimum, yet it fails PL because $\frac{1}{2}f'(x)^2 = 8x^6$ cannot stay above μx^4 as $x \to 0$ for any $\mu > 0$. That failure is precisely why gradient descent crawled on x^4 in Section 35.3.3.3. In short, strong convexity implies PL (as we proved earlier), but the converse is false.

The classic example of a nonconvex PL function is $f(x) = x^2 + 3\sin^2 x$, whose second derivative $2 + 6\cos 2x$ dips all the way to -4 and peaks at $L = 8$. Let us estimate its PL constant numerically on $[-5, 5]$ and run gradient descent from $x_0 = 4.5$ using step size $\eta = \frac{1}{16} = 1/(2L)$. (We choose $1/(2L)$ rather than $1/L$ because at $\eta = 1/L$ the local contraction factor $1 - f''(0)\,\eta$ vanishes at the origin, hiding the asymptotic rate.) At $\eta = 1/(2L)$, the quadratic ceiling guarantees a per-step decrease of $\frac{3}{8L}f'(x_k)^2$, which the PL inequality turns into the contraction factor $1 - \frac{3\mu}{4L}$.

```
f_pl = lambda x: x**2 + 3 * np.sin(x)**2       # nonconvex; f* = 0 at x = 0
df_pl = lambda x: 2 * x + 3 * np.sin(2 * x)
xs = np.linspace(-5, 5, 100001)
xs = xs[np.abs(xs) > 1e-3]                     # avoid 0/0 at the minimizer
mu = (0.5 * df_pl(xs)**2 / f_pl(xs)).min()
print(f'PL constant on [-5, 5]: mu = {mu:.4f}')
print(f"min f'' = {(2 + 6 * np.cos(2 * xs)).min():.2f}  (f is not convex)")
path = [4.5]
for _ in range(80):                            # gradient descent, eta = 1/16
    path.append(path[-1] - df_pl(path[-1]) / 16.0)
path = np.array(path)
```

```
ratios = f_pl(path[1:]) / f_pl(path[:-1])      # per-step contraction of f - f*
j = ratios.argmax()
print(f'guaranteed {1 - 3 * mu / 32:.4f}; largest ratio {ratios[j]:.4f}'
      f' from x = {path[j]:.2f}; last ratio {ratios[-1]:.4f}')
```

```
PL constant on [-5, 5]: mu = 0.1755
min f'' = -4.00  (f is not convex)
guaranteed 0.9835; largest ratio 0.9778 from x = 2.19; last ratio 0.2500
```

The PL constant on $[-5, 5]$ is $\mu \approx 0.1755$, and the minimum of f'' is -4: the function is nonconvex yet PL. The window suffices, because outside it the ratio $\frac{1}{2}f'(x)^2/f(x)$ stays well above this value and tends to 2 as $|x| \to \infty$; Exercise 4 proves the bound.

With this μ the guaranteed factor is about 0.98 per step. The largest measured ratio, about 0.978, comes from $x \approx 2.2$, where $\frac{1}{2}f'(x)^2/f(x)$ attains its minimum μ, so there the guarantee is nearly tight. Near the minimizer the ratio settles at 0.25. That limit comes from the local quadratic: near 0, $f \approx \frac{1}{2}f''(0)\,x^2$ with $f''(0) = 8$, each step multiplies x by $1 - 8/16 = \frac{1}{2}$, and the gap, quadratic in x, by $\frac{1}{4}$.

PL can also hold on part of the space. For $(ab-1)^2$ the gradient satisfies $\frac{1}{2}\|\nabla f\|^2 = 2(a^2 + b^2)f$, so PL holds with constant $2r^2$ on the region $\{a^2 + b^2 \geq r^2\}$ and with no constant near the saddle at the origin. Analyses of wide networks establish such local PL inequalities near interpolating solutions (C. Liu et al. 2022), which gives a rate for the training loss and says nothing about generalization.

35.3.5.3 Implicit Bias

When a loss has many global minimizers, convex or not, the optimizer decides which one it reaches: it has an **implicit bias**. For deep learning this is not a curiosity. A network with more weights than training examples can fit its data in many ways, all with the same training loss and with different predictions elsewhere, so the choice among them decides how the model generalizes. The simplest case is underdetermined least squares, with fewer examples than weights and $\mathbf{X}$ of full row rank. Every gradient $\mathbf{X}^\top(\mathbf{X}\mathbf{w} - \mathbf{y})$ lies in the row space of $\mathbf{X}$, so iterates started from $\mathbf{w}_0 = \mathbf{0}$ never leave it. The limit is therefore the one interpolant in the row space, the *minimum-norm* interpolant that the pseudoinverse computes (Exercise 4 of Section 33.5). For logistic regression on separable data the loss has no minimizer at all, yet the direction of the iterates converges to the maximum-margin separator, the solution of the hard-margin support vector machine (Soudry et al. 2018) (Exercise 8). Which minimizer is selected depends on the model, the loss, the start, and the update rule. A fixed diagonal preconditioner $\mathbf{D}$, for instance, leads to the interpolant that minimizes $\mathbf{w}^\top\mathbf{D}^{-1}\mathbf{w}$ instead of $\|\mathbf{w}\|^2$ (Exercise 7), so the per-coordinate steps of Adam (Section 9.5) need not select the solution that gradient descent selects.

Every result of this section assumes the exact gradient and weights free to range over all of $\mathbb{R}^d$. Training uses minibatch gradients that are right only on average (Section 35.4), and a weight vector confined to a ball, a simplex, or a half-space needs the projections and multipliers of Section 35.6.

35.3.6 Summary

A convex function lies below its chords. For differentiable functions this is equivalent to lying above every tangent, and for twice-differentiable functions to a PSD Hessian; at a corner a subgradient takes the place of the gradient. Because one gradient bounds the function everywhere, a stationary point is a global minimizer, and the descent lemma turns into global rates for gradient descent: $L\|\mathbf{x}_0 - \mathbf{x}^\star\|^2/(2k)$ for smooth convex f, and a factor $1 - \mu/L$ per step with strong convexity, hence about $\kappa \log(1/\epsilon)$ steps. Jensen's inequality is the chord inequality for expectations and gives $D_{\mathrm{KL}} \geq 0$. Four closure rules certify the hinge, ℓ_1, and logistic losses; log-sum-exp, and with it the softmax cross-entropy, is convex because its Hessian is a covariance. Network losses are generically nonconvex. Where a PL inequality holds, the linear rate survives without convexity, and among many minimizers the optimizer's dynamics pick one.

35.3.7 Exercises

1. **Subdifferentials of norms and maxima.** Compute each subdifferential from the definition Equation 35.28.
    1. Compute $\partial\|\mathbf{x}\|_2$ at every $\mathbf{x} \in \mathbb{R}^d$, including $\mathbf{x} = \mathbf{0}$.
    2. Let $f(\mathbf{x}) = \max_i x_i$, and let $\mathcal{A}(\mathbf{x}) = \{i : x_i = f(\mathbf{x})\}$ be its set of active coordinates. Show that $\partial f(\mathbf{x})$ is the convex hull of $\{\mathbf{e}_i : i \in \mathcal{A}(\mathbf{x})\}$. Backpropagation through max pooling passes the incoming gradient to a single maximal input, so it uses one vertex $\mathbf{e}_i$ of this hull. Suppose that two or more inputs tie. Show that a small step along $-\mathbf{e}_i$ does not decrease f. For which $\mathbf{g} \in \partial f(\mathbf{x})$ is $-\mathbf{g}$ a descent direction, and which of them makes the directional derivative of f along $-\mathbf{g}/\|\mathbf{g}\|$ most negative?
    3. Use (a) and the optimality criterion $\mathbf{0} \in \partial(\cdot)$ to minimize $\lambda\|\mathbf{w}\|_2 + \frac{1}{2}\|\mathbf{w} - \mathbf{z}\|^2$ over $\mathbf{w} \in \mathbb{R}^d$, which gives the proximal operator of $\lambda\|\cdot\|_2$. Compare the zero pattern of the solution with that of coordinatewise soft-thresholding, $w_i = \operatorname{sign}(z_i)\max(|z_i| - \lambda, 0)$. What does this penalty do when $\mathbf{w}$ collects the outgoing weights of one hidden unit?

2. **Convex combinations and Jensen's inequality.** Write $\sum_{i=1}^N \theta_i \mathbf{x}_i$ with $\theta_i \geq 0$ and $\sum_i \theta_i = 1$ for a convex combination of N points.
    1. Show by induction on N that a convex set C contains every convex combination of points of C. This is the inclusion that completes the description of the convex hull in Section 35.3.1.
    2. Apply (a) to the epigraph of a convex function f to derive the finite form Equation 35.29 of Jensen's inequality.
    3. Let f be twice differentiable with $\alpha \leq f'' \leq \beta$ on an interval that contains the values of a random variable Z with mean m and variance s^2. Show that the Jensen gap $\mathbb{E}[f(Z)] - f(m)$ lies between $\alpha s^2/2$ and $\beta s^2/2$. Check the bounds on the two-point example of the text, $Z \in \{0, 2\}$ with $f(x) = x^2$, where $\alpha = \beta = 2$. Then apply the result to $f = -\log$ to bound $\log \mathbb{E}[Z] - \mathbb{E}[\log Z]$ for Z with values in $[a, b] \subset (0, \infty)$.

3. **Existence of minimizers.** Let $\ell(\mathbf{w}) = \sum_i \log(1 + e^{-y_i \mathbf{w}^\top \mathbf{x}_i})$ be the logistic loss of labels $y_i \in \{\pm 1\}$, and let $\mathbf{X}$ be the matrix with rows $\mathbf{x}_i^\top$. The uniqueness proposition of Section 35.3.3 states that a strictly convex function has at most one minimizer, and

that a continuous, strongly convex function on a nonempty closed convex set with nonempty interior has exactly one.

1. Suppose that some $\mathbf{w}$ satisfies $y_i \mathbf{w}^\top \mathbf{x}_i > 0$ for every i, that is, the data are linearly separable by a hyperplane through the origin. Show that $\inf_{\mathbf{w}} \ell(\mathbf{w}) = 0$ and that ℓ has no minimizer.
2. Show that ℓ is strictly convex whenever $\mathbf{X}$ has full column rank. Why does this not contradict (a)?
3. Show that $\ell(\mathbf{w}) + \frac{\lambda}{2}\|\mathbf{w}\|^2$ has exactly one minimizer for every $\lambda > 0$ and every dataset. Which hypothesis of the uniqueness proposition does the penalty supply?

4. **The PL condition beyond convexity.** The cell that studies $f(x) = x^2 + 3\sin^2 x$ measures its PL constant $\mu \approx 0.1755$ on the window $[-5, 5]$.

   1. Bound $|f'(x)|$ from below and $f(x)$ from above for $|x| \geq 5$. Conclude that the PL inequality Equation 35.33 holds on all of $\mathbb{R}$ with the constant measured on the window.
   2. Let $\mathbf{X} \in \mathbb{R}^{n \times d}$ with $n < d$ have full row rank, and let $f(\mathbf{w}) = \frac{1}{2}\|\mathbf{X}\mathbf{w} - \mathbf{y}\|^2$. Show that f is not strongly convex and has infinitely many minimizers, but satisfies the PL inequality with $\mu = \lambda_{\min}(\mathbf{X}\mathbf{X}^\top)$, the smallest eigenvalue of $\mathbf{X}\mathbf{X}^\top$. Which linear rate does gradient descent with $\eta = 1/L$ then achieve, and how is L related to $\mathbf{X}\mathbf{X}^\top$?

5. code **Contraction of the distance.** ● The rate Equation 35.32 guarantees the per-step factor $1 - \mu/L$ for $f - f^\star$, but the rate-check cell measures $(1 - \mu/L)^2$. Let f be twice continuously differentiable with $\mu \mathbf{I} \preceq \nabla^2 f \preceq L\mathbf{I}$, and let $\mathbf{x}_{k+1} = \mathbf{x}_k - \eta \nabla f(\mathbf{x}_k)$. Two facts from Section 35.1 are used: the quadratic ceiling $f(\mathbf{y}) \leq f(\mathbf{x}) + \nabla f(\mathbf{x})^\top (\mathbf{y} - \mathbf{x}) + \frac{L}{2}\|\mathbf{y} - \mathbf{x}\|^2$ and the step $\eta^\star = 2/(\mu + L)$, the best fixed step on a quadratic.

   1. Write $\nabla f(\mathbf{x}_k) = \bar{\mathbf{H}}_k (\mathbf{x}_k - \mathbf{x}^\star)$ with $\bar{\mathbf{H}}_k = \int_0^1 \nabla^2 f(\mathbf{x}^\star + s(\mathbf{x}_k - \mathbf{x}^\star))\, ds$. Show that

   $$\|\mathbf{x}_{k+1} - \mathbf{x}^\star\| \leq \max(|1 - \eta\mu|,\ |1 - \eta L|)\, \|\mathbf{x}_k - \mathbf{x}^\star\|. \tag{35.35}$$

   2. Set $\eta = 1/L$ and $\kappa = L/\mu$. Combine (a) with the lower bound Equation 35.27 and the quadratic ceiling, both taken at $\mathbf{x}^\star$, to show that $f(\mathbf{x}_k) - f^\star \leq \kappa\,(1 - \mu/L)^{2k}\,(f(\mathbf{x}_0) - f^\star)$. From which k on is this bound stronger than Equation 35.32?
   3. Predict the per-step contraction of $f - f^\star$ on the $\kappa = 10$ design of the rate-check cell at $\eta^\star = 2/11$. (Hint: both eigen-components are multiplied by numbers of absolute value $9/11$.) Verify the prediction by changing the step in that cell, and explain why, unlike at $\eta = 1/L$, the first ratio is no longer special.

6. **Smoothing the maximum.** ● A maximum of affine functions, the shape of hinge-type and worst-case objectives, has a kink wherever two of its pieces tie. For a temperature $\tau > 0$, let $\mathrm{lse}_\tau(\mathbf{z}) = \tau \,\mathrm{lse}(\mathbf{z}/\tau)$ for $\mathbf{z} \in \mathbb{R}^m$. This smoothing technique is due to Nesterov (2005) .

   1. Show that $\max_j z_j \leq \mathrm{lse}(\mathbf{z}) \leq \max_j z_j + \log m$, and conclude that $\max_j z_j \leq \mathrm{lse}_\tau(\mathbf{z}) \leq \max_j z_j + \tau \log m$.

2. Use Equation 35.34 to show that the largest eigenvalue of $\nabla^2 \mathrm{lse}_\tau(\mathbf{z})$ is at most $1/(2\tau)$, by bounding $\mathrm{Var}(v_Y)$ by $\mathbb{E}[(v_Y - c)^2]$ for a well-chosen constant c. Is the bound attained?

3. Let $F(\mathbf{w}) = \max_j (\mathbf{A}\mathbf{w} + \mathbf{r})_j$ and $F_\tau(\mathbf{w}) = \mathrm{lse}_\tau(\mathbf{A}\mathbf{w} + \mathbf{r})$, and assume that F_τ has a minimizer within distance R of $\mathbf{w}_0$. Show with (b) that F_τ is L-smooth for $L = \|\mathbf{A}\|_2^2/(2\tau)$, and that k steps of gradient descent on F_τ with $\eta = 1/L$ give

$$F(\mathbf{w}_k) - \min F \le \tau \log m + \frac{\|\mathbf{A}\|_2^2 R^2}{4\tau k}. \tag{35.36}$$

Choose τ to minimize this bound, and give the number of steps that guarantees accuracy ϵ. How does the count change when an accelerated method with error $O(LR^2/k^2)$ replaces gradient descent?

7. code **Implicit bias and the optimizer.** ● Exercise 4 of Section 33.5 shows on paper that gradient descent on $\frac{1}{2}\|\mathbf{X}\mathbf{w} - \mathbf{y}\|^2$, for $\mathbf{X} \in \mathbb{R}^{n \times d}$ with $n < d$ and full row rank, started at $\mathbf{w}_0 = \mathbf{0}$, stays in the row space of $\mathbf{X}$ and converges to the minimum-norm interpolant $\mathbf{X}^+\mathbf{y}$. Here the start stays at $\mathbf{w}_0 = \mathbf{0}$ and the algorithm changes. Take a random 4×10 system, and compare the limit of each method and its norm with `np.linalg.pinv(X) @ y`.

   1. Run gradient descent with $\eta = 1/\lambda_{\max}(\mathbf{X}^\top\mathbf{X})$, and track the norm of the component of $\mathbf{w}_k$ orthogonal to the row space, computed with the projector $\mathbf{I} - \mathbf{X}^+\mathbf{X}$.
   2. Heavy-ball momentum updates $\mathbf{w}_{k+1} = \mathbf{w}_k - \eta\nabla f(\mathbf{w}_k) + \beta(\mathbf{w}_k - \mathbf{w}_{k-1})$. Show that its iterates stay in the row space, and predict their limit. Verify the prediction with the step of (a) and $\beta = 0.9$.
   3. Replace the update by the diagonally preconditioned step $\mathbf{w}_{k+1} = \mathbf{w}_k - \eta\,\mathbf{D}\mathbf{X}^\top(\mathbf{X}\mathbf{w}_k - \mathbf{y})$, where $\mathbf{D}$ is a fixed diagonal matrix with entries drawn uniformly from $[0.1, 10]$ and $\eta = 1/\lambda_{\max}(\mathbf{D}^{1/2}\mathbf{X}^\top\mathbf{X}\mathbf{D}^{1/2})$. Use the substitution $\mathbf{u} = \mathbf{D}^{-1/2}\mathbf{w}$ to find the limit in closed form, and verify it numerically. Is the limit still the minimum-norm interpolant? What does this suggest about the implicit bias of adaptive methods such as Adam (Section 9.5), whose per-coordinate step sizes act like $\mathbf{D}$?
   4. Run exact cyclic coordinate descent for 1000 sweeps, with $\mathbf{A} = \mathbf{X}^\top\mathbf{X}$, $\mathbf{b} = \mathbf{X}^\top\mathbf{y}$, and the update $w_j \leftarrow (b_j - \sum_{i \ne j} A_{ji} w_i)/A_{jj}$ for $j = 1, \dots, d$ in turn. Check that the limit interpolates the data. Is it the minimum-norm interpolant, and which step of the row-space argument fails? Repeat the run three times with coordinates drawn uniformly at random. Does the limit depend on the draw?

8. [extended] **Max-margin bias of gradient descent.** ●● On data that a hyperplane through the origin separates, the logistic loss has no minimizer (part (a) of Exercise 3). Soudry et al. (2018) prove that gradient descent on it nevertheless diverges in a definite direction: the iterates satisfy $\mathbf{w}_k = \hat{\mathbf{w}} \log k + \rho_k$, with ρ_k bounded for almost every dataset, where

$$\hat{\mathbf{w}} = \operatorname*{argmin}_{\mathbf{w}} \|\mathbf{w}\| \quad \text{subject to} \quad y_i \mathbf{w}^\top \mathbf{x}_i \ge 1 \text{ for all } i \tag{35.37}$$

is the hard-margin SVM solution, with margin $\gamma = 1/\|\hat{\mathbf{w}}\|$. The vector $\hat{\mathbf{w}}$ is characterized by $\hat{\mathbf{w}} = \sum_i \alpha_i y_i \mathbf{x}_i$ with $\alpha_i \ge 0$, where $\alpha_i = 0$ unless $y_i \hat{\mathbf{w}}^\top \mathbf{x}_i = 1$; the points

with equality are the support vectors.

1. Derive the direction heuristically. Replace the logistic loss by its tail e^{-q} in the margin $q = y_i \mathbf{w}^\top \mathbf{x}_i$, and suppose that $\mathbf{w}_k = g(k)\,\mathbf{u} + O(1)$ with $\|\mathbf{u}\| = 1$ and $g(k) \to \infty$. Show that the negative gradient is asymptotically a nonnegative combination of the points $y_i \mathbf{x}_i$ of smallest margin $y_i \mathbf{u}^\top \mathbf{x}_i$. Conclude that $\mathbf{u}$ is proportional to $\hat{\mathbf{w}}$.
2. Derive the growth rate. Keep only the support vectors in the gradient flow $\dot{\mathbf{w}} = -\nabla \ell(\mathbf{w})$, show that $\dot{g} \approx c\, e^{-\gamma g}$ for a constant $c > 0$, and conclude that $\|\mathbf{w}(t)\| \approx \|\hat{\mathbf{w}}\| \log t$.
3. Take the support vectors $\mathbf{x}_1 = (0.5, 1.5)$ and $\mathbf{x}_2 = (1.5, 0.5)$ with label $+1$, their negatives with label -1, and 12 random points, 6 per class, with $y_i \hat{\mathbf{w}}^\top \mathbf{x}_i > 1$ for $\hat{\mathbf{w}} = (\tfrac{1}{2}, \tfrac{1}{2})$. Let $\mathbf{X}$ be the 16×2 matrix with rows $\mathbf{x}_i^\top$. Run gradient descent on the summed logistic loss from $\mathbf{w}_0 = \mathbf{0}$ with $\eta = 1/\|\mathbf{X}\|_2^2$ for 10^6 steps, which takes seconds in vectorized NumPy. Plot, against k on a logarithmic axis, the norm $\|\mathbf{w}_k\|$, the training loss, the angle between $\mathbf{w}_k$ and $\hat{\mathbf{w}}$, and the margin gap $\gamma - \min_i y_i \mathbf{w}_k^\top \mathbf{x}_i / \|\mathbf{w}_k\|$. Compare the slope of $\|\mathbf{w}_k\|$ against $\log k$ with (b).
4. The training error reaches zero within the first few steps. By what factor do the margin gap and the training loss change between $k = 10^3$ and $k = 10^6$? What does the comparison imply for stopping training as soon as the training error reaches zero?

9. **Convexity of the log-partition function.** This exercise generalizes the log-sum-exp proposition to the log-partition functions that Section 36.4 builds on. For a finite set $\mathcal{X}$, weights $h(x) > 0$, statistics $\mathbf{T}(x) \in \mathbb{R}^p$, and natural parameters $\eta \in \mathbb{R}^p$ (not a step size here), let $A(\eta) = \log \sum_{x \in \mathcal{X}} h(x) \exp(\eta^\top \mathbf{T}(x))$ and $p_\eta(x) = h(x) \exp(\eta^\top \mathbf{T}(x) - A(\eta))$.

   1. Show that $\nabla A(\eta) = \mathbb{E}_\eta[\mathbf{T}]$ and $\nabla^2 A(\eta) = \mathrm{Cov}_\eta[\mathbf{T}]$, with expectation and covariance under p_η.
   2. Conclude that A is convex, and that it is strictly convex if and only if no nonzero $\mathbf{v}$ makes $\mathbf{v}^\top \mathbf{T}(x)$ constant on $\mathcal{X}$.
   3. Recover Equation 35.34 with $\mathcal{X} = \{1, \dots, d\}$, $\mathbf{T}(x) = \mathbf{e}_x$, and $h \equiv 1$, and name the direction in which A is flat.
   4. For observations $x_1, \dots, x_n$ with average statistic $\bar{\mathbf{T}} = \frac{1}{n} \sum_i \mathbf{T}(x_i)$, show that the average negative log-likelihood $A(\eta) - \eta^\top \bar{\mathbf{T}} - \frac{1}{n} \sum_i \log h(x_i)$ is convex in η, and that a minimizer satisfies $\mathbb{E}_\eta[\mathbf{T}] = \bar{\mathbf{T}}$ (moment matching). For the softmax case of (c), why does no minimizer exist when one class is never observed?

35.4 Stochastic Gradient Methods

Training a neural network almost never uses the exact gradient of its loss. Instead of sweeping through the entire dataset for every update, each step computes the gradient on a random minibatch of a few hundred examples. Every section so far assumed exact gradients, where curvature determines the number of steps and convexity turns any stationary point into a global minimizer. A minibatch gradient points in the right direction on average, but it is noisy, and that noise changes the central question of optimization from how many steps a run needs to how close to the minimizer it can get. This section asks what gradient noise costs and how we can overcome it.

Even the simplest possible loss reveals the cost. Consider $f(x) = \frac{1}{2}x^2$, whose minimizer is 0, and suppose we add independent noise of unit variance to every gradient while taking constant steps of size $\eta = 0.1$. With exact gradients, each step would shrink x by a tenth, driving the iterate as close to 0 as we like. With noisy gradients, the iterate never settles: its mean square converges to $0.1/1.9 \approx 0.053$, so it wanders roughly 0.23 away from the minimizer no matter how many steps we take. Three quantities determine how low the loss can get: the size of the noise, the step size, and the number of steps we can afford.

We begin by quantifying the noise of a minibatch gradient. On a quadratic objective, we then compute where a fixed step size stalls and how many steps it takes to get there. Next, we show how decaying step sizes eliminate that stall and what constant a $1/k$ schedule requires, before bounding the error that a constant step tuned to a fixed budget achieves on both convex and nonconvex losses. Finally, we show how to cancel the noise on a finite training set using a stored snapshot gradient. Three takeaways are worth keeping in mind throughout: the noise floor is proportional to the step size, a $1/k$ schedule needs a large enough constant to achieve its rate, and a fixed budget of K steps calls for a step size proportional to $1/\sqrt{K}$. The final subsection on variance reduction can be skipped on a first reading.

35.4.1 Minibatch Gradients

35.4.1.1 The Cost of a Full Gradient

A typical training objective averages the losses of n examples,

$$f(\mathbf{x}) = \frac{1}{n}\sum_{i=1}^{n} f_i(\mathbf{x}),$$

where f_i is the loss on example i and $\mathbf{x} \in \mathbb{R}^d$ holds the model parameters. Because its gradient $\nabla f = \frac{1}{n}\sum_i \nabla f_i$ is also an average, evaluating it touches all n examples. When $n = 10^9$, a single step of gradient descent requires a full pass over the dataset, and gradient descent typically needs thousands of steps. Even on this chapter's running example, $\frac{1}{2}(x_1^2 + 1000\,x_2^2)$, whose curvatures differ by a factor of 1000, the optimal fixed step requires about $7{,}000$ iterations to shrink the error a million-fold (Section 35.1). **Stochastic gradient descent** (SGD) avoids this cost by replacing the full average with the average over a random **minibatch** $\mathcal{B}$ of b indices,

$$\hat{\mathbf{g}}_b(\mathbf{x}) = \frac{1}{b}\sum_{i\in\mathcal{B}} \nabla f_i(\mathbf{x}), \qquad \mathbf{x}_{k+1} = \mathbf{x}_k - \eta_k\,\hat{\mathbf{g}}_b(\mathbf{x}_k). \tag{35.38}$$

Each step now inspects only b examples instead of n: a minibatch of $b = 256$ out of 10^9 examples is roughly four million times cheaper than a full pass. Throughout this section, k indexes optimizer steps, and the step size η_k may vary with k. For our analysis, we draw a fresh minibatch at every step whose b indices are independent and uniform on $\{1, \dots, n\}$ (sampling with replacement). Real training loops usually shuffle the dataset and sample without replacement, which multiplies the gradient variance derived below by $(n-b)/(n-1)$—a factor close to one whenever $b \ll n$ (Section 9.2).

35.4.1.2 Unbiasedness and the $1/b$ Law

How accurate is a minibatch gradient? Two quantities capture its quality: its mean, which tells us whether it points in the right direction on average, and its mean squared distance from the true gradient, which we call its *noise power*. That noise power depends on how widely individual example gradients scatter around their mean, as measured by their covariance matrix.

Proposition (minibatch gradients are unbiased with noise power $\operatorname{tr}\Sigma/b$). *Fix* $\mathbf{x}$ *and let*

$$\Sigma = \frac{1}{n}\sum_{i=1}^{n} \big(\nabla f_i(\mathbf{x}) - \nabla f(\mathbf{x})\big)\big(\nabla f_i(\mathbf{x}) - \nabla f(\mathbf{x})\big)^{\top}$$

be the covariance of a single uniformly drawn example gradient. If the b indices of $\mathcal{B}$ are independent and uniform on $\{1, \dots, n\}$, then

$$\mathbb{E}\big[\hat{\mathbf{g}}_b(\mathbf{x})\big] = \nabla f(\mathbf{x}), \qquad \mathbb{E}\big[\|\hat{\mathbf{g}}_b(\mathbf{x}) - \nabla f(\mathbf{x})\|^2\big] = \frac{\operatorname{tr}\Sigma}{b}. \tag{35.39}$$

Proof. For a single uniform index i, $\mathbb{E}[\nabla f_i(\mathbf{x})] = \frac{1}{n}\sum_i \nabla f_i(\mathbf{x}) = \nabla f(\mathbf{x})$. Every term in the minibatch therefore has mean $\nabla f(\mathbf{x})$, and so does their average. Because the b indices are independent and each term has covariance Σ, the covariance of their sum is $b\Sigma$, and dividing by b scales the covariance by $1/b^2$ to give Σ/b. Finally, the expected squared norm of any mean-zero random vector equals the trace of its covariance matrix. ∎

During optimization, $\mathbf{x}$ is the current iterate $\mathbf{x}_k$ and the minibatch is drawn independently of past steps, so both identities hold conditionally on $\mathbf{x}_k$. Note that unbiasedness depends on uniform sampling: if a sampler draws example i with probability p_i, each gradient must be reweighted by $1/(np_i)$ to keep the estimator unbiased.

Because the noise power decays like $1/b$, its root-mean-square amplitude decays only like $1/\sqrt{b}$: cutting the gradient noise in ten requires a hundred times as many examples per step. Meanwhile, the true gradient signal has squared norm $\|\nabla f\|^2$ regardless of batch size. Signal and noise have equal power at the batch size $b_{\text{noise}} = \operatorname{tr}\Sigma/\|\nabla f\|^2$, which the main text calls the *gradient-noise scale* (Section 9.8); exercise 1 derives its curvature-weighted counterpart.

To see how large this noise is on concrete data, we set up a small logistic-regression problem that we will reuse in the step-size experiment below. It has $n = 200$ examples $\mathbf{a}_i \in \mathbb{R}^5$ with standard normal features, labels $y_i \in \{-1, +1\}$ generated from a logistic model with true weights $(1, -2, 1.5, 0, 2)$, and the regularized loss

$$f(\mathbf{x}) = \frac{1}{n}\sum_{i=1}^{n} \log\big(1 + e^{-y_i \mathbf{a}_i^{\top}\mathbf{x}}\big) + \frac{0.1}{2}\|\mathbf{x}\|^2.$$

The quadratic penalty makes f strongly convex with $\mu \geq 0.1$. The gradient of example i is $\nabla f_i(\mathbf{x}) = -y_i s_i \mathbf{a}_i + 0.1\,\mathbf{x}$, where $s_i = 1/(1 + e^{y_i \mathbf{a}_i^{\top}\mathbf{x}})$ is the probability that the model assigns to the wrong label. The cell below generates the dataset and defines the loss together with a vectorized helper returning all n per-example gradients as the rows of an $n \times d$ matrix.

```
n, d, reg = 200, 5, 0.1                          # examples, parameters, l2 weight
x_true = np.array([1.0, -2.0, 1.5, 0.0, 2.0])
rng = np.random.default_rng()
A = rng.normal(size=(n, d))                       # row i: the features a_i
y = np.where(rng.random(n) < 1 / (1 + np.exp(-A @ x_true)), 1.0, -1.0)

def loss(x, A, y, reg):
    """The regularized logistic loss f(x)."""
    return np.mean(np.log1p(np.exp(-y * (A @ x)))) + 0.5 * reg * x @ x

def example_grads(x, A, y, reg):
    """The n x d matrix whose row i is the gradient of f_i at x."""
    s = 1 / (1 + np.exp(y * (A @ x)))             # probability of the wrong label
    return -(y * s)[:, None] * A + reg * x
```

Since the proposition is exact, simulation serves mainly as a sanity check and to show the actual scale of $\operatorname{tr}\Sigma$ on this problem. Below, we evaluate $10{,}000$ random minibatches of each size at $\mathbf{x} = \mathbf{0}$ and compare the empirical error against $\operatorname{tr}\Sigma/b$.

```
G = example_grads(np.zeros(d), A, y, reg)        # per-example gradients at x = 0
g = G.mean(axis=0)                                # the full gradient
tr_sigma = ((G - g)**2).sum(axis=1).mean()
print(f'tr Sigma = {tr_sigma:.3f}')
for b in [1, 4, 16, 64]:
    idx = rng.integers(0, n, size=(10000, b))    # minibatches, with replacement
    err = ((G[idx].mean(axis=1) - g)**2).sum(axis=1).mean()
    print(f'b = {b:2d}: measured {err:.4f}, tr Sigma / b = {tr_sigma / b:.4f}, '
          f'ratio {err * b / tr_sigma:.3f}')
```

```
tr Sigma = 1.090
b =  1: measured 1.1006, tr Sigma / b = 1.0898, ratio 1.010
b =  4: measured 0.2723, tr Sigma / b = 0.2724, ratio 1.000
b = 16: measured 0.0682, tr Sigma / b = 0.0681, ratio 1.001
b = 64: measured 0.0170, tr Sigma / b = 0.0170, ratio 1.001
```

The single-example noise power $\operatorname{tr}\Sigma$ is about 1.1, and across all four batch sizes the measured error matches $\operatorname{tr}\Sigma/b$ to within a few percent of sampling fluctuation. Knowing the noise of a single step, we can now ask what that noise does over an entire optimization run.

35.4.1.3 The Noise Floor

Does gradient noise average out over many steps, or does it accumulate? Section 9.2 measured the cloud in which SGD settles inside a valley and derived its radius. Here we solve the entire trajectory in closed form, which also tells us how many steps it takes to reach that cloud. The simplest case already contains the full mechanism: a single coordinate of a quadratic, $f(x) = \frac{1}{2}\lambda x^2$ with curvature $\lambda > 0$ and minimizer 0. Model the stochastic gradient as the true gradient λx_k plus random noise ξ_k with mean zero given x_k and variance σ^2. Here σ^2 plays the role of a diagonal entry of Σ/b, so every quantity proportional to σ^2 scales as $1/b$. One SGD step reads

$$x_{k+1} = x_k - \eta\,(\lambda x_k + \xi_k) = \rho\, x_k - \eta\,\xi_k, \qquad \rho = 1 - \eta\lambda.$$

At each step, the deterministic part pulls the iterate toward the minimizer by the factor ρ, just as exact gradient descent does, while the stochastic part delivers a random kick $-\eta\xi_k$. To track the iterate's size, we follow its second moment $e_k = \mathbb{E}[x_k^2]$. Squaring the update and taking expectations, the cross term $-2\rho\eta\,\mathbb{E}[x_k\xi_k]$ vanishes because ξ_k has mean zero conditioned on x_k, leaving

$$e_{k+1} = \rho^2 e_k + \eta^2\sigma^2.$$

Every step contracts the second moment by ρ^2 and injects fresh noise power $\eta^2\sigma^2$. Nearly every result in this section can be read off this one recursion. A linear recurrence with a constant driving term is solved by finding its fixed point V, where $V = \rho^2 V + \eta^2\sigma^2$. Subtracting that fixed-point equation from the recursion shows that the remainder $e_k - V$ shrinks by ρ^2 at every step, giving

$$e_k = V + \rho^{2k}\,(e_0 - V) \tag{35.40}$$

with the **noise floor**

$$V = \frac{\eta^2\sigma^2}{1-\rho^2} = \frac{\eta\,\sigma^2}{\lambda\,(2-\eta\lambda)} \;\approx\; \frac{\eta\,\sigma^2}{2\lambda} \qquad (\eta\lambda \ll 1). \tag{35.41}$$

The floor grows linearly with the step size and the noise variance, and shrinks inversely with the curvature. Both formulas require $0 < \eta < 2/\lambda$, the same stability ceiling as exact gradient descent on a quadratic; above it, the second moment diverges even without noise.

The trajectory splits cleanly into two phases. The transient $\rho^{2k}(e_0 - V)$ decays geometrically, just as in deterministic gradient descent, whereas the floor V is purely an effect of noise. Far from the minimizer, the transient dominates and SGD behaves much like gradient descent. Close to the minimizer, the inward pull $\eta\lambda x$ weakens while the random kicks keep the same variance $\eta^2\sigma^2$, until the two balance at $e = V$. From then on the iterate never converges; instead, its distribution settles into a stationary **noise ball** around the minimizer whose root-mean-square radius, roughly $\sqrt{\eta\sigma^2/(2\lambda)}$, scales as $\sqrt{\eta}$. Figure 35.15 illustrates both phases on a two-dimensional quadratic bowl.

In practice we care about the expected loss rather than the squared distance. Because $\mathbb{E}f(x_k) = \frac{1}{2}\lambda e_k$, the loss floor is

$$\tfrac{1}{2}\lambda V = \frac{\eta\,\sigma^2}{2\,(2-\eta\lambda)} \;\approx\; \frac{\eta\,\sigma^2}{4}.$$

Surprisingly, for small steps the curvature λ cancels out completely: a flatter direction lets the iterate wander farther, by precisely the factor that its flatness discounts from the loss.

On a d-dimensional quadratic, the coordinates along the eigenvectors of the Hessian decouple into d independent copies of this scalar recursion, each with its own eigenvalue λ_i and noise variance σ_i^2. The total expected loss floor is therefore the sum $\sum_i \eta\sigma_i^2/(2(2-\eta\lambda_i))$. Because the σ_i^2 are the diagonal entries of Σ/b in the eigenbasis, they sum to $\operatorname{tr}\Sigma/b$. Whenever every $\eta\lambda_i \ll 1$, the total loss floor simplifies to approximately $\eta\operatorname{tr}\Sigma/(4b)$, which depends on the step size and batch size only through their ratio η/b. Halving the step size and

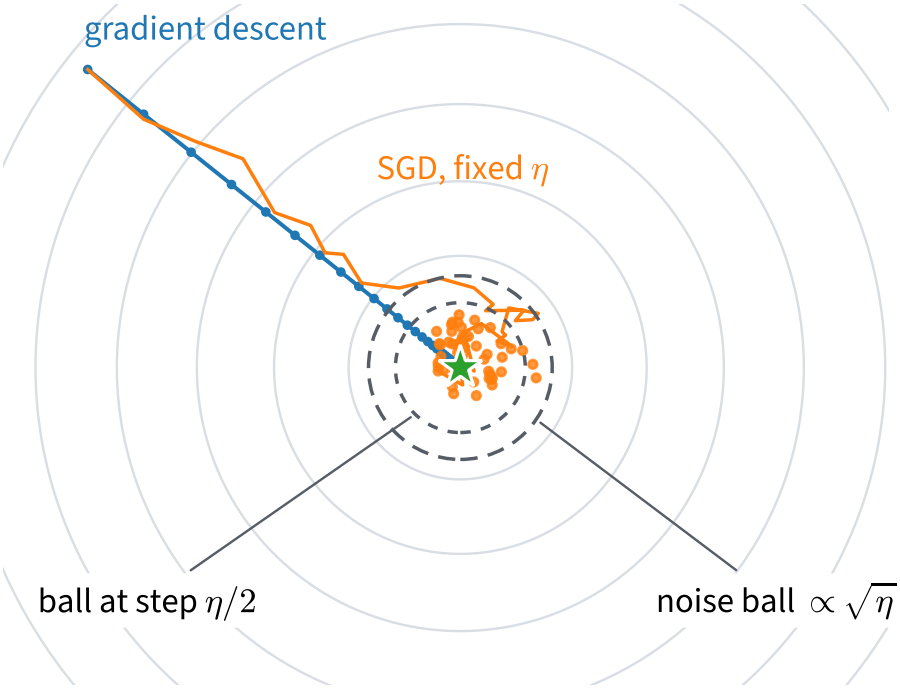

Figure 35.15: Gradient descent and fixed-step SGD on $\frac{1}{2}\|\mathbf{x}\|^2$ with $\eta = 0.15$ and gradient noise of standard deviation 0.6. The full-batch path converges to the minimizer, whereas SGD descends like gradient descent and then fluctuates inside a noise ball. Dashed circles mark the noise ball at this step size and at half the step size; their radii, drawn at three times the per-coordinate root-mean-square distance $\sqrt{\eta\sigma^2/(2\lambda)}$ to enclose the scatter, differ by a factor of $\sqrt{2}$.

doubling the batch size therefore lower the floor by the same factor—the coupling behind the large-batch learning-rate rules in Section 9.8.

How quickly does a run reach its floor? Take $\lambda = \sigma = 1$, as in the opening example, where $\eta = 0.1$ produced $V = 0.053$. Raising the step to $\eta = 0.3$ raises the floor to $V = 0.176$ (a little more than three times as high, with a loss floor of 0.088). Starting from $x_0 = 3$ ($e_0 = 9$), the transient $e_k - V$ drops below a tenth of V after 36 steps at $\eta = 0.1$ ($\rho^2 = 0.81$), compared with just 9 steps at $\eta = 0.3$ ($\rho^2 = 0.49$). Cutting the step size by a third cuts the floor by roughly a third, but demands four times as many steps to reach it. Every method in the rest of this section is a different way of navigating this trade-off between speed and accuracy.

Now return to our running example $\frac{1}{2}(x_1^2 + 1000\,x_2^2)$, modeling the noise directly by adding independent mean-zero noise of variance $\sigma^2 = 1$ to each coordinate of the gradient $(x_1, 1000\,x_2)$ at every step. The two coordinates obey the scalar recursion with $\lambda_1 = 1$ and $\lambda_2 = 1000$. Set $\eta = 1/L = 10^{-3}$, half the stability ceiling $2/1000$. The stiff coordinate has $\rho_2 = 0$: a single step erases its transient completely, leaving it on its floor $V_2 = 10^{-3}/1000 = 10^{-6}$. The slow coordinate has $\rho_1 = 0.999$ and floor $V_1 = 10^{-3}/1.999 = 5.0 \times 10^{-4}$, and its transient takes $\log 1000/(-2\log 0.999) \approx 3{,}450$ steps to shrink a thousandfold. The total loss floor is 7.5×10^{-4}, split between 2.5×10^{-4} from the slow coordinate and 5×10^{-4} from the stiff one. Notice the irony: the stiff coordinate that gradient descent eliminates in one step accounts for two-thirds of the loss floor, because at $\eta\lambda_2 = 1$ its loss floor is $\eta\sigma^2/2$, twice the small-step value $\eta\sigma^2/4$. Ill-conditioning slows down the flat direction, while noise raises the loss along both.

Our closed-form floor is exact only for a quadratic with additive noise. Next, we test whether the scaling "floor proportional to η" still holds on the non-quadratic logistic loss, and see how decaying step sizes break through the floor.

35.4.2 Step-Size Decay

35.4.2.1 The Robbins–Monro Conditions

Because the noise floor scales linearly with η, actually reaching the minimizer requires shrinking the step size toward zero. Shrink it too fast, however, and the iterate stalls short of the goal: with unit-sized gradients, the total distance traveled cannot exceed $\sum_k \eta_k$. The classical conditions of Robbins and Monro (1951) capture both requirements at once,

$$\sum_k \eta_k = \infty, \qquad \sum_k \eta_k^2 < \infty. \tag{35.42}$$

The first condition guarantees that the iterate can travel arbitrarily far from its starting point, while the second keeps the cumulative variance injected by the noise, $\sigma^2 \sum_k \eta_k^2$, finite. The schedule $\eta_k = c/k$ satisfies both conditions, whereas $\eta_k = c/\sqrt{k}$ and a constant step satisfy only the first. Together with unbiased gradients whose variance grows at most quadratically with the distance to the minimizer, these two conditions guarantee that SGD converges to the minimizer of any strongly convex loss (Robbins and Monro 1951; Bottou et al. 2018).

On our scalar quadratic, convergence in mean square actually needs less. Unrolling the recursion shows that $e_k \to 0$ whenever $\eta_k \to 0$ and $\sum_k \eta_k = \infty$ (with $\eta_k < 2/\lambda$); in particular, $\eta_k = c/\sqrt{k}$ yields $e_k \approx c\sigma^2/(2\lambda\sqrt{k})$, which simply tracks the instantaneous

floor of the current step. The stronger square-summability condition is what the general theorem requires to guarantee convergence along almost every individual sample path.

Two questions remain for a non-quadratic objective: does the noise floor still scale linearly with η, and does a decaying schedule push below it? To check on our logistic-regression problem, we first compute the reference optimum $f^\star$ with $4{,}000$ full-gradient steps, then define a minibatch SGD loop that records the suboptimality gap $f(\mathbf{x}_k) - f^\star$ at every step.

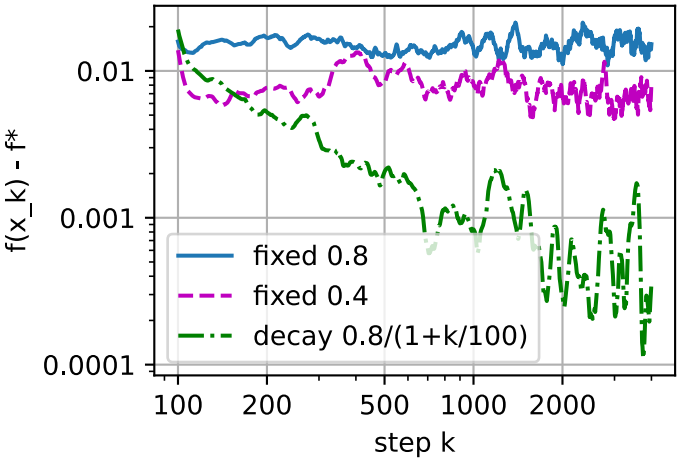
```
x_star = np.zeros(d)
for _ in range(4000):                              # full-gradient reference optimum
    x_star -= 0.5 * example_grads(x_star, A, y, reg).mean(axis=0)
f_star = loss(x_star, A, y, reg)

def sgd(schedule, A, y, reg, f_star, rng, steps=4000, b=8):
    """Minibatch SGD from x = 0; returns the gap f(x_k) - f* after every step."""
    x, gaps = np.zeros(A.shape[1]), np.empty(steps)
    for k in range(steps):
        idx = rng.integers(0, len(y), size=b)
        x -= schedule(k) * example_grads(x, A[idx], y[idx], reg).mean(axis=0)
        gaps[k] = loss(x, A, y, reg) - f_star
    return gaps
```

If the quadratic model is a reliable guide, halving a fixed step size should halve the gap at which SGD stalls. We run $4{,}000$ steps with $b = 8$ using constant steps $\eta = 0.8$ and $\eta = 0.4$, alongside the decaying schedule $\eta_k = 80/(k + 100) = 0.8/(1 + k/100)$, which begins at 0.8. The cell prints the mean gap over the final $1{,}000$ steps of each run, reports the ratios between them, and plots 100-step moving averages on log–log axes.

```
rules = {'fixed 0.8': lambda k: 0.8, 'fixed 0.4': lambda k: 0.4,
         'decay 0.8/(1+k/100)': lambda k: 0.8 / (1 + k / 100)}
gaps = {name: sgd(s, A, y, reg, f_star, rng) for name, s in rules.items()}
tail = [gap[-1000:].mean() for gap in gaps.values()]
print('mean gap, last 1000 steps: ' + ', '.join(f'{t:.1e}' for t in tail))
print(f'floor(0.8) / floor(0.4) = {tail[0] / tail[1]:.2f}, '
      f'floor(0.8) / decay = {tail[0] / tail[2]:.0f}')
window = np.ones(100) / 100                        # plot 100-step moving averages
d2l.plot(np.arange(100, 4001), [np.convolve(gap, window, 'valid') for gap in gaps.values()],
         'step k', 'f(x_k) - f*', xscale='log', yscale='log', legend=list(gaps))
```

```
mean gap, last 1000 steps: 1.6e-02, 6.9e-03, 6.0e-04
floor(0.8) / floor(0.4) = 2.27, floor(0.8) / decay = 26
```



Both fixed-step runs stall. At $\eta = 0.8$, the mean gap over the last $1{,}000$ steps settles around 1 to 2×10^{-2}, and halving the step size cuts it roughly in half: across repeated runs, the ratio fluctuates between about 1.7 and 2.8, centered on the factor of 2 predicted by the quadratic model even though the logistic loss is not quadratic. Meanwhile, the decaying schedule finishes roughly 20 to 90 times below the $\eta = 0.8$ floor, and its curve on the log–log plot is still trending downward despite minibatch jitter. Its large early steps cover the distance to the minimizer quickly, while its small late steps shrink the noise ball.

35.4.2.2 The Constant in a $1/k$ Schedule

The schedule $\eta_k = c/(k + k_0)$ satisfies both Robbins–Monro conditions for any $c > 0$, with the shift k_0 keeping the initial steps safely below the stability ceiling. Does every choice of c achieve an $O(1/k)$ rate? The scalar quadratic with curvature $\lambda = \mu$ gives an exact answer. Writing $t = k + k_0$, the second-moment recursion becomes

$$e_{k+1} = \left(1 - \frac{c\mu}{t}\right)^2 e_k + \frac{c^2\sigma^2}{t^2}.$$

Here the contraction weakens like $1/t$, while the injected noise power falls like $1/t^2$. Which effect dominates depends critically on c: if c is too small, the step size shrinks faster than the iterate can contract toward the minimizer, so the schedule itself becomes the bottleneck rather than the noise.

Proposition (the constant of a $1/k$ schedule). *On the scalar model with curvature μ and step sizes $\eta_k = c/(k + k_0)$, if $2c\mu > 1$ then $k\, e_k \to A$, where*

$$A = \frac{c^2\sigma^2}{2c\mu - 1}. \tag{35.43}$$

If $2c\mu < 1$, then e_k decays like $k^{-2c\mu}$, strictly slower than $1/k$, and at the boundary $2c\mu = 1$ it decays like $\log k/k$. For every $c > 0$, $e_k \to 0$.

We omit the full proof here, deriving the constant A by matching leading terms and sketching the other two regimes informally; exercise 2 provides a complete proof by induction above the threshold and by unrolling the recursion below it.

Derivation of the constant. Try the asymptotic form $e_k \approx A/t$. The left-hand side of the recursion is $A/(t+1) \approx A/t - A/t^2$. On the right-hand side, expanding $(1-c\mu/t)^2 \approx 1 - 2c\mu/t$ gives $A/t - 2c\mu A/t^2 + c^2\sigma^2/t^2$ up to terms of order t^{-3}. The $1/t$ terms match automatically, and equating the $1/t^2$ coefficients yields $-A = -2c\mu A + c^2\sigma^2$, or $A(2c\mu - 1) = c^2\sigma^2$. Notice the subtle term on the left: advancing from t to $t+1$ contributes $-A/t^2$, which is of the same order as the contraction term and creates the threshold $2c\mu > 1$. Ignoring that shift would falsely predict $A = c\sigma^2/(2\mu)$ for every $c > 0$.

Below the threshold (informally). When $2c\mu < 1$, the cumulative contraction sets the decay rate for both the initial error and the early noise. Because $\log(1-u) \approx -u$ and $\sum_{j \le t} 1/j \approx \log t$, the product of contractions behaves as $\prod_j (1 - c\mu/(j+k_0))^2 \approx (k_0/t)^{2c\mu}$, which decays more slowly than $1/t$. At the boundary $2c\mu = 1$, noise injected at step j survives at step t with weight roughly $c^2\sigma^2/(jt)$, and summing over j produces the extra $\log k$ factor.

To see the sensitivity in numbers, take $\mu = \sigma = 1$. Setting $c = 1$ gives $A = 1$, and iterating the recursion from $e_0 = 1$ with $k_0 = 10$ yields $k\,e_k = 1.0001$ at $k = 10^6$. Doubling to $c = 2$ raises the constant only modestly, to $A = 4/3$. Dropping below the threshold is far more damaging: $c = 0.25$ yields a log–log slope of -0.50 between $k = 10^5$ and 10^6, and $c = 0.1$ yields a slope of just -0.20. Minimizing A over c gives the optimal constant $c = 1/\mu$, where $A = \sigma^2/\mu^2$ and $e_k \approx \sigma^2/(\mu^2 k)$. Remarkably, averaging the iterates of a constant-step run achieves the exact same optimal constant without decaying the step size at all (exercise 5). The sharp threshold at $c = 1/(2\mu)$ makes $1/k$ schedules fragile in practice: the smallest curvature μ is rarely known, and underestimating c sacrifices the convergence rate itself. This fragility is one major reason practical learning-rate schedules decay more slowly than $1/k$.

On the running example $\frac{1}{2}(x_1^2 + 1000\,x_2^2)$, the shift k_0 creates a second difficulty. Stability at the very first step requires $c/k_0 < 2/L$, or $k_0 > cL/2$. Choosing the optimal constant $c = 1/\mu = 1$ for the slow coordinate therefore forces $k_0 > 500$. With $k_0 = 1000$ and $\mathbf{x}_0 = (1,1)$, the slow coordinate's transient still retains a fraction $(k_0/(k+k_0))^2 \approx 0.008$ of its initial error after $k = 10^4$ steps, leaving the expected loss at 4.2×10^{-3}—more than five times worse than the constant-step floor of 7.5×10^{-4}. The small initial steps demanded by the stiff coordinate starve the slow coordinate, and the condition number reappears inside k_0.

35.4.2.3 Schedule Shapes under the Exact Recursion
